TABLE 1 COMPARISON OF TEMPERATURES AND CORRESPONDING VISCOSITIES MEASURED BY THE THERMOMETER AND THERMOCOUPLE IN THE TEST BEARING UNDER A WIDE RANGE OF OPERATING CONDITIONS

Test number	1	2	3	4	5	6	7	8	9	10	11	12
Speed (rpm)	800	800	800	800	1600	1600	1600	1600	2400	2400	2400	2400
Load (lb/sq in. of projected area)	109	160	209	281	106	127	188	244	109	170	224	285
Eccentricity factor	0.798	0.855	0.880	0.915	0.770	0.825	0.859	0.880	0.750	0.787	0.817	0.862
Thermocouple temp:												
Leading edge, F	100	101	102	103	119	115	120	124	121	123	123.5	126
Trailing edge, F	113	115	116	117	128	125	131	139	133	135	138.0	142
Viscosity corresponding to thermocouple temp:												
Leading edge (centipoises)	64.5	63.8	62.5	59.0	36.0	40.2	35.0	32.0	34.5	33.0	33.5	29.0
Trailing edge (centipoises)	59.0	54.3	53.5	50.6	28.3	30.5	26.0	21.5	25.0	23.0	22.0	19.9
Average of viscosity at leading and trailing edges	61.8	59.0	58.0	54.8	32.2	35.4	30.5	26.8	29.8	28.0	27.8	24.4
Temperature measured by thermometer, F	96	96.5	96.5	97	114	107	116	115	115	115	113	117
Viscosity corresponding to thermometer reading	74.0	73.5	73.5	72.0	42.0	52.5	39.0	41.5	41.5	41.5	43.8	38.0
Excess viscosity corresponding to thermometer over average viscosity corresponding to thermocouple, per cent	19.7	24.5	26.7	31.4	31.7	48.3	27.9	54.8	39.3	48.3	57.6	55.7

A schematic diagram of the bearing is shown in the writer's Fig. 1. The enlarged insert shows the arrangement of the thermocouple. The position of the thermometer well is also indicated. The bearing itself was a cylindrical steel shell lined with babbitt, with the principal dimensions shown.

Except for the circumferential grooves to which the oil was supplied at either end, the bearing surface was plain. The bearing was so arranged that it could be moved circumferentially without releasing the load, and being a plain cylinder, it always presented substantially the same surface to the load. With this arrangement it was possible to obtain a complete circumferential traverse of the oil-film temperatures with the one thermocouple.

In the writer's Fig. 2 are shown several of the curves of temperature (as measured by the thermocouple) plotted against the circumferential position at which the temperature measurements were made. It will be noted that around the arc of the pressure-carrying oil film there was a very marked and steady increase in temperature. This temperature increase was, of course, due to the cumulative heating effect of the work of friction as the oil was carried through the clearance space. On the "off," or unloaded, side of the bearing the oil was cooled to the inlet temperature again by mixing with fresh oil from the supply grooves.

As the thermocouple was moved from position to position around the bearing in 10-degree increments, the temperature change recorded by the thermocouple was as nearly instantaneous as it was possible to balance the potentiometer, and over a period of as much as thirty minutes the reading for any given position did not change appreciably.

In view of this responsiveness and steadiness of the readings, it is believed that the thermocouple was adequately insulated from the surrounding bearing shell and recorded very nearly the oil-film temperature. Obviously, this method could not measure the temperature gradient from the surface of the bearing to the surface of the journal. However, it apparently measured a temperature that was a reasonable average of the film temperature at each point around the circumference of the bearing.

Table 1 gives a summary of similar measurements made at speeds of 800, 1600, and 2400 rpm, with loads of about 100 to 300 lb per sq in. of projected bearing area. Texaco Regal Oil C, having a viscosity of 320 sec at 100 F; 48 sec at 210 F; and an A.P.I. gravity of 22.6 deg at 60 F, was used in all tests. In addition to the test conditions, the table gives the inlet and outlet (of the load-carrying oil film) temperature and the corresponding viscosity and the numerical average of the inlet and outlet viscosity. It also gives the temperature as measured by the thermometer, and the corresponding viscosity. The final line gives in percentage the amount by which the viscosity corresponding to thermometer reading exceeds the average viscosity as measured by the thermocouple.

R. O. Boswall[10] has shown that the error introduced by assuming a constant viscosity equal to the numerical average of the inlet and the outlet is negligible. Therefore, the percentages which are listed in the last line of Table 1 represent the error that would have been involved in the viscosity measurement had the viscosity been taken as that corresponding to the temperature measured by the thermometer.

An extremely high degree of accuracy in measuring the viscosity of the lubricant in the oil film is not essential because the film thickness and the coefficient of friction do not vary directly as the first power of the viscosity, but, as the author's figures indicate, to a considerably less important extent. However, the differences of 20 to 60 per cent between the viscosity measured as that corresponding to the temperature recorded by a mercury thermometer placed very close to the bearing surface, and the average of the inlet and outlet viscosities corresponding to the temperatures as measured by the thermocouple, represent a significant difference. These data indicate that it probably is not satisfactory merely to stick a thermometer in the oil reservoir or against the bearing shell, as is frequently done, and call the reading so obtained the running temperature of the bearing.

The temperature measurements made by the thermocouple at the leading and trailing edges of the load-carrying oil film in this experimental bearing should correspond to the oil temperatures that occur in the chamfered reliefs usually placed at the leading and trailing ends of commercial bearings. In this case the average viscosity of the oil film could be taken as equal to the numerical average of the viscosities corresponding to the temperatures measured at these points. The writer has no data on this point and it is offered merely as a possible satisfactory procedure.

In Figs. 1 and 3 of Mr. Howarth's paper, he has produced a very useful and practical tool for bearing designers and lubrication engineers and his definition of bearing running temperature and a satisfactory method of measuring it should be of considerable interest to those who desire to apply these data to practical bearing problems.

R. J. S. Pigott.[11] The writer has read with a great deal of satisfaction this further valuable contribution on bearing lubrication. Engineering, as a whole, is as yet too largely an empirical, rather than rational, branch of science, and the design of bearings has hitherto been one of the worst cases of empirical methods.

When we consider that the behavior of bearings is influenced by length, diameter ratio, clearance, speed, location of oil feed, quantity of oil, viscosity, load, misalignment, and last, but by no means least, heat-removal by other means than the lubricant, the complexity of analytical methods is apparent, particularly since none of the factors is completely independent of one or more of the others.

The writer has been convinced for some time that the mere use of pressure and rubbing speed was a relatively loose and incomplete criterion, the use of a friction coefficient even worse; in fact, often quite misleading. It is always useless to predicate the

[10] Theory of Film Lubrication," by R. O. Boswall, Longmans Green & Co., New York.

[11] Staff Engineer, in charge of Engineering, Gulf Research & Development Corporation, Pittsburgh, Pa. Mem. A.S.M.E.

design of any engineering device on two factors, when six or eight are involved. For example, it was customary, for a century, to treat pipe flow as a function of velocity and size only; consequently water, steam, gas and air formulas all differed, and there was no correlation. Reynolds' basic contribution was neglected for thirty years, and then swept the field. By taking into account density, viscosity, and finally roughness, we can now use a single formula for any fluid from molasses to hydrogen.

The writer had occasion to attempt the direct computation of liquid leakage and friction in rotary pumps and motors. Many of the cases involve conditions very similar to those in oil-film bearings. The results were so close to test performance that the latter can be predicted from a paper design within one or two per cent of the actual test. Much of the work will prove useful in bearing analysis.

We have also carried out analyses and tests in the laboratory on flow from a point source to a surrounding field edge, and the results of this work will ultimately be available for analysis of the effect of oil feeds and grooves.

It is clear that the rationalization of bearing design must come along the path taken by Mr. Kingsbury, Mr. Howarth, and their associates. But to render the final development authoritative and beyond question, it seems to the writer that we must have one more device—a bearing- and lubricant-testing machine that will test actual bearings, and yield results that do not require interpretation or extrapolation. The fault that may be found with most testing machines so far used is that they use idealized bearings or sometimes a structure not even faintly resembling a bearing; in many cases, results on one machine do not agree with those on another. Another objection is that none of the machines permits a real pressure, temperature, or leakage search; many do not even give journal displacement. We are developing a machine that we hope will overcome these disadvantages.

Mr. Howarth should not only be congratulated, he should be heartily thanked, for another valuable study of the subject.

A. F. Underwood.[12] The collected material that is presented in Mr. Howarth's paper is interesting in that it shows the lack of uniform bearing design. This may be a necessity when it comes to actual bearings in practice because our experience has shown that bearings which do not conform to the best theoretical designs often run better than when mathematically correct. We do not mean to imply that the theory should be neglected but rather that it is best used as an indicator, especially in the design of new bearings. As a specific example, theory shows that the bearing should be rigid to maintain the correct C/D ratio. Yet it is well known that the flexible cap of an automobile-engine connecting rod will sustain a much higher load than the upper half of the rod which is much more rigid. The reason for this apparent anomaly is that, in the case of the cap, the oil film is distributed over a larger area of babbitt, thereby increasing the fatigue life of the material.

In spite of the nearly universal use of the pressure-velocity factor for bearing design, it is not a criterion of bearing performance. It does become a measure of the heat loss in a bearing if it is in turn multiplied by the coefficient of friction. A number of factors affect the coefficient of friction, and, unless these factors all balance so as to give comparable values of coefficient of friction, the use of the pressure-velocity factor in bearing design may be very misleading.

Author's Closure

In addition to the distortion of bearing surfaces by loading conditions, as pointed out by Mr. Dall, there is the distortion caused by temperature change. With this in mind, Mr. Dall's three considerations which influence one's choice of minimum film thickness become (1) initial perfection, (2) subsequent distortion, and (3) durability.

Durability depends upon careful application of the lubricant and the protection of the bearing films against injury and contamination which obviously means that laboratory conditions must be realized in service. In other words, the bearings must be made fool-proof.

Several interesting comments offered by Mr. Kuhns include definite additions to the author's chartable data. With regard to the specification of lubricating oils, the author indorses Mr. Kuhns' hope that sometime it will be easier to obtain oil by simple description instead of by brand name. The S.A.E. numbers which he mentions are a step in the right direction but they do not go far enough. These numbers are given in Fig. 3 of this discussion, which has been revised from Fig. 7 of the paper, to cover the range needed to show the S.A.E. winter oils 10-W and 20-W. Further refinements are inevitable in the description of oils by numbers that have a real meaning. The addition of 10-W and 20-W to the S.A.E. numbers is but a step in that direction.

Mr. Pearce has given useful data that may well be added to that already charted. The author's use of the projected area of the journal as a basis of comparison for journal bearings was based upon its simplicity. No simple basis of comparison would afford an absolutely true picture of the facts, because of the variety of angular reactions of the bearing films to the journal for different bearing arcs, and because of pressure variations throughout the film. Hence, it is believed by the author that as long as the bearing-arc limitations are kept in mind for each class of bearing, the simpler method of tabulation is the better one to use.

The friction coefficients given by Mr. Pearce seem to include also the rolling friction of the wheel on the rail, if the author interprets correctly the statement, "Expressed in another way, it offers a rolling resistance of 1.86 lb per ton." If such is the case, direct comparisons with optimum bearing conditions are difficult to make.

The wide variation in operating load upon a bearing is not limited to the railroad field. It is found in every machine tool in which the rate of material removal is inconstant. In fact, in a machine tool the bearings are subjected to greater variation of load than in a rail car because while the latter has the minimum though considerable dead weight of the car body, bearings in a machine tool carry loads that are almost wholly due to the working process undertaken, which vary from zero to the maximum. For these reasons the tabulation of data is made on the basis of the normal operating loads the bearings are designed to carry.

The author appreciates the value of plotting test results on the basis of ZN/P as suggested by Mr. Dahlstrom, who recognizes Mr. Hersey as having pointed out the value of such a combined variable in 1915. Mr. Kingsbury[3] has given definite optimum ratios of the friction coefficient λ to a similar combined variable $\sqrt{(\mu N/P_0)}$ for each of his bearings. These range from 0.45 to 0.53 for clearance bearings with arcs varying from 60 to 120 deg. Transforming the μ to Z will give ratios of $\lambda/\sqrt{(ZN/P)}$ for optimum bearings, lying between 2.3 and 2.8×10^{-4} when corrected for side leakage under the assumptions that the bearings are square, i.e., the length is equal to the width. Out of this ratio we cannot obtain any useful low points for reference, but merely a straight line extending to the origin, unless we select a clearance ratio or a minimum film thickness with relation to journal diameter. Proceeding to do this, we find that the value of the friction coefficient for the square

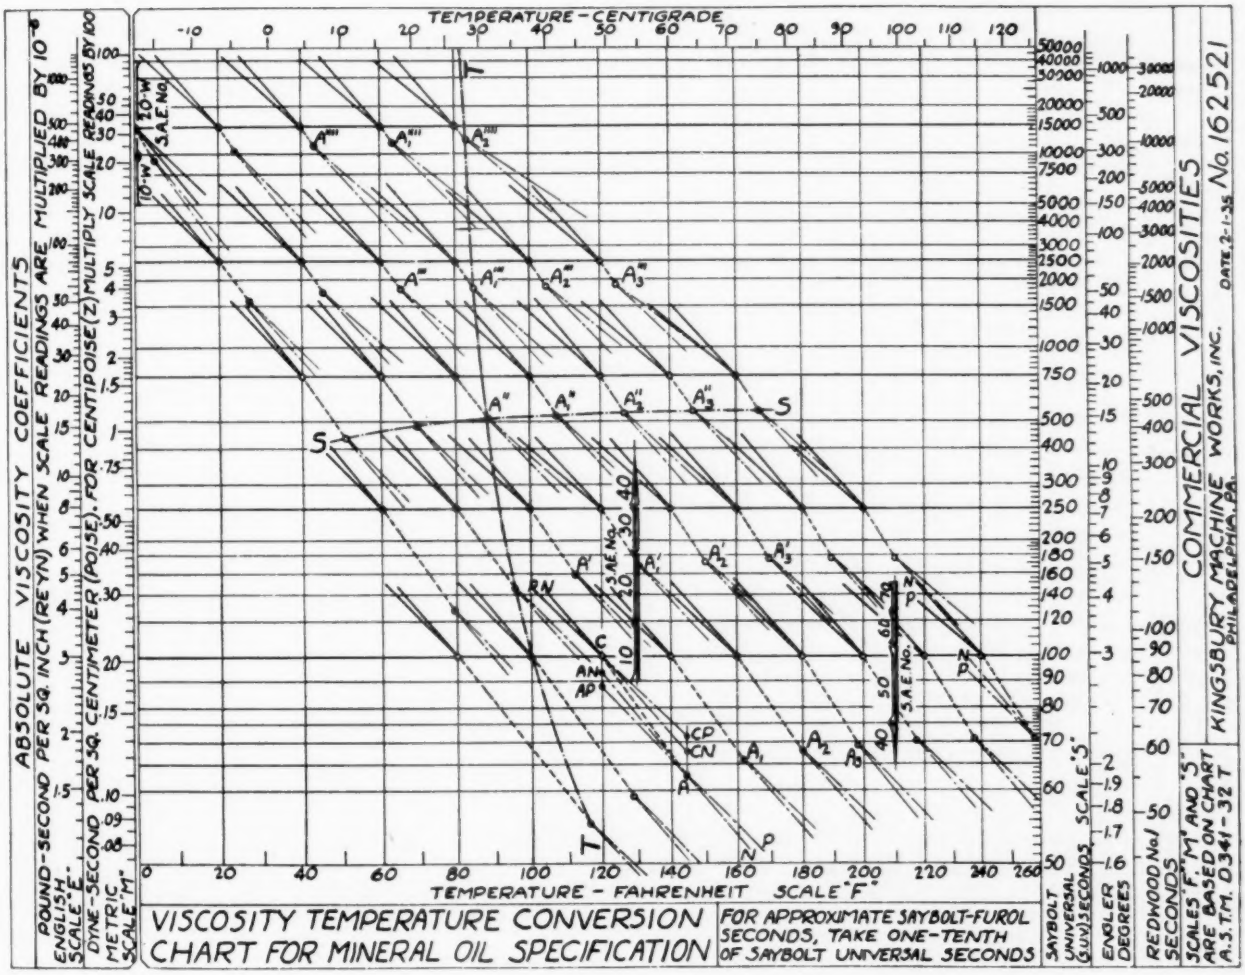

FIG. 3 VISCOSITY-TEMPERATURE CONVERSION CHART FOR MINERAL-OIL SPECIFICATION

(A revision of Fig. 7 of the paper extended to include all the S.A.E. numbers now in use. The intersections for determining the location of the dot-and-dash lines were calculated mathematically as against a graphical method employed in Fig. 7.)

bearing for optimum conditions will be from 2.4 to 3.0 times the clearance ratio. Hence, there is no theoretical bar to the coefficient of friction reaching zero.

Therefore, when a limit is arbitrarily placed upon the value of ZN/P, below which we dare not go, or are unable to go, we admit that there is a similar limit in the perfection of workmanship that is practicable or possible. The author, therefore, believes that it is wise to face the whole problem at once, and not to overrate the correlation of data on charts, the coordinates of which are merely the coefficients of friction λ and the combined variable ZN/P. The clearance ratio must be known to properly interpret such data.

A formula for minimum film thickness, such as derived by Professor Karelitz from works of Michell and of Boswall for flat surfaces, can be deduced readily for clearance or fitted journal bearings from symbol groups No. 10 published in Mr. Kingsbury's "Optimum Conditions in Journal Bearings."[3] A proper constant or series of constants, if more than one be needed, for determining desirable actual minima, must be based on experience. Mr. Kingsbury's experience with his thrust bearings yields the minimum film-thickness values which are given in Table 5 of the paper.

The point stressed by Mr. Barber is an important one and requires considerable space for its complete discussion. It was this fact that led the author to limit the paper to the relation of load and friction to the mean viscosity of the film. This was a definite step forward and it did not seem wise to try to cover adequately at this time the variations of viscosity throughout the grooves and baths of bearings.

The experiments to which Mr. Barber refers were made with a shell designed to simulate the lubrication conditions in a full bearing so far as they can be brought about in a finite bearing operating in an atmosphere of moderate pressure. The shell was designed to explore the distribution of pressures and temperatures and the shore lines of the film natural to such a bearing. Hence, it would be difficult to apply the results reliably to a partial bearing formed between two oil channels. These channels can be used for cooling the bearing, or merely for oil supply, when the cooling is done by water or by conduction to the air. Hence it would be better to seek more comparable temperature-distribution data by experimenting on shells designed to operate like those of the bearings in the machine that is subject to investigation.

The machine that Mr. Pigott mentions as being developed by the Gulf Research and Development Company will be studied with great interest by bearing engineers when it is ready for the market. Resulting from the experience possessed by Mr. Pigott and others of his company, it is to be expected that this will not be "just one more machine" to be set aside as inadequate.

The statement of Mr. Underwood that a connecting-rod cap

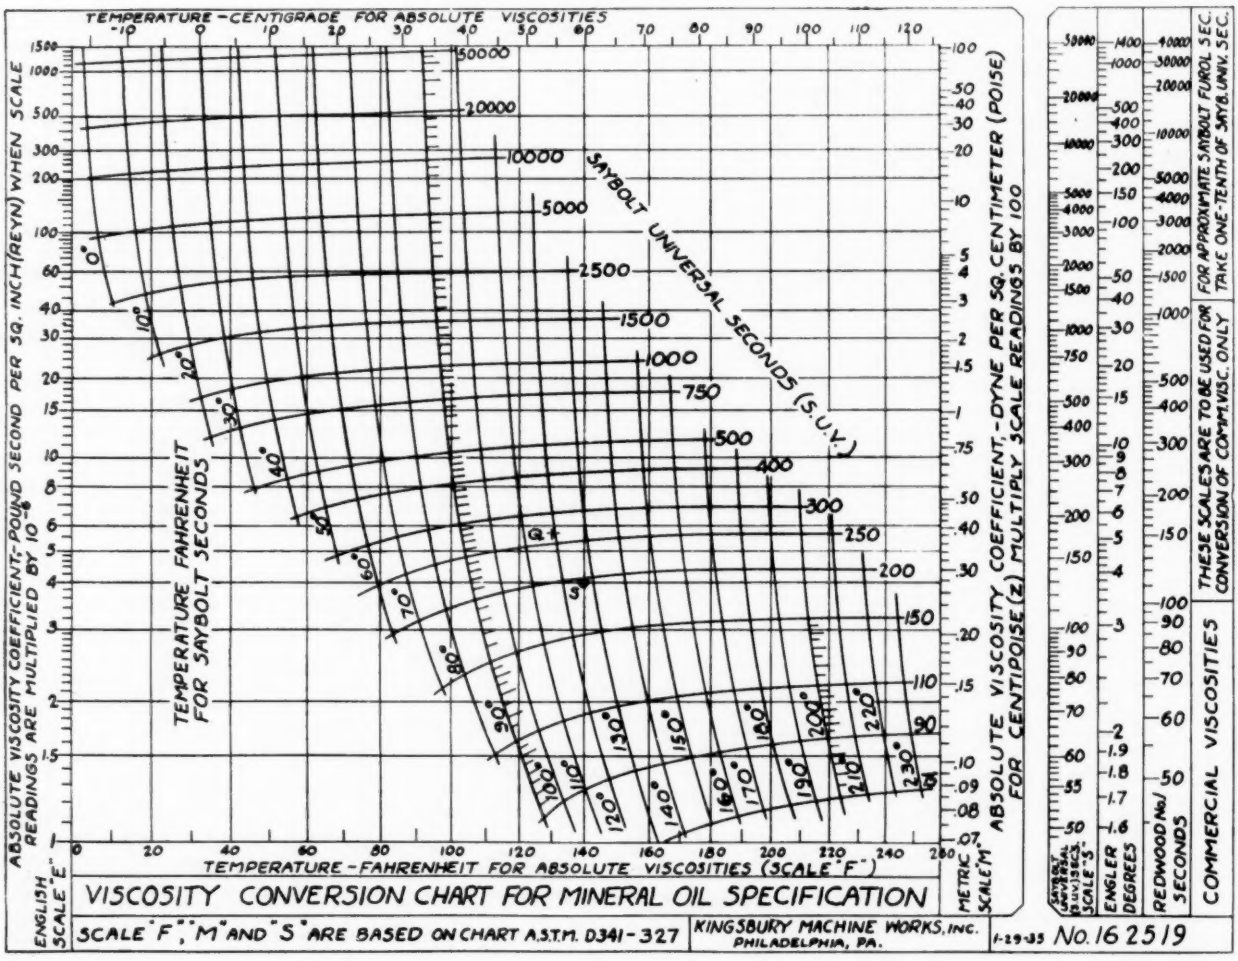

FIG. 4 VISCOSITY-CONVERSION CHART FOR MINERAL-OIL SPECIFICATION

(A revision of Fig. 6 of the paper extended to include all the S.A.E. numbers now in use. A mathematical, rather than a graphical method was also employed for determining the scales of this figure.)

carries load better than the stiffer part backed by the rod is quite interesting. The difference may be due partly to better alignment and partly to the hammock-like surface it presents to the pin. This suggests that a better rod design might be one with a head consisting of two caps held to the rod with a pair of bolts.

In addition to Fig. 3 of this discussion, offered by the author to extend the range of Fig. 7 of the paper to include all the S.A.E. numbers now used, there is also offered a revision of Fig. 6 of the paper. This new chart, Fig. 4 of this discussion, covers the same field as Fig. 3 of the discussion, and has been revised, as was the latter, to be more accurate than the original. The intersections which determine the locations of the dot-and-dash lines of Fig. 7, and thereby the special scales of Fig. 6, were located graphically, and were, therefore, subject to minor errors because of near parallelism. Therefore, a more accurate way of locating them was sought with the result that J. F. Spiegel, one of our engineers, evolved a mathematical method for calculating the intersections that is much more accurate than the graphical method. The redetermination of these intersections occupied a number of weeks. The results, however, warranted the time expended because Fig. 3 and Fig. 4 of this discussion are apt to be widely used. This seems reason enough for repeating them. Obviously, if the paper is ever rewritten only the better set of charts need be included.

Tractive Effort of Steam Locomotives (Locomotive Ratios—II)[1]

A GIESL-GIESLINGEN.[2] It is gratifying that Dr. Lipetz in response to the discussion evoked by his paper of two years ago,[3] has furthered the development of his method for evaluating locomotive tractive effort in order to make it adaptable to cylinders with widely varying proportions. The earlier paper[3] stated that his method was suited to locomotives of normal modern proportions and, assuming only limited fluctuations in relative dimensions of boiler and machinery, a single curve of moduli was developed to answer this stated purpose.

Meanwhile, locomotives have been cited which, with relation to boiler capacity, have cylinders that are as much as, or more than, 50 per cent larger than those upon which the curves in the earlier paper[3] were based. In the paper being discussed, Dr. Lipetz established correction curves in order to accommodate such cases. The writer fully endorses the use of a standard curve of moduli for locomotives with normal cylinder proportions, and of

[1] Published as paper RR-56-6, by A. I. Lipetz, in the December, 1934, issue of the A.S.M.E. Transactions.

[2] Assoc-Mem. A.S.M.E. New York, N. Y.

[3] "Horsepower and Tractive Effort of Steam Locomotives" (Locomotive Ratios), by A. I. Lipetz, Trans. A.S.M.E., vol. 55, 1933, paper RR-55-2, p. 5.

correction curves expressing the deviations in case cylinders of other proportions are provided. However, he suggests some changes in the author's curves.

The author's Fig. 5 shows his correction curves as a function of the locomotive characteristic K, which established a yardstick for the relation between boiler capacity and cylinder size. (See author's Equation [10].) It is obvious that larger cylinders mean a smaller value of K. The author assumes that no corrections should be applied for values of K equal to 14.26 and over, but if the cylinders are enlarged so as to result in values of K smaller than 14.26, then his corrections begin and rise very sharply at first and then at a diminished rate. This is not logical.

To better illustrate the case, reference is made to the writer's accompanying Fig. 1 which was drawn for the New York Central 4-6-4 type locomotive, class J-1. In this graph, the abscissa shows the values of K, each point corresponding to a certain cylinder volume and $K = 15.28$ corresponding to the locomotive's actual cylinder of 25 in. diameter. The heavy line indicates the Lipetz correction curve for 50 rpm. According to Dr. Lipetz we can now enlarge the cylinders until $K = 14.26$ and $d = 25.9$ in., without having to apply any correction to tractive power or performance. But if we increase the diameter only $^1/_2$ in. further to 26.4 in., tractive power according to the author should jump 6.7 per cent for 50 rpm.

We are also allowed to assume a smaller cylinder, perhaps equaling the proportions of locomotive No. 1 in the author's Table 4 for which $K = 16.88$. Therefore, $d = 23.8$ and, according to the author, no correction would be applied. If we would now enlarge the cylinder again, the author's correction curve for 50 rpm would imply that a diameter increase of 2.1 in. (a volume increase of 18.5 per cent) will not influence tractive power, but if we add another 2.1 in., reaching 28-in. diam, tractive power will jump 16 per cent. This is clearly impossible. The correction curve cannot have an edge at $K = 14.26$ but must be a smooth curve of some kind and, if $K = 14.26$ actually characterizes the cylinder proportions for which the 1932 moduli are valid, the proper correction curve will cross the zero line at that point as indicated by the tentative broken line for $n = 50$ rpm.

How large shall the correction be for any point where K differs from 14.26? In his 1932 paper[3] the author develops his method by first obtaining a curve of steam production varying with revolutions per minute in accordance with well established (even though not quite undisputed) experience, and then obtaining horsepower and tractive effort by establishing a curve of steam consumption per indicated horsepower-hour also drawn against revolutions per minute. These two curves were then combined into one representing the Lipetz moduli. The assumption of a definite figure for steam consumption per indicated horsepower-hour at a given speed implies (among other things) that there is, for each given number of revolutions per minute, a definite relation between the volume of the consumed steam and cylinder volume; this will be the case if $K = \frac{E_e}{Vp_b}$ is the same for all engines. If an engine has larger cylinders, then a smaller cut-off must be used to consume the given steam volume and, at least at moderate speeds, better utilization of the steam and higher output will result. The amount of steam generated by the boiler is practically uninfluenced by cylinder size, and if we do not wilfully change the basic curve of steam production established in the 1932 paper,[3] then the changing rate of steam consumption per indicated horsepower-hour is the only factor determining the correction curves for the Lipetz moduli. It is interesting to note that the Kiesel formulas as presented by Mr. Vincent in his discussion of the 1932 paper give a very good answer to this problem: by a simple transformation of the KV-formulas and by making $P_1 v$ const. 506, we can write the KV-formula in the following form:

$$C_i = 13.9 + 58.9 \frac{H}{VP_1 n}$$

where C_i is the steam consumption (excluding auxiliaries), lb per ihp-hr; H is the boiler steam available for the cylinders, lb per hr; V is the combined volume of all cylinders, cu ft; P_1 is the boiler pressure minus 10 lb; and, n is the speed, rpm. If we substitute 96 per cent of the boiler pressure for P_1, and the denominations used by Dr. Lipetz, then we obtain

$$C_i = 13.9 + 61.3 \frac{E}{Vp_b n}$$

where $\frac{E}{Vp_b}$ corresponds to the locomotive characteristic K established by Dr. Lipetz. Within the scope of the Lipetz

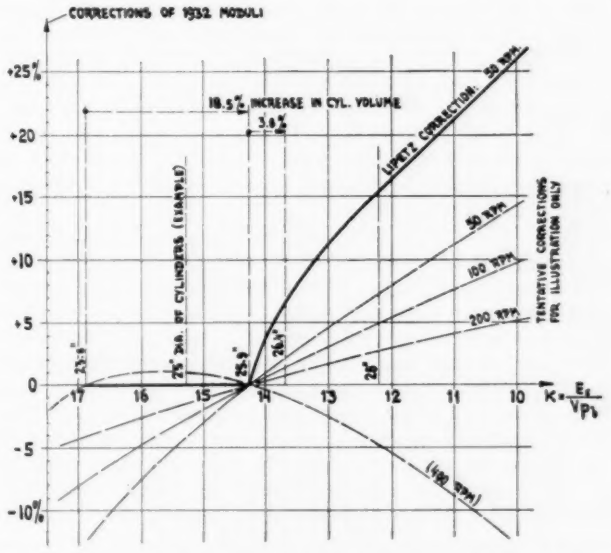

FIG. 1 TENTATIVE CORRECTION CURVES FOR LIPETZ' 1932 MODULI AT 50, 100, AND 200 RPM

moduli, the KV-formula for steam consumption so developed very well represents the trend of steam consumption for varying factors on the right side of the equation, and it is helpful in calculating the correction curves for the Lipetz moduli. Thus, correction curves for 50, 100, and 200 rpm are tentatively shown in Fig. 1 of this discussion. A tentative curve for 400 rpm is illustrated as an example to indicate that the trend will be reversed at very high speeds; this region is, however, entirely outside of the scope of both the present Lipetz moduli and the KV-formula.

Dr. Lipetz, in his present paper, does not limit himself to corrections derived from the changes in the rate of steam consumption. He applies much greater corrections at low speed (50 rpm), arbitrarily chosen to suit the performance curves presented by Mr. Vincent. Thus, for locomotives with large cylinders he abandons the boiler evaporation curve used as a basis in his 1932 paper, and leaves us without a clue as to what is expected from the boiler at low speed, except for saying that the boiler has to be "forced." The explanation for this forcing as given on page 926 of the author's paper is purely psychological: it is claimed that the engineer is induced to force the boiler at low speeds. But certainly there is no necessity of

forcing it because the cut-off could be shortened sufficiently, just as rather small cylinders will permit forcing at higher speeds if the engineer should choose to lengthen the cut-off. To clear up this confusing situation we have to go back to the premises in the author's 1932 paper wherein Dr. Lipetz defined his performance curves as those obtained when a good engineer pilots the engine so as to develop a "reasonable maximum" performance. Later he determined overall thermal efficiency for such a case and found that it lay in the neighborhood of 6 per cent over the whole range of speed. This gave the reasonable result that an engine crew operating a locomotive at a good high rate without overstraining it, deriving its judgment from such observations as: ease in holding the steam pressure, clearness of the stack gases, sound of the exhaust, etc., is operating it at a fairly constant rate of overall efficiency. Under these conditions an average curve of steam production is obtained which at low speeds (50 rpm) remains considerably under the figures which hold at higher speeds (200 rpm), not as an absolute necessity perhaps, but as a good practical result in average cases. By taking such an average evaporation curve as a function of revolutions per minute and relating it to the Cole evaporation, a definite basis of steam production is obtained, to be used uniformly for all locomotives with modern boilers. This method is very practical. Two different locomotives can be compared on such a basis because it is known how much steam each one is expected to generate, and if one of them should fall short of power it is possible to determine whether the fault lies with the boiler or with the steam engine.

With the author's 1934 correction curves, this important advantage has been lost. Each cylinder size, for values of K less than 14.26, implies a different and unknown rate of steam production; even though correction curves for the corresponding steam production could be established, our basis of comparison would become too involved to be practical. Moreover, the supposition is now that steam engine and boiler are working at a "forced" rate at low speeds while they are working at a "reasonable" rate at high speeds. There is none or only a small reserve capacity at low speeds and 15 to 20 per cent reserve capacity at high speeds, while with the 1932 basis of a definite evaporation curve we knew that we had the reserve capacity over the whole range of speed.

That the engine crew is "induced" to work the boiler harder if the locomotive has larger cylinders is true to a limited degree, but this applies to the whole range of speed. Even if this influence were of any importance we had better neglect it in order not to upset our basis of comparison. But there certainly cannot be an inducement for the engineer to operate the larger cylinder with an even greater cut-off than the smaller cylinder as implied by the author's correction curve for $n = 50$; see Fig. 1 of this discussion. It is seen therefrom that a 3.8 per cent increase in cylinder volume (from $d = 25.9$ in. to 26.4 in.) can give the 6.7 per cent increase in performance corresponding to the author's curve only if the cut-off for the larger cylinder is lengthened by about 3 or 4 per cent, which is not logical. The author's corrections in the neighborhood of $n = 50$ have apparently been brought about by the desire to suit the performance curves presented by Mr. Vincent. This, however, was not necessary because we knew that the Vincent curves correspond to a state of greater forcing with small or no reserve capacity over the whole range of speed. Incidentally, this is brought out well by the author's example of the Boston & Albany locomotive. If the new correction curves would be applied to it, the calculated performance at $n = 50$ would be 15 per cent over the road performance and therefore excessive. Dr. Lipetz explains that since this engine has 60 per cent limited cut-off the cylinders could be called about normal, although $K = 12.27$, and he indicates that no correction should be applied. But since he applies the full correction to the Pennsylvania Class I-1s locomotive with only 55 per cent limited cut-off, and likewise to all other examples, it would be inconsistent not to do the same for the Boston & Albany locomotive. However, the 1934 correction method would destory the coincidence between calculated and test figures if this were done.

In conclusion, the writer makes the following recommendations:

1 To use a uniform curve of steam production for all locomotives. It might be investigated whether the 1932 curve is not a few per cent too low at low speeds, and whether it is not falling off slightly too fast at high speeds, but it should be retained in principle.

2 To apply corrections for cylinder size merely in accordance with the rate of steam consumption per indicated horsepower-hour.

3 To adopt the inclined Vincent curve of cylinder tractive effort and to use the straight line only if adhesion is the limiting factor. However, I feel with the author that the "transition curve" is too arbitrary and may better be omitted.

In this way the point of intersection between cylinder and boiler tractive effort will not be at 50 rpm as arbitrarily chosen by Dr. Lipetz for all large-cylinder locomotives, but its location will be a function of cylinder size as it should be.

The great merit of the Lipetz moduli lies in the ease with which they can be adapted to progress in locomotive design. Perhaps we should not try to adjust the moduli to all the locomotives which have been cited by Dr. Lipetz and his discussers. Some of these are no longer modern in their steam engines and all have widely differing draft appliances. With all our progress in steam-locomotive design we have not yet come to sufficiently uniform and accepted design rules. For instance, I cannot agree with Dr. Lipetz on his definition of over-cylindered locomotives; under-cylindering is more frequent. But a large-cylinder locomotive requires a better design of valve gear, steam passages and draft appliance and also better balancing and lighter working parts than we usually have. Under-cylindering covers up deficiencies in design, but of course it manifests itself in deficient performance and economy.

Here is a splendid opportunity for the Association of American Railroads. Individual builders and railroads have not sufficient staff nor the means to fully investigate the subject, nor are their views likely to be generally accepted. If the Association diligently assimilates the information now available here and abroad, the writer ventures to say that we would have standardized, highly efficient designs ready before a new rush in locomotive building starts. We would eliminate a great deal of the uncertainties which today manifest themselves in so many unjustified miscellaneous differences in locomotive design and proportions and cause an entirely unnecessary waste of money in manufacture, upkeep, and operation of our modern locomotives.

Dr. R. Eksergian.[4] The Cole method for the power proportioning of locomotives was at its introduction of fundamental value in rationalizing the relations between boiler and cylinder capacity and coordinating horsepower and tractive-effort speed relations. It gave a measuring stick of the performance of a locomotive in terms of a horsepower unit.

With improvements in the design and proportions of locomotives, and the requirements of more accurate data as to power performance, the inadequacy of the Cole method was felt by all locomotive engineers. For instance, the unit horsepower by

[4] Edward G. Budd Manufacturing Co., Philadelphia, Pa. Mem. A.S.M.E.

the Cole method was based on a cylinder steam consumption (including auxiliaries) of 20.8 lb of steam per hp-hr, and the 100 per cent boiler was such as to evaporate sufficient steam to supply the cylinders in developing a rated cylinder horsepower at 1000 fpm piston speed.

Aside from lower steam consumption in modern power, one difficulty of the method, however, was that it gave no real procedure of estimating the variation of horsepower against speed. For instance, at the lower speeds, with longer cut-offs, the cylinder steam consumption increases and there is a decrease of the evaporative yield of the boiler. At piston speeds around 250 fpm, the possible horsepower might fall considerably below 60 per cent of the rated horsepower at 1000 fpm.

Dr. Lipetz, in his Locomotive Ratios I,[3] recognized the need for a modification of the Cole method and its rationalization to a consistency with the performance of modern power. While it was recognized that cylinder steam consumption is a function of cut-off, speed, and proportions of cylinder design, Dr. Lipetz also brought out the point that evaporative yield was a function of decreasing speed at the lower speeds. This latter deduction was based on the fact that in locomotives investigated, the actual steam consumption of the cylinders fell short of the evaporative capacity of the boiler at the higher speeds. Using the Cole evaporation value as unity, he introduced a coefficient β to take care of this varying evaporative yield. The evaporative yield at 50 rpm was about 65 per cent of the maximum yield at 200 rpm. Considering the increased cylinder steam consumption at the low speeds, it was possible to evaluate a modulus M_p used in the present paper, which, when multiplied by the Cole evaporation value gives the horsepower.

The variation of the modulus M_p really accounts for the variation in horsepower against speed, and was deduced from actual performance data of road locomotives, nearly all of which had long starting cut-offs. In large-size cylinders with limited cut-off, the variation in the total modulus M_p or the corresponding tractive-force modulus M_t may be different. We can have, in effect, the shifting of the maximum part of the horsepower curve to a lower speed range and the criterion of the performance of such engines at 200 rpm no longer holds. The original early cut-off locomotives were designed for slow drag service and their performance became very much limited at the higher rotative speeds, under which conditions their boiler performance was undoubtedly inadequate.

A matter of considerable importance to the writer appears to be whether or not in long cut-offs at the low-speed range, the power percentage of horsepower when compared with the peak horsepower of 200 rpm is due more in part to evaporation deficiency or to limitation of cylinder performance itself. After all, we know only that at 50 rpm the horsepower is roughly a given per cent of a rated horsepower at 200 rpm. With due allowance for increased steam consumption at the lower speeds, the total steam demand of the cylinders still falls short of the boiler evaporation at its normal rating at 200 rpm. But, do we know whether this is chargeable to cylinder limitations or reduced evaporation at the lower speeds? Now, assuming the boiler proportioned to the cylinders, or vice versa, at 200 rpm, then it is usually found that the cylinder tractive effort falls short of the boiler tractive effort, assuming the boiler evaporation constant at its rated value at 200 rpm. If the cut-off is lengthened, wire-drawing becomes excessive and the card factor results in a mean effective pressure practically the same as with a somewhat earlier cut-off. The increased steam consumption for the longer cut-off practically yields no increase of tractive force. In such a case it would appear that the cylinder performance may possibly be the limiting factor in a low-speed range of 50 rpm and not the boiler.

It can be seen, therefore, that the relative proportions of boiler and cylinders in the low-speed range may not be entirely limited to an assumption of limited evaporation of the boiler alone with due allowance for increased steam consumption of the cylinders. It would appear that we might have cylinders with considerable variation in steam consumption with very little change in the maximum mean effective pressure at the low speed of 50 rpm and in such a case, even with an unlimited boiler capacity, the tractive force could not be increased.

One difficulty appears to be that cylinders proportioned for one operating high speed, say 250 rpm, and consistent with the evaporation for that speed, may be quite different from cylinders proportioned against evaporation for operating speeds at 180 rpm. In the latter case, assuming the same evaporation and roughly the same cut-off for minimum steam consumption (neglecting the difference of wire-drawing for the two speeds) the cylinders will be larger than the former, so that the author's K will be smaller.

As an extreme case, let us consider a locomotive with an operating speed at 90 mph, with 84 in. drivers and thus an operating rpm around 360. With orthodox but long-travel valves, economical cut-off may be around 20 per cent or lower. Assuming a suitable card factor for wire-drawing, condensation effect, etc., we arrive at given cylinder proportions. Such cylinders may be inadequate for starting conditions, resulting in a high factor of adhesion. The boiler capacity would be sufficient to sustain long cut-offs for a considerable range at the low speeds, but wire-drawing would cause a drop in tractive force irrespective of boiler capacity. In this case, with low operating speeds say from 40 to 80 rpm, the tractive effort would appear more limited by cylinder size than boiler adequacy.

With locomotives as discussed by Dr. Lipetz operating at 200–250 rpm, the demand on the boiler usually comes at a critical speed around 50 rpm. With limited cut-off locomotives, and, therefore, with large-size cylinders required for starting conditions, the cylinder steam consumption would be too great and therefore inconsistent with the evaporative capacity of the boiler at 200–250 rpm. With the lower steam consumption effected by the shorter starting cut-off, the rated starting tractive effort can be nearly maintained at 50 rpm with less demand on the boiler than for longer starting cut-offs. On this basis a boiler proportioned for this condition would be inadequate for high operating speeds.

With increasing tendencies toward higher operating speeds from 200 to 250 rpm coupled with the desire for maintaining more economical steam consumption at the lower speeds by the use of shorter cut-offs in this latter range, the danger of inadequate boiler capacity is apparent particularly when the boiler adequacy is based on its sufficiency at 50 rpm. Dr. Lipetz has given us an interesting and most ingenious analysis for providing boiler adequacy for this latter condition. If the rated tractive effort T_r gives the tractive effort T_{i50} based on boiler adequacy, this condition will insure adequate boiler capacity for operating speeds around 200–250 rpm.

While the writer is more or less in agreement with Dr. Lipetz' analysis, he would appreciate the author's consideration of the following point. Reviewing the basic analysis

$$P_i = \frac{E_e(1-x)}{s_h} = \frac{E_e}{S_e} = \frac{\beta E_e}{S_e} \text{ for the power}$$

$$T_i = \frac{375P_i}{V} = \frac{375P_1}{\frac{n}{336}D} = \frac{126{,}000\,\beta\,E_e}{nDS_e}$$

$$M_t = \frac{126{,}000\,\beta}{nS_e},\ T_i = M_t\frac{E_e}{D}$$

From test data at a given n, he obtains βE_c, this data being obtained mostly for locomotives with a long starting cut-off. Knowing the power developed or tractive force, he obtains S_a (or S_h). Taking $\beta = 1$, at say 200 rpm, he obtains E_c and compares or corrects for Cole's original evaporation constant E_c. Therefore, at some lower speed he obtains β from the power developed and the steam consumption S_a. At 50 rpm, the tacit assumption is that the power developed is entirely limited by the boiler evaporation capacity so that knowing S_{a50}, the coefficient β_{50} is obtained and likewise the modulus M_t, which also could be obtained directly. If now we assume the locomotive limited by cylinders rather than by boiler capacity at 50 rpm, then β_{50} would not necessarily be the true evaporative coefficient. With large cylinders and more economical cut-off at starting, aside from S_a being decreased, if the true β_{50} were greater than assumed by the author's deduction, M_t would be greater and therefore the boiler adequacy $\frac{T_{i50}}{T_R}$ would appear improved.

Now, of course, as the speed increases where there can be no question about cylinder-performance limitations, the values of the author's β obtained must greatly increase in precision. After all, the question of boiler adequacy is more dependent on conditions at operating speeds. With large-size cylinders, economical cut-offs at these higher operating speeds would be around 20–25 per cent or the same as with long cut-off locomotives. For this reason adequate boiler capacity would demand somewhat larger boilers for speeds around 200–250 rpm and the ratio of horsepower to initial tractive force would increase as compared with long starting cut-offs.

With slow heavy drag service as on grades, etc., the power developed at such low speed ranging from 50–80 rpm, is of particular interest. In this case it is of importance to ascertain whether cylinder performance limitations or boiler capacity is the more critical limitation.

The writer would prefer the analysis of performance simply on the formulas

$$P_i = \frac{\beta E_c}{S_a}, \; T_i = \left[\frac{126{,}000\,\beta}{nS_a}\right]\frac{E_c}{D}$$

with more test considerations as to β, S_a for different speeds, cut-offs, etc., and further analysis of limiting values of M_t at very low speeds. It would be interesting to consider E_c for $\beta = 1$ at several operating speeds, and the variation of β and S_a for different speeds relative to the particular operating speeds considered.

LAWFORD H. FRY.[5] For judging locomotive proportions Dr. Lipetz offers his locomotive characteristic K which is equivalent to E_c/Vp_b, where E_c is the Cole boiler evaporation. Unfortunately, Dr. Lipetz does not give in either the present paper nor in his earlier paper[3] complete information for computing this Cole boiler evaporation.

The writer believes it is unnecessary and undesirable to use an assumed figure such as E_c in comparing boiler and cylinder proportions. Dr. Lipetz concedes something in this direction by saying: ". . . .a constant very similar to K, but with the boiler evaporation replaced by H_e, the evaporative surface in square feet

$$\delta = H_e/Vp_b$$

may also be very useful for comparative purposes."

The writer suggested, in a paper read before the New York Railroad Club in 1903, a boiler factor very similar to the above. This was $B = T_r/H_e$, where T_r is the rated tractive effort in pounds. B and δ are inversely proportional to each other. B has the practical advantage that it is computed from the rated tractive effort, and an additional calculation to find the cylinder volume is unnecessary. δ has a slight advantage in the fact that it is directly proportional to the boiler capacity, so that a large value of δ indicates a large boiler in proportion to the cylinders.

If B is used, it is convenient to note that it measures the pounds of rated tractive effort which must be developed by each square foot of heating surface when the locomotive is working in full gear.

To bring the comparison to a basis of revolutions per minute instead of miles per hour, the writer proposed multiplying B by D, the driving-wheel diameter. This gives

$$BD = \frac{T_r D}{H_e}$$

It can be shown that if the locomotive is working in full gear, the factor BD is proportional to the foot-pounds of work which must be developed at each revolution by each square foot of heating surface. The lower the value of BD, the higher the speed at which the rated tractive effort can be developed. A low value of BD indicates a locomotive with large boiler capacity designed for high-speed service.

For many years the technical papers when publishing accounts of new locomotives gave values of B and BD. This has provided a large amount of information available for the comparison of various locomotive designs.

If it is decided that a newer method of comparison is desirable, the writer would prefer to see Dr. Lipetz' δ used instead of K. It seems to him desirable to make the comparison simple and direct, involving only definite dimensions of the locomotive and avoiding the introduction of any assumed values such as a calculated boiler evaporation.

Discussion of the second phase of the subject, that is the prediction of the tractive power which can be developed at various speeds, cannot be made in detail without full information as to the method of computing the Cole boiler evaporation. This is not given in either of Dr. Lipetz' papers. Dr. Lipetz shows, however, that his method gives computed tractive-power curves which are surprisingly close to the actual curves derived from experiment.

H. RUBENKOENIG.[6] Undoubtedly there is necessity for revision of some of Cole's ratios and other formulas used in calculating tractive effort for locomotives. The generally accepted formula

$$T = KPC^2S/D$$

for determining what is variously designated as cylinder tractive effort, starting tractive power, theoretical tractive force, etc., does not seem to hold for some of the newer locomotives built during the last two or three years.

K in this formula depends upon whether or not the valve has a limited cut-off, and whether or not auxiliary starting ports are used. One of the recently built heavy passenger locomotives of the 4-8-4 class is described as having a rated tractive effort of 69,800 lb. If K is taken as 0.85 (the proper coefficient for 90 per cent cut-off), the tractive effort from the foregoing equation becomes

$$T = 0.85 \times 260 \times 28^2 \times 31/77 = 69{,}300 \text{ lb}$$

[5] Railway Engineer, Edgewater Steel Company, Pittsburgh, Pa. Mem. A.S.M.E.

[6] Professor of Railway Mechanical Engineering, Purdue University, Lafayette, Ind. Assoc-Mem. A.S.M.E.

This locomotive is described as having a valve gear which gives 70 per cent maximum cut-off, but no mention is made of auxiliary starting ports. Assuming auxiliary starting ports, the value of K is 0.78, which when applied to the foregoing formula gives a tractive effort of 64,100 lb. In other words, the rated tractive effort is more than 5000 lb too high if the generally accepted formulas for calculating tractive effort be used.

Since predictable locomotive performances at speeds above starting speeds are based upon data which include suitable corrections being made from the basic figure of capacity tractive effort, it seems that some revision of calculation methods is necessary. It would be interesting to know what assumptions were made in deriving the figure for rated tractive effort of the locomotive previously mentioned.

The 1932 and 1934 papers by Dr. Lipetz are distinct contributions to the subject of locomotive tractive effort and horsepower, and they indicate the direction in which locomotive designers may work in improving the efficiency of the modern steam locomotive.

W. A. Pownall.[7] Dr. Lipetz states that drafting arrangements in particular may cause disagreements or differences between the tractive-effort curves and actual performances. The Wabash railroad has had considerable experience during the past few years with the Kiesel front end which uses an annular-ported exhaust nozzle of large area and a cylindrical draft netting, extending from the stack to the bottom of the boiler, without the usual draft or deflector plates.

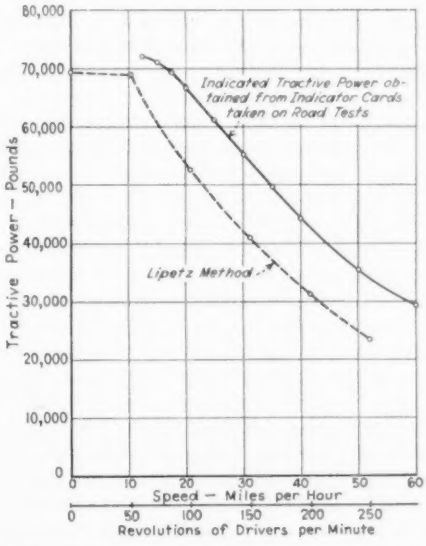

Fig. 2 Cylinder Tractive-Power Curve of a Mountain-Type Locomotive With Kiesel Front End Compared With Lipetz' Calculated Tractive Effort

Fig. 2 of this discussion shows the cylinder-tractive-power curve obtained on a mountain-type locomotive equipped with a Kiesel front end. For comparison, the tractive-effort curve as calculated by Dr. Lipetz' method is also plotted on this figure. The curve as obtained from indicator cards on road tests was not an extreme condition, but was obtained on a large number of runs. It will be noted that at 40 mph, the engine in question actually developed about 35 per cent more tractive power than shown by the Lipetz method. This engine is equipped with a type-E superheater and a feedwater heater.

Fig. 3 of this discussion shows a similar curve for a Mikado-type locomotive equipped with a type-A superheater and without a feedwater heater. The difference between the actual road results and the Lipetz curves is not as pronounced as with the mountain-type locomotive, the excess of the actual tractive power over the Lipetz curve being 17 per cent at 30 mph and 14 per cent at 40 mph. These results are worth attention in showing the increased actual locomotive capacity that can be obtained by drafting arrangement other than the conventional.

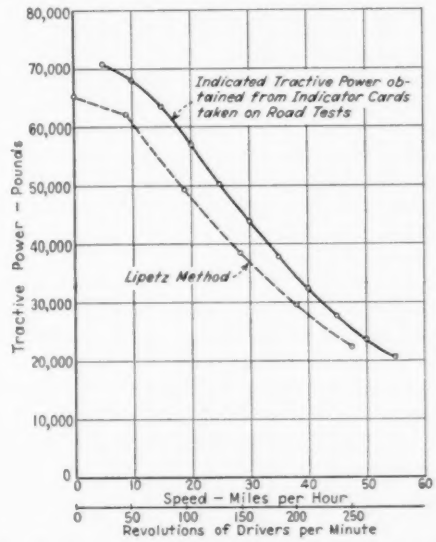

Fig. 3 Cylinder-Tractive-Power Curve of a Mikado-Type Locomotive Compared With Lipetz' Calculated Tractive Effort

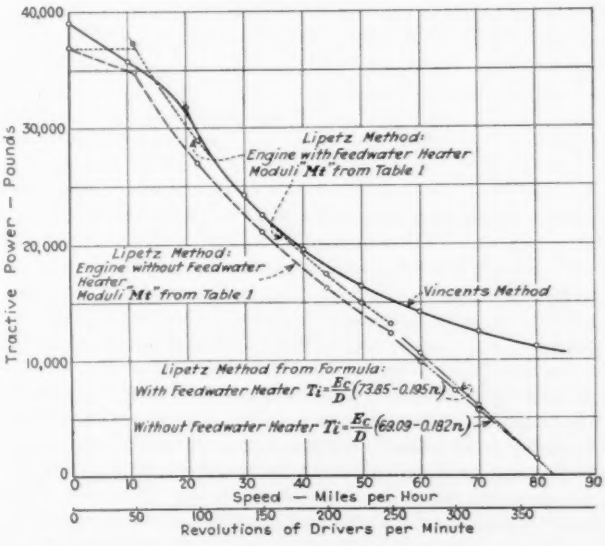

Fig. 4 Cylinder Tractive-Effort of a Pacific-Type Locomotive as Derived From the Vincent and Lipetz Methods

In view of the present interest in high-speed passenger trains there is a definite demand for a knowledge of the draw-bar tractive effort that can be developed by steam passenger locomotives at speeds between 70 to 100 mph.

Fig. 4 of this discussion shows the cylinder tractive effort of a Pacific-type locomotive as derived from the Vincent and Lipetz methods. For speeds above 60 mph, the Lipetz formula would produce a tractive-effort curve considerably lower than the

[7] Mechanical Engineer, Wabash Railway Company, Decatur, Ill.

Vincent curve and also lower than has been obtained in actual service. For example, if the engine resistance were deducted from the Lipetz cylinder tractive effort, there would be nothing remaining to pull the train at about 75 mph, while the engine for which these curves are shown, actually pulled a seven-car train weighing 560 tons, exclusive of the engine and tender, at a speed of from 80 to 83 mph on level track, at which speed it developed an approximate cylinder tractive-effort of 9680 lb. It may be that Professor Lipetz does not intend his formula to be used at driver speeds of over 250 rpm. This actual performance is somewhat less than the value indicated by the Vincent curve and considerably higher than that calculated from the Lipetz formula.

There should be some fairly definite information developed as to available draw-bar tractive effort of locomotives at speeds between 70 and 100 mph.

Author's Closure

While Dr. Giesl-Gieslingen reiterates his agreement with my 1932 method, as given in the previous paper,[3] he takes exception to my 1934 modifications and rejects them summarily. He is in favor of the fundamentals of my 1932 theory and admits the value of the moduli, but thinks that I rather rashly abandoned the strict consistency of that method in order to satisfy the curves presented by Mr. Vincent. I must, therefore, so to speak, defend myself against myself, and this makes my task rather difficult. However, I am afraid that Dr. Giesl-Gieslingen misunderstood the underlying thought of the 1934 modifications and probably forgot the principal object of the 1932 method.

Dr. Giesl-Gieslingen maintains that my theory of 1932 was based, on the one hand, on a certain evaporation curve which he considers more or less correct, although maybe somewhat conservative, and, on the other hand, on a steam-consumption curve with which he also is more or less in agreement. As pointed out in both the 1932 paper and in its closure, the procedure which I followed in the first part of my 1932 paper was used only in order to establish the correct and logical relations between phenomena in a locomotive, which led to a simple formula. I checked it later against all locomotive-test data at my disposal at that time. In other words, while the 1932 method had a theoretical basis, it was purely empirical, and in proving the practicability of the 1932 moduli, I did not attempt to defend the absolute correctness of figures, or curves, of evaporation and steam consumption on which my formula was based. I admitted that the Cole evaporation figure E_c, evaporation-coefficient β and steam-consumption curves may be only approximately correct, but as the formula was later checked against test results and the moduli, specially introduced for that purpose, were corrected so as to conform with these results, the formula, which in its final form was very simple, must have been right and could be used for practical purposes. The user need not go back to the underlying data and examine them. This made the method very simple, as it required the use of only one formula with constant moduli depending upon the rotative speed of the wheels, and at the same time very flexible, because the moduli could be changed when conditions warranted that.

In the 1934 modifications I followed the same principle. In studying the test results of locomotives brought to my attention in Mr. Vincent's discussion of my 1932 paper, I realized that all the locomotives on which I had data at my disposal in 1932 had long cut-offs, and that the locomotives analyzed by Mr. Vincent, especially those for which my 1932 moduli showed discrepancies, were types with limited cut-offs. In my 1932 paper I also considered, among others, the Boston & Albany A-1 locomotive and found that it showed fairly good agreement with my 1932 moduli, although it was of the type with limited cut-off. In analyzing this, I found that the good results of my 1932 moduli, in application to this locomotive, were due to the fact that while the locomotive had limited cut-off, its cylinder sizes were not excessive and very close to the sizes they should have had for a limited cut-off of 60 per cent ($K = 12.27$ instead of $K = 13.09$) while all other locomotives with limited cut-offs which he cited had excessively large cylinders, larger than the limited cut-off would require. The conclusion was, therefore, evident: it was necessary to modify my moduli for locomotives with large cylinders, irrespective of whether or not they were types with limited cut-off or full cut-off. I found a method for doing it and disclosed it in my 1934 paper. Again in order to prove that this method was correct and practicable, I showed that its application to all locomotives on which data were available, both with small and large cylinders, gives very good results. This fact was fully realized and appreciated by Lawford H. Fry in his discussion, and I am very grateful to him for pointing out this fact. It was not a question, as Dr. Giesl-Gieslingen thinks, of satisfying Mr. Vincent's curves. It simply was the question of showing that the locomotives for which Mr. Vincent had test data and which, he thought, were best represented by his formula, could be satisfied by my moduli, if proper modifications are made.

Dr. Giesl-Gieslingen evidently overlooked this point entirely. He thinks that the curve on Fig. 5 of the paper is arbitrary. While it is true that no formula was given for this curve, it was arrived at through a long study of test results and was later checked against all locomotives for which test data could have been obtained. It is the author's opinion that it has more value than a curve like the one shown by Dr. Giesl-Gieslingen in Fig. 1 of this discussion, for which no attempt was made to show its application to any locomotive. Only when a formula has been verified for a reasonable number of locomotives may it be considered seriously, and not before, no matter how scientifically the curve may appear to have been derived.

As an example of another misunderstanding by Dr. Giesl-Gieslingen, the aforementioned Boston & Albany A-1 locomotive can be cited. He says "Lipetz explains that since this engine has 60 per cent limited cut-off the cylinder could be called about normal, although $K = 12.27$, and he indicates that no correction should be applied." What I said was that notwithstanding the fact that this engine has a limited cut-off of 60 per cent, $K = 12.27$ instead of 13.09, if the proper relations of cylinder sizes with respect to the correct α for a cut-off of 60 per cent is taken into consideration. But I did not say that corrections should not be made. They certainly should be made, as they were made in all other locomotives with large cylinders, irrespective of whether they were types with long cut-off or limited cut-off (see, for instance, Texas & Pacific locomotive G-lb, Fig. 8), as 12.27 is less than 14.26. Dr. Giesl-Gieslingen further states "since he applies the full correction to the Pennsylvania class I-ls with only 55 per cent limited cut-off, and likewise to all other examples, it would be inconsistent not to do the same for the Boston & Albany locomotives." Yes, it would be inconsistent, and the correction should be made, but while the I-ls locomotive has a limited cut-off of 55 per cent, very close to 60 per cent of the A-1 locomotive, the cylinders are so large that the K for this locomotive is only 8.53, whereas it should be, according to formula [9a] of the paper, $0.75/0.0596 = 12.55$. Therefore, the cylinders of this locomotive are about 47 per cent larger, and a greater correction is necessary.

As to the Boston & Albany A-1 locomotive, after the correction for the tractive effort at 50 rpm is made, its value will lie above the rated tractive effort, and according to the rules given in the paper, the curve with this point at 50 rpm should be cut off. The remaining part of the curve will not differ much from the test curve.

Dr. Giesl-Gieslingen discusses what I would call "discontinuity

of functions," when he cites in the beginning of his discussion various values of Fig. 5 for smaller and larger cylinders. He refers to the figures "jumping" suddenly by 6.7 and 16.0 per cent, but he forgets that he also jumps $^1/_2$ in. and 2.1 in. in cylinder sizes, or 4.0 and 16.6 per cent in piston areas, respectively. Every continuous function would do that.

Dr. Giesl-Gieslingen is surprised that the Lipetz correction curve for 50 rpm should have an edge at $K = 14.26$. There are many cases like that in engineering practice. A loose tire on a locomotive wheel puts no strain in the wheel rim or in the tire, but if the bore of the tire is several hundredths of an inch smaller than the outside diameter of the wheel, the stress suddenly goes up and it will continue going up with the increase in this difference, most probably with an edge in the curve. The effect of large locomotive cylinders is of about the same nature. If they are too small, there is plenty of steam for them, just as there is plenty of clearance in a loose tire around a wheel, and T_{i50} (indicated tractive effort at 50 rpm) cannot be increased, as a rule, because in small-cylinder locomotives it is equal to T_r (rated tractive effort), corresponding to a maximum cut-off of 85 per cent. However, if the cylinders are larger than what the ordinarily generated amount of steam for the tractive effort at 50 rpm would require, naturally more steam can be utilized by the cylinders, if a certain forcing of the boiler is permitted. Then a modification is, of course, necessary, and the law of modification may go up suddenly, following a curve with an edge. This is what probably happens, and there is nothing illogical in that.

I do not think that it is necessary to go through Dr. Giesl-Gieslingen's other statements except possibly one, in which he says that the reader is left without a clue as to what he might expect from the boiler when it is forced. Dr. Eksergian in his discussion touches on this point in connection with the coefficient β. In order to amplify Dr. Eksergian's thought, and to reply fully to Dr. Giesl-Gieslingen's statement, I am going to present several charts which recently came to light. They were not known to me at the time when the present paper was prepared. A very interesting book,[8] recently published on a 2-10-2 locomotive, series FD, developed and built in U.S.S.R., came into my possession. For the development of this engine the locomotives built in America in 1931 for U.S.S.R. were taken as examples and, therefore, the locomotives are in many respects similar to regular American-built engines. They have large grates, steel fireboxes, firebrick arches, type-E superheaters, feedwater heaters, stokers, boosters, etc. They differ only in having fireboxes of the Belpaire type instead of the round-top shape. A 2-8-4 passenger-type locomotive, series JS, has also been developed and built by the U.S.S.R. In this type, boilers and cylinders are identical with those of the FD engines, the principal difference being in the chassis: frames, wheels, boxes, etc.

TABLE 1 PROPORTIONS AND RATIOS OF U.S.S.R. SERIES FD AND JS LOCOMOTIVES

Locomotive	Russian 2-10-2 FD Class	Russian 2-8-4 JS Class
Cylinder dimensions		
Diameter, d, in.	26.4	26.4
Stroke, s, in.	30.3	30.3
Heating surface, H_e, sq ft	3177	3177
Boiler pressure, p_b, lb per sq in	213.4	213.4
Cole evaporation, E_c, lb per hr	44859	44859
Superheater type	E	E
Feed water heater	Yes	Yes
Max indicated ratio, α_{max}	0.78	0.78
M_t at $n = 50$	65.6	65.6
Driving wheel diameter, D, in.	59	72.8
Boiler adequacy, $a_b = \frac{T_{i\,50}}{T_r}$	0.837	0.837
Boiler percentage (Cole)	0.809	0.809
Cylinder volume, V, cu ft	19.20	19.20
$\delta = \frac{H_e}{VP_b}$	0.775	0.775
$K = \frac{E_c}{VP_b}$	10.95	10.95

The principal dimensions of these two engines are shown in Table 1 of this discussion, which is compiled in the same manner as Table 4 of the paper. In view of the similarity between these two types and American engines, the test results of these U.S.S.R. locomotives are of great interest to us for the present purpose.

The book[8] just referred to describes in detail the U.S.S.R. 2-10-2, Series FD locomotive, and in Appendix 1 gives results of very elaborate tests in the form of charts according to the method worked out years ago by Professor Lomonossoff in Russia.[9] Fig. 602 of the book is reproduced in this discussion as Fig. 5. The abscissas are speeds in kilometers per hour; the ordinates are indicated tractive efforts in kilograms. The full-line curves correspond to constant evaporation, the figures on them showing kilograms of steam per hour consumed by the cylinders (excluding auxiliaries), the steam being referred to one square meter of outside heating surface. The dashed curves correspond to constant cut-off, the figures on them representing percentages of cut-off. In Fig. 6 of this discussion the constant-evaporation curves of Fig. 5 are reproduced in English measurements. The notations

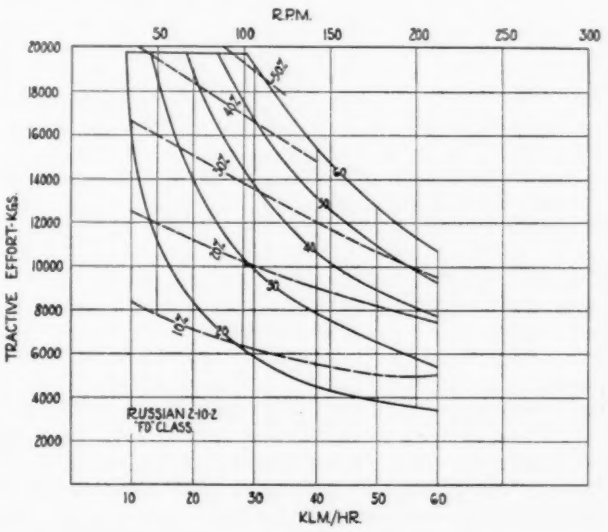

FIG. 5

(Full-line curves are constant-evaporation lines, the figures on them representing kilograms of steam consumed by cylinders per hour, referred to a square meter of outside heating surface. Dashed curves are constant-cut-off lines; figures on them represent percentages of cut-off.)

on the axes are made to conform with the practice of the author's 1932 and the present papers. Full lines are constant-evaporation curves, figures on them representing pounds of total steam generated by the boiler per square foot of outside heating surface per hour. These figures were obtained from the metric-evaporation figures by adding 10 per cent for auxiliaries, as this amount of steam has not been included in the Russian curves. In addition, the author's 1932 and 1934 curves have been added to the chart.

The locomotive characteristic K, as can be seen from Table 1 of this discussion, is equal to 10.95, and corrections have been made in accordance with Fig. 5 of the paper. It is interesting to note that the 1934 curve follows, as to the general trend, all other curves, but it lies outside of all of them, even that which corresponds to the maximum evaporation of 13.5 lb of steam per sq ft of outside heating surface. By extrapolation it can be found that the 1934 curve corresponds to an evaporation of about 14.2.

[8] "Locomotive Felix Dzerjinsky" (published in Russian), Moscow, 1934.

[9] "Object of Locomotive Tests and Their Method," by G. Lomonossoff, St. Petersburg, 1914.

Now, the Cole evaporation figure for this locomotive is 44,859 lb per hour. The outside heating surface is 3177.08 sq ft. The evaporation per sq ft is, therefore

$$E_c/H_e = 44{,}859/3177.08 = 14.15$$

very close to the foregoing figure of 14.2. This agreement is remarkable, or, using Mr. Fry's expression, "surprising." In reality it is natural, if we consider that the Series FD locomotive is of, what may be called, American design, and has, as it will be

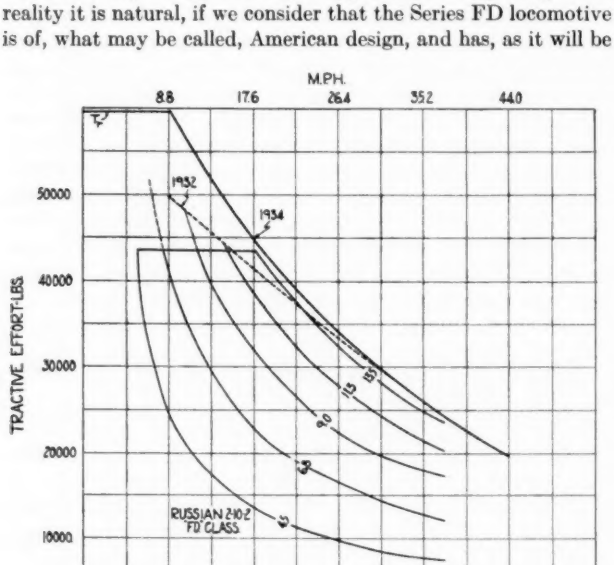

FIG. 6

(Full-line curves are constant-evaporation curves, the figures on them representing pounds of steam generated per square foot of outside heating surface per hour.)

shown later, the regular circular exhaust nozzle, for which the author's curves have been established. The above agreement also shows that the 1934 curve for the Series FD locomotive follows the Cole evaporation figure with a β equal to 1.00 for all speeds; in other words, in order to obtain the 1934 tractive effort at low speeds, the boiler has to be forced. This answers Dr. Giesl-Gieslingen's and Dr. Eksergian's questions as to how high β at low speeds must be. For the Series FD locomotive with $K = 10.95$ it is evidently 1.00. For other cylinder ratios it may be different. It can be figured out approximately from the modification curve by following the trend of Dr. Eksergian's thoughts and the formulas given in his discussion.

In this connection Fig. 6 of this discussion also shows that the 1932 curve would intersect the tractive effort curves at other lower evaporations. For instance, an evaporation of 11.3 would intersect the 1932 curve at about 83 rpm. An evaporation of 9.0 would permit a speed of about 59 rpm, and at 50 rpm the 1932 curve would probably correspond to an evaporation of somewhere between 6.8 and 9.0. It can be found by interpolation to be 8.01, which is about 56.7 per cent of 14.15, which is close to the β assumed by the author for 50 rpm, if we remember that the coefficient β was established as an average of data from many locomotives.

About the same time (1933) the Russian Government developed and built the Series JS passenger locomotive. This locomotive, as has already been stated, has the same boiler as the Series FD locomotive, and has cylinders of the same size. It differs only in the size of driving wheels, which were about 73 in. in diameter instead of 59 in. As our locomotive formulas are based on the boiler evaporation, and the modifications are based on the cylinder dimensions, these two locomotives should give the same power curves, differing only with respect to the tractive efforts in so far as they are affected by the size of driving wheels. Boiler evaporation should be exactly the same. For purposes of comparison, Figs. 7 and 8 of this discussion have been prepared. They correspond to Figs. 5 and 6 for the FD locomotive. Again, Fig. 7 is an exact reproduction of Fig. 12 of the publication on the JS locomotive,[10] while Fig. 8 is the same as Fig. 7 converted to English measurements, with the author's 1932 and 1934 curves added. Furthermore, in order to compare the relation of the 1934 curve on Figs. 6 and 8 of this discussion the highest constant-evaporation curves of Fig. 8 are omitted and the 13.5 curve is retained as the highest, the same as in Fig. 6. It can

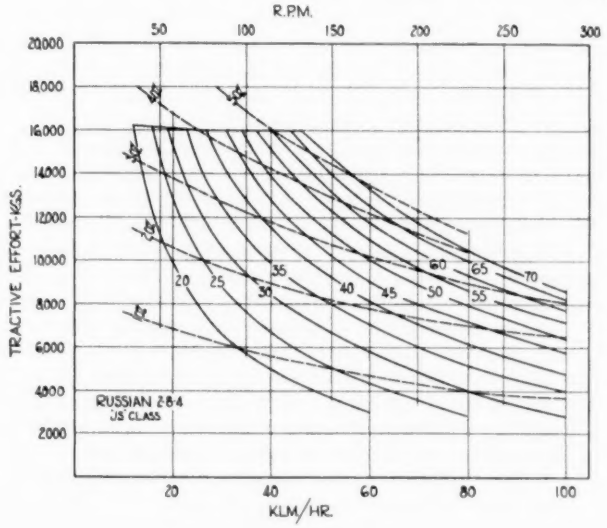

FIG. 7

[10] "Principal Test Results of the First Type 2-8-4, Series JS Locomotive" (in Russian), Moscow, 1934.

be seen, however, from comparing Figs. 5 and 7 that the maximum evaporation on the tests of the JS locomotive was much higher than on those of the FD locomotive; 70 against 60 kg per sq meter per hr, or 16.7 per cent higher. This result was somewhat puzzling, but a careful study of the tests of the second locomotive showed that the two locomotives which are supposed to be alike, when actually tested, had different exhaust nozzles: the FD locomotive had the ordinary round nozzle, while the JS locomotive had a special nozzle with separate exhausts from the right and left cylinders, and four round openings for the escape of steam which had a total area 32 per cent larger than that of the single opening of the round nozzle used on the FD locomotive.[11]

This difference probably explains the higher evaporation and may also explain why the 1934 curve, which in Fig. 8 of this discussion has in general the same characteristics as the one described in reference to the FD locomotive (Fig. 6), is switched so as to coincide more with the 12.4 evaporation curve than to be coincident with the 14.2 curve. This is the result of reducing the back pressure of the JS locomotive and, incidentally, reducing the minimum steam consumption of the latter locomotive, per equal power which was 15.5 lb per rail horsepower, as compared with 17.4 of the FD locomotive.[12]

It is also interesting to note that notwithstanding the differences just mentioned, the trend of the 1934 curve and its relation to the constant-evaporation curves is about the same in Fig. 8 for the JS locomotive as in Fig. 6 for the FD locomotive, and that in the JS locomotive it also corresponds to a constant evaporation (about 12.4), which, however, because of better efficiency is lower than the Cole evaporation per square foot of outside heating surface (14.15). In this case β has a constant value of about 0.88. Thus, the tractive effort of a JS locomotive, if tested under the usual American conditions, would give a $1/0.88 = 1.14$ increase ratio for the same amount of steam, and a further increase due to 16.7 per cent higher evaporation, a total increase in the ratio of $1.14 \times 1.167 = 1.33$, or a 33 per cent increase, with the same "strain of forcing," so to speak.

The above explanations, I think should satisfy Drs. Giesl-Gieslingen and Eksergian as to the question of what evaporation the modifications of 1934 actually represent, and should also corroborate Mr. Pownall's statement as to the increase in locomotive capacity due to the use of a drafting arrangement other than the conventional. Mr. Pownall's figure of a 35 per cent increase is about the same as the 33 per cent increase cited previously.

In order to finish with Dr. Giesl-Gieslingen's discussion, a few words should be said about his suggestions. Of course, one should welcome the recommendation that some institution, for instance, the Association of American Railroads, should accumulate and assimilate all possible information now available on results of locomotive tests. The author himself has gone even further and suggested some time ago that a central institution, the best of which at present is the Association of American Railroads, should conduct a similar research of its own.[13] This is now on the program of the Association, and the author understands that tests with modern locomotives with a view to establishing fundamental data for locomotive ratios are now being contemplated. The author hopes that the tests will soon be made and he is confident that their results will help to confirm, or modify, his moduli and his correction curve (Fig. 5 of the paper).

As to Dr. Giesl-Gieslingen's recommendations 1, 2 and 3, they have no bearing on this paper. The recommendations are not new and are too general. Besides, the recommended tests when carried out, cannot obviate the necessity of having a simple method by which a reasonably correct evaluation of the power and tractive effort of a locomotive could be made without going to elaborate tests and calculations. This was the object of the author's papers.

Dr. Eksergian's apprehension as regards the difficulties with β which we may run into, if we follow the author's suggestion regarding boiler adequacy at 50 rpm, probably can be answered better by saying that while the adequacy, as shown in the paper, comes out close to 1.00 instead of Cole's 100 per cent, the author has not stated definitely what percentage he would recommend for either drag, limited cut-off, or high-speed locomotives. This, following his usual policy, has not been made for the reason that no test data are yet available on high-speed locomotives. His feeling, however, is that 1.00 and greater figures will serve just as well with respect to the boiler adequacy, as Cole's 100 per cent, or larger, boiler. For locomotives with large-size cylinders, both coefficients automatically will come out smaller. Following his line of reasoning, the cylinders have to be dimensioned on the basis of starting tractive effort and he does not expect that any difficulty will arise at high speeds on account of the insufficiency of cylinder dimensions, as long as the boiler is given sufficiently large proportions; corresponding to a boiler adequacy of 1.00, but the larger, the better, especially for high-speed locomotives.

As an example, the high-speed streamlined 4-4-2 locomotive recently completed by the American Locomotive Company for the Chicago, Milwaukee, St. Paul & Pacific could be cited. The Cole boiler-percentage figure for this locomotive is 108.8. The author's boiler adequacy is 1.116, which indicates the close approximation of both coefficients to their respective normal values (100 and 1.00 per cent). The author does not advise that the Cole evaporation figure, with which railroad mechanical men have become familiar, should be replaced by the new conception of boiler adequacy, although he thinks that the latter imparts greater definiteness to the meaning of boiler proportions, for reasons explained in the paper. The main reason for the author's suggestion of this new conception was only because in some quarters it was felt that when the Cole speed factors are replaced by the author's moduli, the Cole boiler-percentage figure is lost sight of. The author, therefore, tried to establish something which could take the place of the Cole boiler-percentage figure, if his moduli are used for the evaluation of horsepower and tractive effort instead of the Cole factors. If it is desired to figure the Cole boiler percentage, it can be done, but then additional calculations of some of Cole's figures, which are not needed for the author's method, will have to be made, without arriving at a substantially different figure, except that one (the Cole) is in per cent, while the other (the author's) is in fractions.

Reverting to Mr. W. A. Pownall's discussion, it can be added to what has been already said, that the discrepancies which he noticed between his curves can undoubtedly be explained by the difference in drafting arrangements. The 1932 and 1934 methods correspond to the ordinary round nozzle and A.A.R. smokebox arrangement, as it has been brought out by the agreement between the author's moduli and test results. The Kiesel front may be giving better results, and probably permit forcings of the boiler, without corresponding reduction in the efficiency, similar to the case with the drafting arrangement on the U.S.S.R., Series JS locomotive.

As to the use by Mr. Pownall of the author's analytical formula

---

[11] "Principal Test Results of the First Type 2-8-4, Series JS, Locomotive" (in Russian), Moscow, 1934, p. 41.

[12] Compare Fig. 34 of "Principal Test Results of the First Type 2-8-4, Series JS, Locomotive," with Fig. 609 of "Locomotive Felix Dzerjinsky" previously referred to.

[13] "Coming Motive Power and Locomotive Research," by A. I. Lipetz presented before the Canadian Railway Club, April 9, 1934, concluding paragraph.

for very high speeds and revolutions per minute (up to 360), this has not been intended by the author. The formulas are simplifications of the moduli. They give approximately the same results and should not be used for speeds higher than the moduli themselves, namely, 250 rpm.

In his 1932 and 1934 papers the author hesitated to extend his curves beyond 250 rpm simply for lack of data. When the tests to which Mr. Pownall refers are published, with all details which would permit judging the efficiency, evaporation and other features of the performance, the curves could be extended for higher speeds. The advantage of the author's method is the ease with which the modifications of moduli can be made if dictated by test results. Simply as an example, but not as a matter of recommendation, the author may say this in reference to higher speeds:

A comparison of his 1934 curves with the curves on Fig. 8 of this discussion and others show a great probability that his moduli for 250 rpm may have been slightly underestimated. It is probable that at higher speeds, especially with better drafting arrangements, the supposition of Mr. Cole, that after a certain limit of speed the horsepower remains constant, is true. If this should be so, say, after 200 rpm, the Mp moduli would be as given in Table 2 of this discussion.

TABLE 2 VALUES OF THE M_p MODULI FOR SPEEDS ABOVE 200 RPM

Revolutions per minute, n	200	250	300	350
Locomotives with feedwater heaters, Modulus $M_p \times 1000$	54.0	54.0	54.0	54.0
Locomotives without feedwater heaters, Modulus $M_p \times 1000$	50.5	50.5	50.5	50.5

Then accordingly, on the basis that Mn = constant, the M_t moduli should be as follows:

Revolutions per minute, n	200	250	300	350
Locomotives with feedwater heaters, Modulus M_t	34.1	27.4	22.8	19.6
Locomotives without feedwater heaters, Modulus M_t	31.8	25.2	20.9	17.9

As the boiler can always be forced to a certain extent, especially at high speeds, it may be safe to use the moduli of Table 2 in all cases when curves have to be extended for high speeds, before reliable test data are available. Of course, they will have to be watched very carefully and checked against test data, and as we are soon going to have high-speed locomotives on many railroads, from which high-speed test results undoubtedly will be obtained, this can be easily done.

In view of the fact that some readers may be tempted to extend the formulas, given at the end of the paper, to speeds higher than 250 rpm, as Mr. Pownall has done, the author thinks it advisable to give formulas corresponding to the preceding tabulation of constant moduli M_p and hyperbolic moduli M_t. In such a case, strictly speaking, it must be noticed that the constant-horsepower line should be tangent to the horsepower curve at its maximum point; then the hyperbola will follow smoothly the straight line of the tractive effort. The approximate speed at which this takes place for formulas [13a] and [13b] is 190 rpm (the exact values are 189.4 and 189.9 rpm).

Incidentally, at the rotative speed of 190 rpm, the modification y is equal to zero. Thus, the following formulas can be recommended:

For locomotives equipped with feedwater heaters and speeds up to 190 rpm

$$T_i'' = \frac{E_e}{D}(73.85 - 0.195n)(1 + y) \quad \ldots\ldots [16]$$

where E_e is the Cole evaporation figure, lb per hr, D is the diameter of drivers, in. and n is rpm. Modification coefficient y should be figured in accordance with formula [15], which is here repeated

$$y = \left(\frac{30}{n + 10} - 0.15\right)\frac{15 - K}{7} \quad \ldots\ldots [15]$$

This formula eliminates from Fig. 5 the sharp edge at K = 14.26, so objectionable to Dr. Giesl-Gieslingen, and replaces it by a blunter point at K = 15.0. A number of small-cylinder locomotives, practically all of any importance, will be thus included.

At 190 rpm $y = 0$, and $T_i''_{190} = \frac{E_e}{D}36.8$

The corresponding horsepower will be (see formulas [5] and [9] of the 1932 paper)

$$P_i''_{190} = \frac{T_i'' \times V}{375} = \frac{T_i'' \times nD}{375 \times 336.134} = \frac{E_e}{D} \cdot \frac{36.8 \times 190 \times D}{126{,}050} = E_e \times .05547$$

Thus, modulus $M_p \times 1000$ = 55.47 instead of 54.0 for the maximum horsepower at 200 rpm, a difference of +2.7 per cent. This represents the approximation of the formula and the error in replacing 190 for 200 rpm as the speed at which the horsepower is maximum.

For speeds higher than 190 rpm, the tractive effort, the horsepower remaining constant, will evidently be

$$\frac{P_i'' \times 375 \times 336.134}{nD} = \frac{E_e \times 0.05547 \times 126{,}050}{nD} = \frac{6992\ E_e}{nD}$$

Thus, the tractive effort, for speeds above 190 rpm, can be figured in accordance with formula

$$T_i'' = \frac{E_e}{D}\frac{6992}{n} \quad \ldots\ldots [17]$$

For locomotives without feedwater heaters the corresponding members of the formulas will be reduced in the ratio of 100:107. They will be, for speeds up to 190 rpm

$$T_i' = \frac{E_e}{D}(69.09 - 0.182n)(1 + y) \quad \ldots\ldots [18]$$

and for speeds higher than 190 rpm

$$T_i'' = \frac{E_e}{D}\frac{6557}{n} \quad \ldots\ldots [19]$$

The author wants to emphasize again that these formulas are approximate. They are of such a nature as not to be easily memorized, and have to be looked up for references. Therefore, it might be just as well to use moduli instead of the formulas. In case a simple formula for memorizing should, nevertheless, be desired, the one given in the paper (14′) could be used. It is here repeated

$$T_i = \frac{E_e}{D}(75 - n/5) \quad \ldots\ldots [14']$$

The modification for locomotives with K less than 15.0, in accordance with formula [15], will have to be made.

This formula is also good up to 190 rpm. At this speed the value in brackets is 75 — 38 = 37. The corresponding formula for speeds above 190 rpm would be $T_i = E_e \times 7030/Dn$, because $37 \times 190 = 7030$. We can simplify the formula by making

$$T_i = \frac{E_e}{D}\frac{7000}{n} \quad \ldots\ldots [20]$$

which is approximately the same as formula [18] and sufficiently simple to be remembered.

Curves of formulas (14′) and (20) intersect at n = 200. At

this speed the factor in the brackets in formula [14′], which is M_v is equal to $75 - \frac{200}{5} = 35$, instead of 34.1 according to the previous tables. This is sufficiently close for an approximate calculation.

For locomotives without feedwater heaters the values of formulas [14′] and [20] must be reduced in the ratio of 100 : 107.

Mr. Fry, who is in general agreement with the author's method, brings out a point which may be of interest. He refers to his contributions made about thirty years ago and indicates that instead of Cole evaporation (E_c), the outside (evaporating) heating surface (H_e) could be used. This is approximately correct, because the ratio between these two figures, namely, the average Cole evaporation per hour per square foot of outside heating surface, differs very little. For locomotives given in Table 4 of the paper and in Table 1 of the present closure, it fluctuates between 11.50 (No. 3) and 14.72 (No. 1). For more modern locomotives it varies between 12.91 (No. 10) and 13.96 (No. 17). An average figure of probably 13.5 could be adopted, but it would still be an approximation and would in many cases destroy the good agreement between curves and test results, to which reference was made by Mr. Fry himself.

Mr. Fry's objection is mainly due to the fact that he had difficulty in computing the total Cole evaporation figure. As is known, Cole's figure is based on 55 lb of steam per hr per sq ft of direct heating surface (firebox plus brick arch tubes plus syphons), and average evaporations for tubes and flues, depending upon their size, length, and spacing. Tables of these specific evaporations are given in the locomotive handbook published by the American Locomotive Company in 1917, and reference to it was made in the author's 1932 paper. New figures regarding tubes of $3^1/_2$ in. outside diameter (without superheater units) and $3^1/_2$-in. flues (with superheater units), which came into use after the publication of the A. L. Co. handbook, in pounds of steam per hour per square foot of outside heating surface for various lengths of tubes and flues and various spacings, have been given by the author in Appendix No. 2, page 16 of the 1932 paper.[3] The author is surprised at Mr. Fry's statement that "Lipetz does not give in either the present paper or his earlier paper complete information for computing this Cole boiler evaporation." While this is literally correct, proper references to the A. L. Co. handbook were made. It is true that the locomotive handbook is now becoming very rare, but it has been in use by practically all railroads for years, and copies can be found in libraries. A new edition is contemplated.

Apart from the reason of the momentary difficulty in finding access in some cases to the A. L. Co. handbook, there is no good argument in favor of using the heating surface, as approximation, instead of the Cole evaporation figure, as the latter, when the basis of computation is available, can be determined easily. However, if a change should be desired, there would be no difficulty in substituting the total evaporating heating surface (H_e) for the Cole evaporation (E_c), if the author's moduli are increased in the ratio of, say, 13.5, which, as we saw above, represents the average evaporation figure for modern locomotives in pounds per hour per square foot of total evaporating heating surface. However, correction curve (Fig. 5 of the paper) would have to be accordingly modified, so as to use the author's δ instead of K. This would be another example of the flexibility of the author's method, which can be easily adjusted to simplifications when they are thought necessary, or to new data when they become available.

There remains Prof. H. Rubenkoenig's discussion, which is directed more to the starting tractive effort. He refers to auxiliary starting ports, for which he would like to have a coefficient in the tractive-effort formula. The author's paper did not consider the tractive effort at the moment of starting. This differs from the maximum, or the rated tractive effort, which can be indefinitely developed at a certain speed (about 50 rpm), depending upon the capacity of the boiler. Under these conditions, the author gave in his discussion coefficients for the rated tractive effort in his closure on page 33 of the 1932 paper.[3] The author does not think that the auxiliary ports can increase materially the tractive effort and, therefore, he did not give any corrections for that.

Before closing the author would like to call attention first to the maximum boiler tractive effort, and, second, to the types of locomotives for which his method and moduli should be used. Some railroad engineers claim that they are not interested in the "performance" curves obtained under conditions defined by the author in his 1932 paper and its closure, but in the maximum-tractive-effort curve, which represents the top values at various speeds under hardest working conditions. On some roads they are called "capacity curves." The author did not attempt to give these curves, because they depend upon the specific properties of a locomotive and the individual method of operation, which cannot be easily generalized. At least, there are not yet sufficient data, even on modern American locomotives, to predict with accuracy what the maximum curve can be. The author attempted to give a general method for the evaluation of the performance curve which corresponds to usual every-day methods of operation with a reasonable efficiency. His curves are lower than what occasionally can be materialized, but they have the advantage that they can be safely developed with reasonable efficiency and without excessive maintenance. The maximum curve depends upon the extremes in efficiency and maintenance to which the operator is willing to go, and cannot be adopted generally. This curve has to be established by the operating railroad from actual experience. But even then, it might be found advantageous to compare the test curve with the performance curve, and when enough information is accumulated by the railroad on a number of locomotives, a method of evaluating particular locomotives can be worked out by a comparison with the basic performance curves.

The other point, closely connected with the first, refers to the designs of locomotives which were used as a basis when the method and moduli were established. It was called the modern locomotive, under which term it was understood a locomotive with sufficiently large grate area, a brick arch, type-E or a well-proportioned type-A superheater, 225 to 300 lb per sq in. boiler pressure, simple expansion cylinders, properly designed valve motion according to latest practice, round exhaust nozzle, and A.A.R. smokebox arrangement. It would be erroneous to use the formulas for locomotives which differ from the described standard design. If some improvements are being tried out, say, for instance, an improved drafting arrangement, tests should be made and the difference would indicate the gain resulting from this improvement. The same would apply to poppet valves and similar innovations. It is evidently incorrect to compare actual test data from locomotives of other, especially non-American, designs, with these formulas, as has been done, for instance, by Mr. André Chapelon in his very informative article on the French High Speed 4-8-0 Type Locomotive of the Paris-Orleans Railway. He checks the high power obtained from these locomotives against the Lipetz formula and shows that the power is more than twice the maximum obtained from the formula.[14] In this case the boiler was made up mostly of tubes of the French Serve type, which have $2^9/_{16}$ in. OD and have inside ribs. The engine has four cylinders compound, rotary-cam Lentz-Dabeg poppet valves, and a double Kylchap drafting arrangement. The author does not understand how the Cole evaporation figure

[14] *Revue Generale des Chemins de Fer*, March, 1935, p. 281.

could be computed for a boiler with Serve tubes and how the Lipetz curve could be plotted. The increase in power as compared with the Lipetz formula is probably due to the high forcing of the boiler and to the enumerated improvements.

The author based his moduli on tests with modern American locomotives He has not extended them yet to other types of locomotives, like high pressure, double expansion, etc., mainly for lack of data, and secondly, because the main object of the paper was to show that the method based on boiler evaporation, rather than that based on cylinders (Cole method), gives more consistent results in regard to establishing the power of a locomotive.

The Intake Orifice and a Proposed Method for Testing Exhaust Fans[1]

R. D. Madison.[2] Fig. 11 shows a proposed arrangement which seems to apply particularly to axial-flow fans mounted in ducts. For wall-mounted disk fans the box arrangement shown in Fig. 10 is not only desirable but it must be used if the flow lines through the fan are to duplicate actual conditions. For the centrifugal fan without inlet boxes, the fan should not be tested on the inlet. For centrifugal fans with inlet boxes, the method of providing the box (or boxes) with bell-mouthed entrance duct (as shown on plate *G* of the N.A.F.M. and A.S.H. & V.E. codes) seems to have everything to commend it, since a short discharge duct should be provided in any case. The applicability of the intake orifice to fan testing, as far as code procedure is concerned, is still open to discussion. Although the intake orifice is much simpler than the rounded nozzle to construct, its application is quite limited.

Two points should be mentioned in the use of the inlet orifice which the authors have not fully covered. No provision is made for eliminating chance spiral flow that may be present in the test room and which will be accelerated as the orifice is approached. An open door or the fan's own discharge may provide this spiral impetus. Even a simple form of crisscross straightener a short distance ahead of the orifice should suffice. Practically all wind tunnels are equipped with some such device.

Again, as the orifice approaches 100 per cent pipe diameter, the flange should extend appreciably beyond this point to keep the flow lines at entrance substantially constant. The coefficient for an open-end pipe is different from an orifice in a flat plate and when the pipe is tested with full pipe opening the flange should be sufficiently extended to approximate flat-plate conditions. It would seem more practical, in the case of the 100 per cent orifice, to use a tap at full pressure recovery and the corresponding coefficient of discharge. This would require a less critical placing of the tap.

The diagram, Fig. 4*a*, is likely to be confusing to those not familiar with air flow. The vena contracta is shown more than one pipe diameter from the orifice to correspond with the readings obtained at the pressure taps. Now the actual vena contracta is in the neighborhood of $^1/_2$ orifice diameter from the orifice plate and the flow approaching it corresponds closely to the conventional rounded nozzle. From this point to that of maximum recovery pressure there is considerable turbulence and some of the outer mass of air is flowing in a direction opposite to the central stream. The static pressure is not necessarily uniform over any given cross-section and the static-pressure taps do not record the static pressure except in the outer region adjacent to them. The gradual rise in pressure from the lowest point to that at the orifice plate is probably due to a slowing up of the counter current flow and an attendant increase in static pressure. While the positions of the taps recommended by the authors are logical from the standpoint of stability of readings and are, therefore, the most accurate to use, there is no need to attempt to correlate the flow as indicated in Fig. 4*a*. To do so will only lead to confusion.

Authors' Closure

The authors cannot agree with Mr. Madison in the statement that a centrifugal fan without inlet boxes should not be tested on the inlet side. Single-inlet exhaust fans which are usually directly connected to a duct should be tested on the inlet side as such a set up will exactly duplicate the way in which the fan is intended to be used. The inlet orifice is a simple and accurate device for such tests.

The test room used was so large compared with the orifice area that there was no perceptible air motion a few feet away from the plate. The possibility of spiral flow in the room ahead of the plate was remote indeed. The use of air-flow straighteners would hardly be feasible with the intake orifice and it should not be used if there is an unusually bad approach condition.

The statement was made in the paper that the flange on the end of the pipe was acting as the orifice in the case of the 100 per cent orifice. The authors agree with Mr. Madison that the coefficient would be different if this flange were absent. The 100 per cent orifice is not recommended for measuring purposes and was only investigated as a matter of interest.

No distances are marked on Fig. 4a but the discussion of the behavior of the air below the plate must be accepted by the authors since it comes from one who must be considered one of our authorities on air-flow behavior in general.

Pulverized Fuel-Burning Experiences at Buzzard Point Station[1]

E. G. Bailey.[2] The boilers and furnaces at Buzzard Point station represent a new type of steam-generating unit in which have been incorporated the best features of existing installations together with additional features which make it an outstanding development. The furnace is completely water cooled, the lower portion being of the stud-tube construction; vertical turbulent burners are used, which direct the flame down onto the liquid-slag bath; a furnace slag screen divides the furnace into two portions, a lower combustion chamber and an upper cooling chamber which is covered with smooth iron blocks to obtain maximum cooling of the gases before entering the convection surface; straight tube sections of the header type resemble conventional design, but the head is greatly increased permitting high ratings per section; the superheater is supported directly from vertical circulating tubes and is divided into two sections with a desuperheater between to give flat steam temperature; the economizer is entirely within the setting and supported on vertical circulating tubes.

Burning coal in pulverized form presents two major problems, the first of which is to burn practically all of the carbon in the limited space and time available with the high liberations dictated by economy. This is not easy to do with the low-volatile coal used at Buzzards Point but the low unburned-carbon loss reported in the paper confirms the correctness of the burner and

[1] Published as paper FSP-56-18, by H. G. Thielscher, in the December, 1934, issue of the A.S.M.E. Transactions.

[2] Vice-President, Babcock & Wilcox Company, New York, N. Y. Mem. A.S.M.E.

furnace design. Recent tests have shown average combustible in the flue dust of 4.0 per cent corresponding to a heat loss of 0.07 per cent at a low rating of 68,000 lb per hr of steam and at a high rating of 313,000 lb per hr of steam the combustible in the flue dust averaged 10.8 per cent corresponding to a heat loss of 0.34 per cent.

The second problem is to dispose of the ash. The vertical burners direct the ash directly against the liquid-ash floor where a large portion is caught. The walls of the lower chamber are wetted with slag and trap additional amounts of ash. The furnace slag screen, which is studded and covered with refractory, catches still more of the ash as the gases impinge on the tubes in passing through. In this way the coarsest, stickiest and most objectionable portion of the ash is caught in the furnace and tapped out as liquid slag. The dust collectors remove practically all of the remaining dust and the appearance of the stacks is very good indeed.

The rate of heat release of 36,800 Btu per hr per cu ft of total furnace volume is no doubt the highest yet obtained from low-volatile coal with a satisfactory low-carbon loss. It is possible to further increase this rate. The furnace slag screen is an important factor in this design. It forms a barrier which shields much of the radiant heat of the flame adjacent the burners and of the slag pool from reaching the boiler tubes, thereby permitting the tapping of ash of higher fusing temperature and reducing the slagging of tubes in the boiler bank.

The proportioning of heating surface between the furnace, boiler and superheater was influenced more than it should have been, evidently, by data obtained from coal of higher volatile and other characteristics different from that being burned. The spacing of the furnace slag-screen tubes might also be further improved in subsequent designs for similar coal. It should be noted, however, that these units are designed for a maximum output of 412,000 lb steam per hr each, corresponding to a heat release of 41,600 Btu per hr per cu ft. This rating cannot be obtained with only one turbine in the station.

The steam scrubbers installed in these boilers have proved satisfactory, proof of which is evidenced by turbine performance.

The modifications required on the burners were necessitated by the combination of high preheat on the secondary air with a readily coking coal. Reducing the number of primary nozzles and increasing their width has been quite successful. The practice of running cold air through an idle burner a few minutes just before putting it into service is a simple procedure which is quite helpful in preventing coking.

This design of boiler unit is well adapted for wide application, especially for capacities considerably above that for which these units are designed.

A. G. Christie.[3] One is impressed with the high ratio of water-wall area to true boiler-surface area in the Buzzard Point boilers. Evidently the greatest advantage is taken of heat transfer by means of radiant heat. In fact, the furnace itself is water cooled practically to the same extent as a Scotch Marine boiler.

The low-volatile coals of Virginia and West Virginia have comparatively high-fusing-point ash. One would not expect these to be best suited for use in slag-bottom furnaces. Apparently the fluid ash can only be tapped with ease under certain favorable high-load and high-furnace-temperature conditions. It is rather surprising to note that the use of various fluxing materials has not resulted in more fluid slag. This must have been due to lack of proper mixing in the slag. Normally such flux material should have combined with the ash and increased fluidity. The author states that these fluxes were introduced in a powdered state. Possibly they were carried over to the electrostatic precipitator instead of entering the slag. Why not try the introduction of limestone in lumps?

Apparently no difficulty has resulted from the pressure and temperature employed, viz., 670 lb and 835 F. This should encourage designers to use still higher steam pressures and temperatures on the next station to be built. It may be noted that some difficulty is being experienced in this station to secure sufficient superheat.

Fig. 3 indicates an interesting distribution of the temperature drop of the gases. About one quarter goes to the water walls, another quarter to the boiler surface proper, a third quarter to the superheater, and the final quarter to economizer and air heater. This emphasizes the growing importance of the secondary heat-recovery apparatus under modern operating conditions of high pressure and temperature.

There are rumors that difficulties have been experienced with the horizontal tubes in the air preheater. Possibly the author may be willing to tell us of these experiences.

The performance of the hydraulic fan couplings as shown in Table 3 indicates too slow a response to load changes. This coupling has many distinct advantages but needs further development to improve its speed of response to load changes.

The rates of heat release in this furnace are higher than has generally been used in the past. No ill effects from bad slagging have been noted. This would indicate that still higher rates of heat release with correspondingly smaller furnaces may be considered for future installations where the furnace is water cooled throughout and a slag-bottom furnace employed. At present the space above the dust screen must serve to a considerable extent as a secondary combustion chamber with flames penetrating completely through the dust screen. The author states that at times there was a tendency to slag the lower tubes of the boiler itself. This suggests that conditions might be improved by wider spacing of the tubes in the dust screen with more rows of tubes in depth in this dust screen and with the whole dust screen placed just below the tubes of the boiler proper. What advantages are claimed for the present position of the dust screen intermediate between the primary and secondary combustion chambers?

The need of dust catchers in the flue gases is evident from the author's statement that 50 per cent of the ash was caught in the electrostatic precipitators.

Little comment can be made on the boiler efficiency or station performance. These are excellent results.

M. K. Drewry.[4] Cited experiences with slagging raise the general question as to whether freedom from undesirable deposits in any slag-tap installation can ever be sustained under varying conditions of load and with various types of coal. It is true that ash accumulations are limited in the high-temperature zone by fluidity of the molten ash, and in the lower-temperature zone by mechanical breakage due to weight. However, at some intermediate point plastic sticky ash is always present near some heat-absorbing surface and, at that point, accumulation of adherent slag is without limit.

Why ash of higher fusion temperature should cause clogging farther into the boiler tubes of the Buzzard Point installation was not readily apparent until some study indicated that clogging moves progressively in the direction of gas flow until equilibrium of gas temperatures and ash melting point occurs.

Variable insulation of surfaces ahead of the superheater causes lack of uniformity in its performance, which suggests a second reason for using superheat-regulating equipment.

[3] Professor of Mechanical Engineering, Johns Hopkins University, Baltimore, Md. Mem. A.S.M.E.

[4] Assistant Chief Engineer of Power Plants, Milwaukee Electric Railway & Light Company, Milwaukee, Wis. Mem. A.S.M.E.

One of the major merits of pulverized-fuel-firing equipment is its adaptability to firing any kind of coal as the market changes. The moderate-temperature installations appear the best answer to the variable-coal, variable-load problem.

Many operating companies have formed the policy of using at least two mills or feeders per furnace, guarding against momentary interruption of all coal supply to the furnace. Buzzard Point employs automatic relighting with gas, the failure of which is perhaps as improbable as the simultaneous failure of two mills.

E. L. Hopping.[5] The author discusses the use of hydraulic couplings with automatic combustion control, for varying speeds on forced- and induced-draft fans and it is noted that because of the slow response of the coupling with the Weir type of control it was necessary to apply additional automatic control to the draft dampers, supplementary to fan speed change.

The Philadelphia Electric Company is now installing a 165,000-kw turbo generator with two 600,000 lb per hour pulverized-fuel-fired boilers in their Richmond Station and are providing hydraulic couplings for operation of forced- and induced-draft fans and variable-speed condensate pumps. The decision to use this speed-changing method was based partly on the experience at the Buzzard Point Station, together with experience gained by installation of a hydraulic coupling with hand-operated Weir control on one of the present test boilers in the older section of Richmond Station. It was realized that Weir control would be too sluggish for the best operation with automatic boiler regulation, and the coupling manufacturers agreed to make comparative tests on a coupling using Weir control in one case and a small auxiliary pump either for removing or replacing oil in the coupling in the other case. These tests indicated that with the auxiliary pump it was possible to reduce the time required for a given speed change to about one-third of that resulting from Weir operation.

It is expected that a satisfactory rate of speed change will be secured on fans for the new Richmond boilers without supplementing the speed control with automatic damper regulation.

Ten Years of Stoker Development at Hudson Avenue[1]

J. S. Bennett.[2] The authors have performed a most useful service in presenting the results of their studies in analyzing losses sometimes disregarded. The figures given on cinder losses are particularly interesting. In the writer's opinion, certain warnings should be uttered against applying these figures too literally. At 75 lb per sq ft, the cinder loss is shown to be nearly 8 per cent. Assuming that the cinder loss is entirely eliminated and that the unit under these conditions is operating at 83 per cent efficiency, the efficiency would be increased by only 6.5 points, not 8 points, because only 83 per cent of the heat in the cinders would be transferred to the water and steam.

Considerable work has been done in developing means for minimizing this loss. The authors point out that a certain proportion of the cinders was trapped in the last pass of the boiler and returned above the ash pit. This improved the performance somewhat, but the method of cinder trapping in the last pass was inefficient as provisions had not been made in the original design for cinder return. The cinders were fed in above the fire, which had a tendency to recirculate part of them. It has been found far more effective to return cinders with the coal feed at the front of the stoker. Cinder trapping can be provided in any new design, with the cinders returned by gravity to the stoker coal hopper. This is particularly simple in the case of double-fired boilers. The writer's Fig. 1 shows an installation of this type put into service recently. In this arrangement, the cinders enter at the bottom of the retort and are covered by fresh coal. They cannot be recirculated, and are fed up slowly from the bottom of the retort where they burn in the same manner as the rest of the fuel bed. Other schemes for cinder return are shown diagrammatically in Figs. 2 and 3 of this discussion. Assuming that 80 per cent of the cinders discharged were trapped and returned as shown, at a coal-burning rate of 75 lb per sq ft, the cinder loss at Hudson Avenue would have represented only 1.6 points in efficiency and these, if burned, would represent an increase in efficiency of 1.3 points.

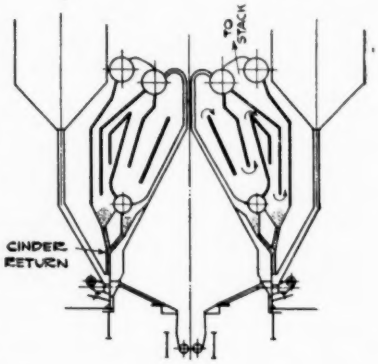

Fig. 1

The authors have emphasized the fact that their experience has been obtained with one grade of coal. It might be interesting to compare the results obtained with other coals using preheated air. The curve shown in Fig. 11 of the authors' paper is reproduced in Fig. 4 of this discussion. The cinder loss of a coal selected for test because of its tendency to produce cinder losses and operating with preheated air where the cinder recovery was somewhat more effective, is shown by the curve marked *B*. The same job, burning a Pittsburgh-district coal, without any cinder return, gave a very much reduced cinder loss, marked *A*. These curves show that the cinder loss is influenced very strongly by the coal used. The low-volatile, high-Btu coals used quite generally in New England and New York City, ordinarily show much higher cinder losses than the coals with higher volatile matter or coals containing ash with lower fusing temperatures.

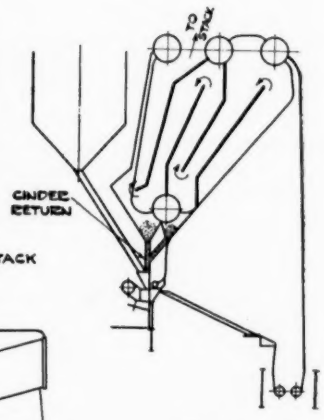

Fig. 2

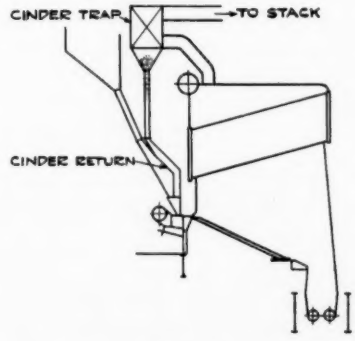

Fig. 3

The authors imply that their experience shows that a short underfeed stoker with a long overfeed section will permit higher sustained fuel-burning rates than the full underfeed-type stoker.

[1] Published as paper FSP-57-3, by J. M. Driscoll and W. H. Sperr in the February, 1935, issue of the A.S.M.E. Transactions.

[2] Mechanical Engineer, American Engineering Company, Philadelphia, Pa. Mem. A.S.M.E.

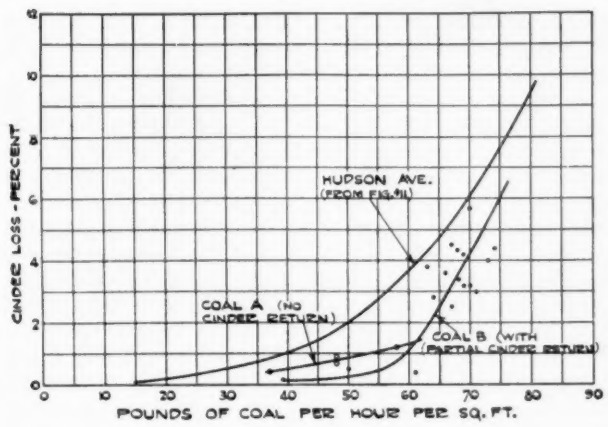

FIG. 4

This conclusion is based on a comparison of relatively small stokers of one make with the longest stokers ever built by a different manufacturer and underfeed stokers of still another make built ten years ago. Where comparisons have been made directly between machines of the same size of the two types, this improvement in coal-burning capacity has not been shown.

Where sustained high fuel-burning rates are required, it is poor policy to rely upon the skill and agility of the operator to maintain the fuel bed. It is better to provide means for distributing the air that will indicate and correct fuel-bed weakness long before the human eye can detect the trouble. Zoned-metered-air control provides this means.

V. G. GAHNKIN.[3] The paper shows that long underfeed stokers are apparently limited to an efficient maximum burning capacity of 55 lb of coal per hr per sq ft of grate area, and that to get higher combustion rates it is necessary to add either a movable link-grate section or to introduce an air-zone method of controlling the windbox pressure.

The improvement effected by air-zone control in the efficiency of boiler No. 74 at high ratings and the increase in capacity from 350,000 to over 500,000 lb per hr continuous rating is very remarkable. The air-zone control by permitting regulation of air pressure to just overcome the fuel-bed resistance in each section makes it possible to reduce excess air and carry higher ratings with the same thickness of fuel bed without danger of lifting portions of the fuel bed from the grate. This should permit the building of larger and more efficient stokers in the future.

The authors have made a comparison of stoker performance in their Fig. 10 based on the heat absorbed by the boiler unit per square foot of projected grate area. It seems that a better comparison of stoker performance could be made on the basis of pounds of coal burned per square foot of projected grate area and thus eliminate the effect of the efficiency of heat absorption by the boiler unit since the effect of the difference in the heating values of the coal is small. In Fig. 5 of this discussion, a comparison of the stoker performance on boilers Nos. 54 and 74 has been made on this basis and shows a much closer agreement on overall efficiency than that shown in the authors' Fig. 10.

The stoker losses, namely, the loss due to combustible in ash and the cinder loss, closely agree for both stokers. At a combustion rate of 75 lb per hr, the combustible-in-refuse loss is about 0.6 per cent higher on No. 54 boiler, while the cinder loss is lower by 0.8 per cent, making the combined loss practically the same for both units.

[3] Chief Testing Engineer, Brooklyn Edison Company, Brooklyn, N. Y. Mem. A.S.M.E.

The difference in overall efficiencies between boilers Nos. 74 and 54 is due therefore to the losses which depend upon the design of furnace and heat-absorbing surfaces. There is 25 per cent more furnace volume per square foot of grate area in No. 74 than in No. 54 boiler; hence, the heat release per cubic foot for a given burning rate is higher for the No. 54 installation, being 65,000 Btu per hr per cu ft for No. 54 and 48,000 for No. 74 at a combustion rate of 75 lb per hr. There is a greater possibility therefore of having an incomplete combustion loss due to CO, H_2 and hydrocarbons in the smaller furnace at the higher ratings. The loss due to incomplete combustion of CO was about the same for both installations. The loss due to unconsumed hydrogen and hydrocarbons was not determined in the No. 54 boiler test.

There is more waterwall, superheater and economizer surface in boiler No. 74 than in No. 54 and the per cent of heat absorbed by each of them is different in both installations, resulting in a higher overall efficiency of No. 74 at high ratings, although the dry-gas loss is greater on boiler No. 74 than on No. 54.

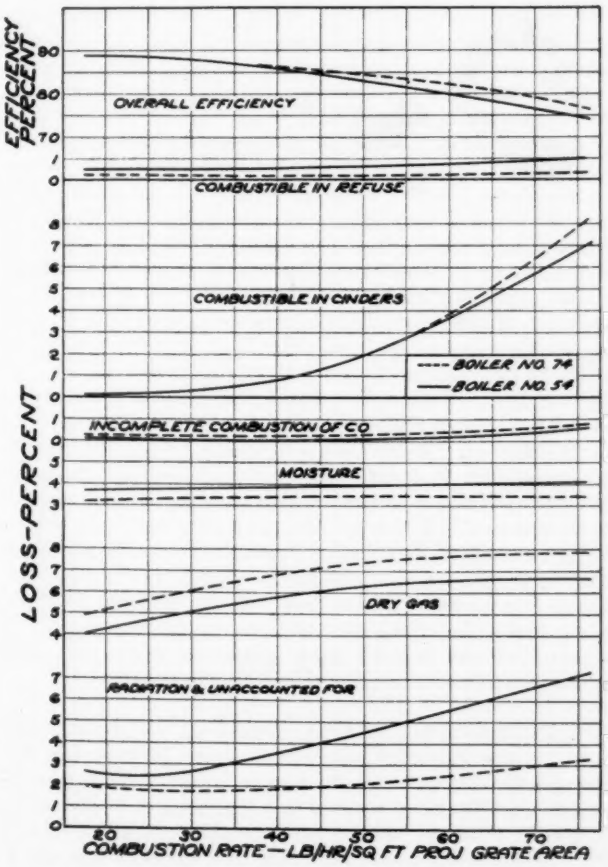

FIG. 5 COMPARISON OF TEST PERFORMANCES OF BOILERS NOS. 54 AND 74, HUDSON AVENUE STATION

The only losses which differ a great deal in the two installations are the radiation and unaccounted-for losses. Even if the hydrocarbon and hydrogen losses determined on No. 74 are added to the radiation and unaccounted-for losses, at a combustion rate of 75 lb per hr, the total is as much as 4 per cent less than on No. 54. If a correction is applied, to take care of radiation and unaccounted-for loss difference, the efficiency curves of both installations become identical, having an efficiency of about 75 per cent at a combustion rate of 75 lb per hr.

In order to show how nearly equal the actual performances of the two stoker and boiler installations are when compared on the same combustion rate, refer to the authors' Table 5. The yearly operating figures for efficiency and combustion rates are very close for the Westinghouse and Taylor stokers. The average combustion rate for 1932 and 1933 for the fifth and sixth rows of boilers was 24.4 lb per hr; for the seventh and eighth rows, the combustion rate was 25.1 lb per hr and their respective efficiencies were 86.0 and 86.3 per cent. These figures include also the banking hours and the low-steaming periods which decrease the actual combustion rates by 15 per cent. For the operating range up to combustion rates of 40 lb per hr, both installations are identical in efficiency. Higher combustion rates are only run for short periods during the peak, and therefore affect the yearly efficiency only slightly.

In conclusion, it might be said that both installations are doing equally good work and are equally efficient when based on the same combustion rates. The fifth and sixth rows are simpler in design and are liked by the stoker operators. The operators are, however, becoming used to the more complex air-zone control of the seventh and eighth rows and have already developed a high operating efficiency.

P. W. Keppler.[4] The authors state that for the very long stokers of units Nos. 7 and 8, 55 lb per sq ft of total projected grate area was found to be the maximum fuel-burning rate obtainable for long periods without zoned air control. They also state that for shorter underfeed stokers of this make, more capacity would undoubtedly be obtainable, but that experience had not been gained regarding this at Hudson Avenue. At Hell Gate, many capacity tests were run at high fuel-burning rates. The peak for long periods was reached on June 25, 1925, on boiler No. 63, when 78 lb of coal per hr per sq ft of total projected grate area were burned for 12 hours. The stoker had a projected length of nearly 16 ft and a total projected grate area (including pit) of 378 sq ft. The heat content of the coal was 14,333 Btu so that 78 lb of this coal are equivalent to 80 lb of 14,000-Btu coal. The limitation to capacity was induced draft, not the stoker; in order to obtain the required gas flow, the furnace had to be put under 0.4-in. pressure, so that the fire could not be observed. With ample induced draft, affording an opportunity to carefully watch and regulate the fire, still higher fuel-burning rates should be obtainable. Furthermore, great improvements in stoker design have been made since this test. The capacity of shorter stokers of this type, if operated without zoned-air control, is likely to be limited more by smoke and combustion losses than by lack of fuel-burning ability.

T. E. Purcell.[5] The large amount of field development following the successive installations serves to exemplify the uncertainty with which results can be predicted for stoker installations. When it is realized that the successive installations were only a step in advance of the previous installation, and that the development was carried on in a single station with a specific type of coal, emphasis must be placed on the fact that there is a dire need for more knowledge concerning the functions of the stoker and the process of burning coal thereon. This paper, it seems to me, points to the great need for cooperation and combined effort on the part of designers, manufacturers, and users of stokers to the end that sufficient knowledge may be made available so that stoker performance can be predicted with some degree of certainty. It appears quite evident to us that each installation must be designed for the specific grade of coal to be used, and that stokers cannot be designed to burn varieties of coal with entire satisfaction and with the best results.

Experience with underfeed stokers at the Colfax and James H. Reed Power Stations may be used as an illustration. The combustion rate in pounds of coal per hour per square foot of grate surface for the stokers in the Colfax Power Station is from 15 per cent to 20 per cent less when burning coal from the Sewickley seam than with coal from either the Pittsburgh or Freeport seams, all three seams being common to the Pittsburgh district. On the other hand, the stokers at the James H. Reed Station, which are of a later design equipped with the link-grate overfeed section and adjusted to burn Sewickley coal, will consume equal quantities of either Sewickley or Pittsburgh coal; but severe burning of the stoker parts and high maintenance cost accompany the use of Pittsburgh coal. Unquestionably, to burn Pittsburgh coal to the best advantage, the stokers would require considerable alteration. The stokers at the James H. Reed station, although prototypes of the link-grate stokers developed at Hudson Avenue and later successfully applied in the High Bridge Station of the Northern States Power Company, required major alterations in the field before they were considered satisfactory operating units.

The authors seem to be fully convinced that stokers provide the better method of burning coal in the Hudson Avenue Station. After ten years of experience with both stokers and pulverized-fuel equipment at Colfax and four years of experience with stokers at Reed, the writer is not prepared to believe that one method is definitely superior to the other. Each new installation merits special investigation of both methods of firing, giving due consideration to the latest developments. Each method of firing has its advantages and disadvantages. In my opinion, a great advantage in pulverized-fuel firing over stoker firing lies in the greater consistency in the results obtained. Uniform performance can be expected, when burning coals having widely varying characteristics, in pulverized-fuel furnaces with either horizontal or vertical firing and with more or less water-cooling surface exposed to the furnace. On the other hand, as stated above, stoker operation is influenced greatly by the characteristics of the coal, and continuous attention and adjustments must be given the equipment. Even then consistent fuel-bed conditions and maximum steaming capacity are not always assured.

I. E. Moultrop[6] and G. C. Eaton.[7] The history of the development of the Hudson Avenue stokers during the past ten years contains much valuable information. One must applaud the courage of the Brooklyn Edison Company engineers who, after carefully considering the merits of the various types of fuel-burning equipment then available, decided in 1922 on the use of underfeed stokers, especially when one considers that the fuel they were to burn was high-grade Eastern bituminous coal. While such coal is a very excellent bituminous coal, it is probably more difficult to handle on an underfeed stoker than a lower-grade coal having a higher ash content. In the light of today's knowledge, no one could criticize the decision, but at that time it certainly required very careful consideration and the courage of one's convictions.

The first stokers installed at Hudson Avenue were very good machines as of that time. The story of the various steps taken to improve the stoker and its performance during the decade from 1924 to 1934 makes very fascinating reading, especially to

[4] Testing Engineer, Hell Gate Station, United Electric Light and Power Company, New York, N. Y. Jun. A.S.M.E.

[5] General Superintendent of Power Stations, Duquesne Light Company, Pittsburgh, Pa. Mem. A.S.M.E.

[6] Chief Engineer, Edison Electric Illuminating Company, Boston, Mass. Mem. A.S.M.E.

[7] Head, Mechanical Technical Engineering Division, Generating Department, Edison Electric Illuminating Company, Boston, Mass. Jun. A.S.M.E.

those who have been through a similar experience and have given much thought to the art of burning fuel for power purposes.

These developments appear to have been a simple procedure when one reads about them, but it should be borne in mind that to accomplish such results, much patience, courage and painstaking study is required to meet and solve the many discouraging situations. Much money also was needed.

The improvements in boiler-unit performance with each installation are remarkable and praiseworthy, the most unusual following the installation of the zoned-and-metered-air equipment on the Taylor stokers. This improvement is noteworthy, not only because of the ability of the equipment to burn very much larger quantities of coal per square foot of grate, but its ability to do this with a relatively flat efficiency curve. A stoker equipped with zoned-air control is really in a class by itself. With further experience in the use of this equipment, an even better performance with the stoker of the future may be confidently expected.

The high combustion rate obtained with stokers having air-control is bound to cause a considerable cinder loss. This should not be considered a serious drawback. With suitable cinder catchers, much of the cinder rejected by the furnace can be reclaimed and burned in the ash pit, materially reducing the cinder loss. Even if this loss must be looked upon as a more or less serious item, it should be remembered that one cannot get something for nothing. If, with a given piece of equipment, much greater capacities are to be obtained, it will usually be at the expense of something which is not desired. If tremendous overloads can be obtained from a given size stoker by running it at very high ratings, the capital investment is kept down and the overhead charges thereby reduced. The savings in these overhead charges which apply to every minute in the life of the plant will offset many times the relatively small cinder loss for the very short time that the overload capacity is required.

It is interesting to note that No. 74 stoker is installed under approximately the same boiler surface as No. 54 stoker, the former giving about double the steam output of the latter. To be sure, No. 74 stoker has an economizer surface 50 per cent greater than that of No. 54, which would compensate for some of this increased capacity.

The maintenance costs of the various stokers are instructive to the reader. There are several questions which come to mind. Because of the many changes and experiments made on all the stokers after they were installed, much of the maintenance expense was no doubt borne by the manufacturer. Were the maintenance costs given corrected for this fact? Were units 1 to 3 and 1 to 4, inclusive, operated during 1932 and 1933, respectively? No costs were given for these unit periods. Maintenance costs of occasionally used units are often of interest. The lack of noteworthy difference between maintenance costs of similar units with and without preheated air is unexpected. Have the authors any explanation for this lack of difference?

The discussion about the omission of air preheaters on the later installations is very interesting and the arguments for their non-use seem to be sound. It is our opinion that if the Brooklyn Edison Company were to build another station now, they would find it desirable to add a certain amount of preheater surface because certainly added economy could be obtained thereby. However, one must not lose sight of the fact that there is now a very definite limit to the amount of preheating desirable with underfeed stokers.

The authors mention that the first installation at Hudson Avenue did not contemplate the use of fans, the thought of the designers being that the chimney draft would be sufficient. It is the opinion of many that the high-capacity plant of today requires the use of both forced- and induced-draft fans. There is a point which the average designer is apt to overlook, namely, that the capacity of both types of fans, particularly the induced-draft, must be ample. Probably more errors in judgment have been made in determining the capacity of the induced-draft fan than in almost any other part of a given installation. The size of this fan fixes the absolute limit of boiler-unit capacity.

Fig. 12 is difficult to read. This group of curves would be very much more valuable to the average reader if its ordinate were doubled. The over-lapping of lines and areas is very confusing. The freedom with which the authors change from boiler numbers to row numbers, from output in terms of millions of Btu per hour per square foot of stoker area to output in pounds of coal burned per hour per square foot of stoker area, is also very confusing to the average reader. If the references and terms could be narrowed down, considerable hunting through the paper would be saved the reader.

Authors' Closure

Mr. Bennett's point that any recovery of cinder will be utilized at some efficiency less than 100 per cent in the event all the cinder is returned to the stoker is important and must be taken into consideration when evaluating this loss. In reference to his statement regarding the Hudson Avenue installation, "The cinders were fed in above the fire, which had a tendency to recirculate them," tests made since obtaining the results presented in the paper indicate:

1 Approximately 46 per cent of the total cinder produced and leaving the stoker was trapped in the boiler hoppers and returned to the furnace.

2 Approximately 25 per cent of that cinder trapped was recirculated, this percentage tending to decrease at the higher burning rates.

3 Between 35 and 40 per cent of the total cinder produced remained in the ash pit to be burned. From the ash-pit combustible-in-refuse loss, reported in a recent paper on the performance of the Hudson Avenue stokers,[8] it is evident that this 35 to 40 per cent returned is completely burned.

Since the presentation of the paper, a permanent system of drain lines has been installed on another row of boilers in the station, running from the dry-type cinder catchers through the rear furnace walls to the ash pit. These lines have operated in a satisfactory manner, conducting the entire catch of the cinder trap back to the furnace.

Mr. Bennett's design providing for the return of cinder to the stoker feed hopper, particularly when it can include the drains from efficient cinder catchers, is an inviting one. It will be interesting to follow the operating experience with the design in Fig. 1 of the discussion.

In considering the significance of the cinder loss, the point brought out by Messrs. Moultrop and Eaton regarding the usual short duration of high-capacity loadings and the investment saving by working equipment at high rating is important in judging the economic value of this loss.

Mr. Gahnkin raised a number of points regarding Fig. 10 of the paper. The efficiencies of the generating units in this figure were shown plotted against output because this is a usual manner of indicating efficiency of steam-generating equipment. The output values were derived directly from Fig. 3 of the paper to illustrate the effect of the reduction of results to a unit grate-area basis. It is true that the extent of heat-absorbing surface of the boiler and economizer affects the overall performance, and for this reason the dry-gas loss was illustrated in Fig. 10 along with the efficiencies in order to show the relatively small differ-

[8] "The Test Performance of Hudson Avenue's Most Recent Steam-Generating Units," by P. H. Hardie and W. S. Cooper, Trans. A.S.M.E., November, 1934, vol. 56, no. 11, paper FSP-56-15.

ence in the magnitude of this loss at comparable outputs per square foot of grate for the three installations provided with economizer or air-heater surface. Using the coal input as abscissa as suggested by Mr. Gahnkin, and basing calculations on the same acceptance-test data used for the reports in the paper, the difference in efficiency of the two equipments, No. 74 and No. 54, at a coal-burning rate of 60 lb per sq ft per hr is about 3.75 points on the efficiency scale. This difference in favor of No. 74 would be further increased slightly if correction were made for difference in dry-gas loss chargeable against the heat-recovery equipment. This would be a part of the difference indicated between the curves in the lower part of Fig. 10. Beyond the rate of 62 lb per sq ft per hr, the efficiency data for 24-hr duration runs are not available for No. 54 boiler.

In comparing the relative flatness of the efficiency curves shown by Mr. Gahnkin in Fig. 5 of the discussion with the curves in the original paper, it should be noted that the use of input as an abscissa tends to flatten the curve because the input increases more rapidly than the output with falling efficiency. Also the vertical scale used by Mr. Gahnkin is smaller, the overall effect of the two changes being the equivalent of spreading the horizontal scale on the original curves about tenfold while maintaining the same vertical scale. The choice of scale appears to be largely a matter of preference depending on whether emphasis is to be placed on small differences or on general similarities.

Mr. Gahnkin's discussion of the variation in furnace volume, heat release and loss due to unburned hydrocarbons is in general agreement with the authors' paragraph 6 under "Discussion of Results" in the paper. However, Mr. Gahnkin apparently favors crediting the stoker with those parts of the unburned-gas and unaccounted-for loss which are chargeable to less favorable furnace size and design. Unfortunately it is not possible to isolate these parts from the parts of the same losses which may properly be chargeable to the stoker itself. It appears a proper apportionment could only be made by a test comparison of otherwise identical units of equipment having different furnaces but having fuel and other operating conditions identical. The conclusion drawn by Mr. Gahnkin that the efficiency curves for both stokers is identical throughout the entire range does not appear to be supported by the data except under conditions of the assumption made by him. The approximate equality in the lower ranges of rating as quoted by Mr. Gahnkin is not at variance with efficiency differences indicated by the author in Fig. 10 of the paper.

Mr. Keppler's statement gives data on the capacity of a short stoker. The Hell Gate stoker cited, of nearly 16 ft projected length, has an underfeed section approximately 9 ft in length as compared with the 13-ft underfeed section of the stokers on the No. 4 unit at Hudson Avenue, which are the shortest stokers tested there without draft limitation. The example of the Hell Gate stoker is a definite instance of the statement in the paper that the capacity limitations discussed do not apply to shorter stokers. It is the belief of the authors, based on the observations of many tests, that ability to operate at high ratings for short periods even up to 12 hours is not an indication that the same rating can be carried continuously for 24 hours. Nevertheless, the Hell Gate tests, if repeated at approximately this load and duration, must be accepted as an indication of the ability of the shorter stoker in comparison with the data presented on the long stokers.

Mr. Purcell's comment that each stoker installation must be designed for the specific coal to be used is an important one from the viewpoint of the prospective user of large stokers. From the relation of his experiences, the statement seems well founded on fact. The authors know of other installations where numerous troubles developed in the initial application, and stoker-design changes were required before satisfactory operation was attained.

The authors do not wish any inference to be drawn from the paper regarding expressions on the superiority of stokers or pulverized-fuel firing, but would agree with Mr. Purcell that each new installation merits special investigation of both methods of firing for the particular conditions and the taking into consideration of the latest developments of each method. This was done at Hudson Avenue. In this connection, the tabulation of yearly boiler efficiencies given in Table 5 in the paper is believed to compare not unfavorably with pulverized-fuel installations.

Regarding the first question raised by Messrs. Moultrop and Eaton on maintenance, it can be said that in general the manufacturer was assigned a single stoker on which to do his experimenting and he carried the maintenance expense of all parts which were not standard in the other stokers. The figures quoted do not contain any of the costs which the manufacturer carried on the experimental unit.

In reference to the operation of Units 1 to 3 and 1 to 4, inclusive, in the years 1932 and 1933, respectively, the number of operating hours of these stokers and boilers in these years was so low as to make unit maintenance costs of no value for comparison.

As to the difference in maintenance cost of the stokers with and without preheated air, the only feature which the authors can point to as being different from many other preheated-air installations is the relatively low temperature of air. The average temperature is 350 F while the maximum is 380 F. It should be noted that it was in 1931 that the No. 4 row was first operated with link-grate stokers. In 1932 the maintenance costs for the No. 4 row rose sharply, largely because the operating hours for 1932 was less than one third the number for 1931. The authors hesitate to predict just how the maintenance for row No. 4 and row No. 5 would have compared had they continued in parallel operation for several years at approximately the same number of service hours and coal-burning rates.

The comments on Fig. 12 and on limiting the use of terms are well taken.

A New Method of Investigating Performance of Bearing Metals[1]

C. S. Cole.[2] There are many sides to this bearing question—the properties of the bearing, of the lubricant, and the mechanical design of the bearing itself. In the first of these phases the Copper & Brass Research Association undertook an intensive study last year at Battelle Memorial Institute, on the properties of six of the more commonly used materials. The results of this work were published in a paper[3] presented before the American Foundrymen's Association in June, 1934. These data are available either in the Transactions of that Society or as preprints which this Association would be glad to send any one interested. It would be most interesting to see the correlation of these studies with tests such as Mr. Connelly is making.

L. M. Tichvinsky.[4] The paper by Mr. Connelly presents an interesting manner of attacking the complicated problem of wear of bearing metals. Metal-to-metal contact occurs fre-

[1] Published as paper IS-57-1 by John R. Connelly in the January, 1935, issue of the A.S.M.E. Transactions.

[4] Research Laboratories, Westinghouse Electric & Manufacturing Co., East Pittsburgh, Pa.

quently in small and medium-sized bearings[5] at the moments of starting and stopping of the machines. The rate of wear, therefore, in some bearings may be very large and special provisions should be made in order to secure a safe performance of the bearing.

It is known that the present methods of wear measurements are still insufficient for obtaining complete wear criteria. This may be explained by the great number of parameters constituting the function of wear of metals. The New International Association for the Testing of Materials discussed in 1930 in Zürich the problem of wear of metals. The wear there was expressed[6] as follows:

$$W = f(S, H, M, MS, P, p, v, F, f, L, t)$$

where S is the state of the surface
H = hardness
M = molecular forces
MS = microstructure
P = full load
p = specific load
v = peripheral velocity
F = force of friction
f = coefficient of friction
L = work of abrasion deformations
t = temperature at the rubbing surfaces.

This large number of variables will still increase if properties of lubricants used will be included and duration of test considered.

Referring to the author's paper, it seems that it will be more advisable to have the rate of wear plotted against time instead of unit pressure.

The coordination of action of those involved in wear testing of metals will approach the time of optimum wear-test methods which may be accepted by engineering institutions.

Author's Closure

This new method utilizes a new mode of attack and makes possible the investigation of certain characteristics of bearings heretofore undetermined.

The author wishes to emphasize the value of and need for some central clearing agency for work in bearings. Much work has been done by independent investigators. Mathematicians, chemists, and metallurgists have all contributed. Yet the fundamental problems remain unsolved and no particular theory has received general acceptance.

It is hoped that the A.S.M.E. Main Research Committee will see fit to establish a subcommittee on bearings to act as a coordinating body for all the work on bearings which will include metals and other solids, lubricants, and the various physical factors.

Unnecessary duplication will be largely avoided and more economical coordinated research made possible.

[5] Large bearings are usually provided with a high-pressure pump for the purpose of leading the oil under the journal and lifting it at the moments of starting and stopping.

The Design and Performance of a High-Pressure Axial-Flow Fan

By LIONEL S. MARKS[1] and THOMAS FLINT,[2] CAMBRIDGE, MASS.

This paper deals with the design and performance of an eight-bladed axial-flow fan to give high pressures and an approximately constant horsepower characteristic. The performance in the laboratory indicates the attainment of a static pressure of 22.2 in. of water at a peak efficiency of 77.5 per cent, with a peripheral speed of 40,000 fpm. The no-flow horsepower is only 16 per cent greater than at peak efficiency. The performance is compared with that predictable from wind-tunnel tests of a cascaded series of air foils.

A PAPER[3] published in the A.S.M.E. Transactions in 1934 discussed the design of a three-bladed axial-flow fan and gave results of tests conducted with it. This fan gave a peak efficiency of 80 per cent and could develop a static pressure (according to tests at 18,000 fpm peripheral velocity) of 18.5 in. of water at the permissible peripheral speed of 4000 fpm. There was one feature about the performance of this fan which is shared with many other fans but which was regarded as unsatisfactory, namely, the horsepower output increased steadily as the air flow was restricted until at the no-flow condition it was approximately 125 per cent greater than at peak efficiency.

The present paper deals with an attempt to design a fan (1) for still higher pressures, approximating the practical limits for the axial-flow type and (2) with a horsepower input which does not rise materially above its value at peak efficiency. It was realized that in order to obtain these objectives it would probably be necessary to accept an efficiency lower than that of the three-bladed fan, but this did not seem important as long as the efficiency was high.

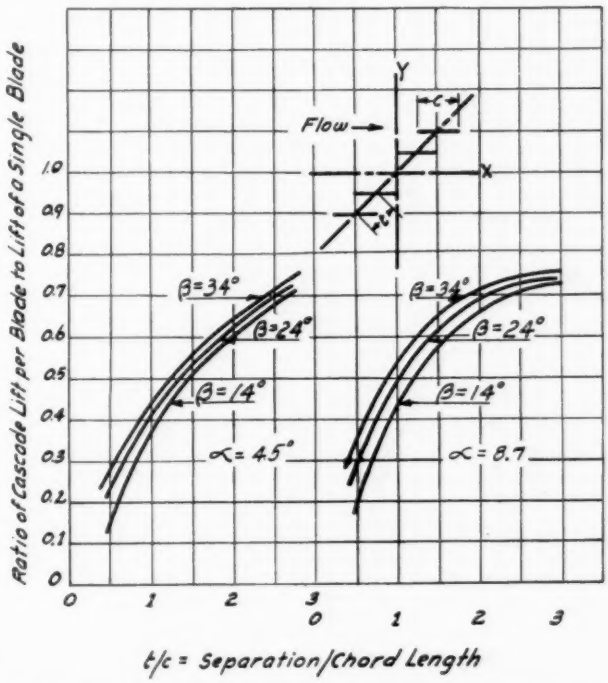

Fig. 1 Lift Coefficients for a Cascade Series of Airfoil Sections

Various considerations indicate that a larger hub would be necessary and a larger number of blades desirable. It was decided arbitrarily to use eight blades.

Cascade Tests

It was proposed to base the design on airfoil theory and wind-tunnel constants. No wind-tunnel data were found in the literature on the effect of mutual blade interference in a cascaded series of airfoils. To supply this information, S. Ober, Associate Professor of Aeronautical Engineering, Massachusetts Institute of Technology, conducted a series of wind-tunnel tests on a cascade of five identical airfoils with boundary walls at both ends (representing the hub and casing of a fan) and determined the lift and drag of the central airfoil which was free from the boundary walls. The Gottingen No. 429 profile with a straight chord was investigated, and tests were made for various stagger angles β, for two angles of attack α, and for a series of values of the ratio of separation along the line of stagger to chord length t/c. Ratio of the lift observed to the lift on a single blade is shown in Fig. 1.

According to Professor Ober, these tests are neither extensive nor accurate enough to warrant complete confidence. The fact that they are strongly at variance with the theoretical values of Numachi[4] would seem to invalidate Numachi's theory rather than cast doubt on the test results.

In view of these uncertainties the proposed basis of design was abandoned. The analysis of the actual fan performance on the basis of the coefficients given in Fig. 1 shows, however, that the cascade-test results cannot be much in error and indicates the desirability of further work of this kind as the basis of axial-flow-fan design.

Design Method Used

The design method decided upon was based on the equations recently presented by O'Brien and Folsom,[5] although, subsequently,

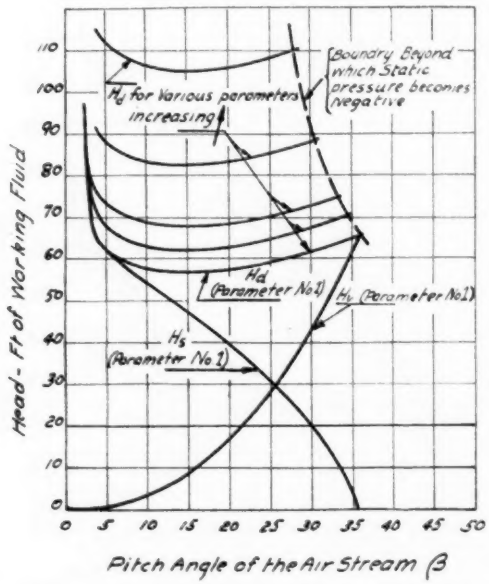

Fig. 2 Variation of Developed Head, Velocity Head, and Static Head With Pitch Angle of the Air Stream for one Particular Value of the Parameters C_L, c/t, and λ as Taken From O'Brien and Folsom's[5] Equations
(U = 100 fps and g = 32.2 ft per sec per sec.)

it was found to be less accurate than the method employing the results of the cascade-tests. In a discussion[6] of the paper[2] on the design and performance of an axial-flow fan, O'Brien and Folsom showed that these equations gave results agreeing satisfactorily with the observed performance. On this somewhat meager basis, it was decided to utilize the O'Brien and Folsom procedure. As stated by them, "The method of computation is essentially that used by Pfleiderer[7] with, however, modifications which result in a better agreement between the computed and the measured head-capacity characteristics."

In these equations, the following symbols are used and apply to any cylindrical section:

H_d = the total or developed head, ft of the working fluid
H_v = velocity head, ft of the working fluid
H_s = static head, ft of the working fluid
U = the tangential velocity of the blade section, fpm
V_{u3} = the tangential velocity of the air at exit, fpm
V_f = the axial velocity of the air at entrance, fpm
C_L = the lift coefficient with infinite aspect ratio
C_D = the drag coefficient with infinite aspect ratio
c = the chord length, ft
t = the circumferential distance between blades, ft
β = the pitch angle of the air stream, or the angle between the geometric mean value of the relative velocities in front of and behind the blade and the direction of blade motion
λ = $\tan^{-1}(C_D/C_L)$.

Combining the equations of O'Brien and Folsom

$$H_d = \frac{2U^2}{g} \frac{\left[C_L \frac{c}{t} \frac{\sin(\beta+\lambda)}{\cos\lambda}\right]}{\left[4\sin\beta\cos\beta + C_L \frac{c}{t} \frac{\sin(\beta+\lambda)}{\cos\lambda}\right]} \quad [1]$$

$$H_d = H_v + H_s \quad [2]$$

$$H_v = (V^2_{u3} + V_f^2)/2g \quad [3]$$

$$V_{u3} = H_d\, g/U \quad [4]$$

$$V_f = (U - \tfrac{1}{2} V_{u3}) \tan\beta \quad [5]$$

A graphical representation of Equation [1] is shown in Fig. 2, in which H_d is plotted against β. A series of H_d curves is given for constant values of C_L, c/t, and λ. For the lowest H_d curve shown, there are added corresponding velocity-head and static-pressure curves. At values of β greater than that at which the H_d and H_v curves intersect, the static pressure becomes negative. The bounding broken curve on the right gives the values of β at which the static pressure becomes zero.

The velocity of the air stream at entrance V_f is assumed constant at every cylindrical section. As the tangential velocity of the blade section varies with the radius, the pitch angle of the air stream must increase from blade tip to hub as seen from Fig. 3. Fig. 2 shows that the static pressure diminishes continuously to zero as β is increased. The greater the combined value of the parameter determining H_d, or the greater C_L, c/t, and λ, the sooner this effect occurs. In order to keep H_d constant at every cylindrical section and thus avoid losses from re-

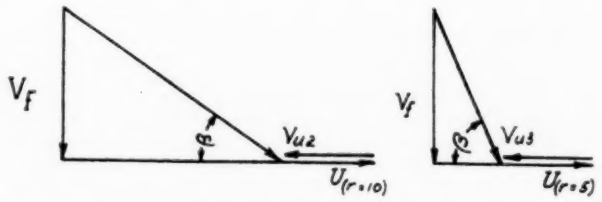

Fig. 3 Variation of Pitch Angle of the Air Stream With Tangential Velocity of Airfoil

circulation through the fan, it is necessary to increase C_L and c/t. It is obvious, therefore, that for efficient high-pressure operation a large hub must be used.

There are three ways by which the head developed H_d may be maintained as the tangential velocity decreases toward the hub:

1 By choosing increasingly thick or increasingly curved profiles. This will increase somewhat the value of C_L with an attendant slight increase in C_D.

2 By increasing the angle of attack α. This angle is the difference between β and the pitch angle of the blade section, at any cylindrical section. This method increases the value of C_L rapidly but soon begins to increase C_D at an even greater rate, as shown in Fig. 4.

3 By increasing the length of the blade-section chord. This method produces a reasonable increase in lift without excessive

[5] "Propeller Pumps," by M. P. O'Brien and R. G. Folsom, Trans. A.S.M.E., vol. 57, July, 1935, paper HYD-57-3, pp. 197–202.

[6] Discussion by M. P. O'Brien and R. G. Folsom of "The Design and Performance of an Axial-Flow Fan," by L. S. Marks and J. R. Weske, Trans. A.S.M.E., vol. 57, August, 1935, p. 344.

[7] "Die Kreiselpumpen," by Carl Pfleiderer, Julius Springer, Berlin, 1932.

increase in drag and was the method selected for the design of this fan. Another important reason for choosing this method in preference to the conventional method (increasing the angle of attack) was that it rendered it possible to design the fan so that no blade section had a pitch angle greater than the angle of attack at which that section would "burble" or break down. It was hoped that the elimination of the break-down point, with its attendant increase in drag, would effectively prevent the rise of horsepower input at low capacity.

After selecting a convenient speed for the fan design, an approach velocity V_f was selected so as to give reasonable capacity. The profile section was chosen from those listed in the N.A.C.A.

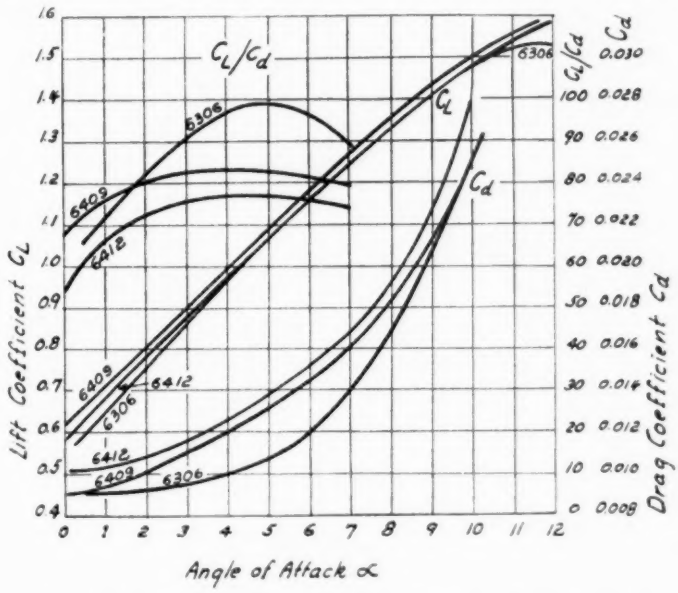

FIG. 4 PROPERTIES OF THE N.A.C.A. PROFILES USED FOR THE AXIAL-FLOW FAN

Report No. 460, having in mind high efficiency (high lift-drag ratio), a high value of the angle of attack at the burbling point, and adequate strength for the inside section. The properties of the three sections selected are shown in Fig. 4.

The outside section was designed first, the outside diameter of the fan being determined by existing laboratory equipment. At each section, the angle of attack used was that for maximum lift-drag ratio at the design point of the fan. The value of t for any cylindrical section was determined by the number of blades. From this point on, a cut-and-try procedure was followed. A value of H_d was chosen somewhat higher than the desired static pressure. The tangential velocity of the air at exit V_{u3} was found from Equation [4], β from Equation [5], H_s from Equation [3], and H_s from Equation [2]. A weighted average, based on the square of the radius of each section designed, was taken of the static heads developed at the three sections designed. These were (1) the outside section with a radius of 9.65 in., (2) the section next to the hub with a radius of 6.76 in., and (3) a section midway between these two with a radius of 8.2 in. If this average gave the desired static head, the original H_d was used; if not, a new calculation was made. When the proper value for H_d was found, Equation [1] was solved for c for each section. The hub diameter was taken as that at which the pitch angle of the blade exceeded the angle of attack at which burble occurs.

The section at the hub and the center section were designed in the same way, keeping H_d and V_f constant for all sections.

Each of the static heads resulting was corrected for section-drag loss H_p, which equals $C_L(c/t)(V^2/2g)$ (tan λ/sin β), where $V^2 = V_f^2 + (U - \frac{1}{2} V_{u3})^2$.

No correction was made for losses from friction in the air passages because of the shortness of the passages.

The details of the fan design are given in the pattern drawing, Fig. 5. Its arrangement in the casing is shown in Fig. 6. The stationary nose is supported by three streamline struts. The stationary streamline continuation of the fan hub is centered in the casing by a spider of five radial blades and contains the ball-bearings which support the shaft at the fan end. The guide vanes are located between the fan and the radial blades. The guide vanes were designed after the fan was built and are based on measurements of air-discharge angles from the fan when operating at 3600 rpm and at capacities of 3000 and 4000 cfm. The angles were determined by the use of a directional tube,[8] and also by threads, and were measured at the three design sections. The measured angles are listed in Table 1. The inside and outside section readings are affected by boundary conditions. Guide vanes were made with angles corresponding to those measured at 4000 cfm and are shown in Fig. 7.

TEST RESULTS

The arrangements for the fan tests were substantially the same as those described in the paper by Marks and Weske[3] and illustrated in Fig. 6 of that paper. The only notable change is that calibrated orifices were substituted for the nozzle for measuring air and the fan shaft was halved in length, which made it possible to operate with speeds up to 3600 rpm.

Complete tests were made at 3600 rpm both with and without guide vanes and at 2400 rpm with guide vanes. Fig. 8 gives a comparison between the performance with and without guide vanes, while Fig. 9 gives a comparison between the performance at the two speeds.

The horsepowers shown in Figs. 8 and 9 and used in the calculations of efficiency are net horsepowers obtained by subtracting the friction horsepower from the dynamometer horsepower. Friction horsepower was determined by replacing the fan with a bladeless hub of the same form and weight

TABLE 1 MEASURED AIR-DISCHARGE ANGLES AT THREE DESIGN SECTIONS

Radius, in.	Discharge angle, deg	
	3000 cfm	4000 cfm
9.65	58	40
8.21	52	35
6.76	57	38

and observing the dynamometer horsepower required to rotate it at various speeds. When operating at 2400 rpm, the horsepower input is low and the friction horsepower is about 20 per cent of the dynamometer horsepower. Any considerable error in determining the friction horsepower would have an appreciable effect on the calculated value of the net horsepower at this speed. At 3600 rpm this source of possible error is negligible, since the friction horsepower is then a small fraction of the net horsepower. The question of possible error of the horsepower determinations at 2400 rpm is raised here because the peak efficiency at this speed is 82.5 per cent as compared with 77.5 per cent at 3600 rpm. This same variation of peak efficiency with speed was found in the three-bladed fan[3] and was commented upon as having been previously observed in the operation of propeller and centrifugal pumps.

[8] "The Determination of the Direction and Velocity of Flow of Fluids," by L. S. Marks, *Journal of the Franklin Institute*, vol. 217, 1934, p. 207.

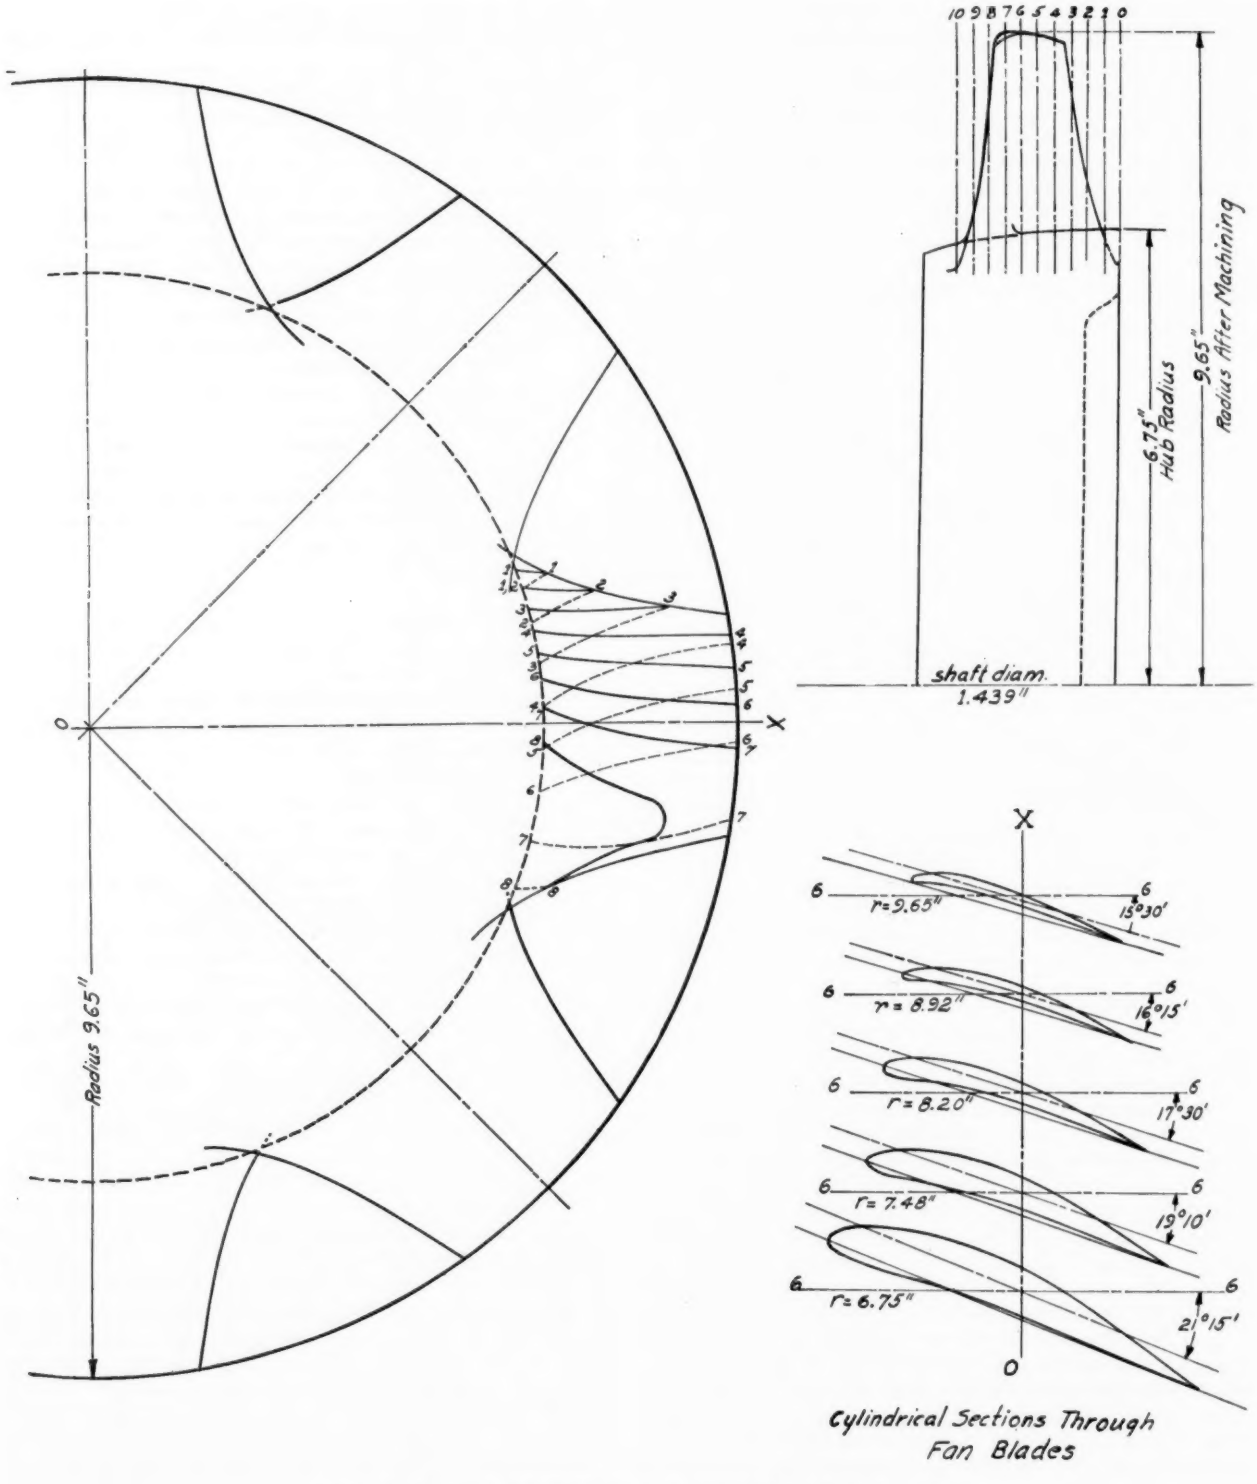

FIG. 5 PATTERN DRAWING OF THE AXIAL-FLOW FAN TESTED

The following observations may be made on the test results:

1 The static pressure at 3600 rpm and at peak efficiency is 4.7 in. of water, which corresponds to a static pressure of 22 in. of water with a tip speed of 40,000 fpm. This is an increase of 22 per cent over the static pressure obtained in the three-bladed fan.[3]

2 The net horsepower at no-flow is 16 per cent greater than the net horsepower at peak efficiency and compares with an increase of 125 per cent for the three-bladed fan.[3] This is a most important result since it permits the use of driving equipment of only half the power of that necessary for the three-bladed fan.[3]

3 The peak efficiency (total efficiency) is 77.5 per cent as compared with 80 per cent for the three-bladed fan.[3] However, a comparison of peak efficiencies alone may be misleading; the efficiency is maintained better with the fan described in this paper than with the three-bladed fan.[3] For example, at half the capacity giving peak efficiency, the present fan has an efficiency of 54.5 per cent as compared with 45 per cent for the three-bladed fan. At capacities above that giving peak efficiency, the efficiency falls off very rapidly.

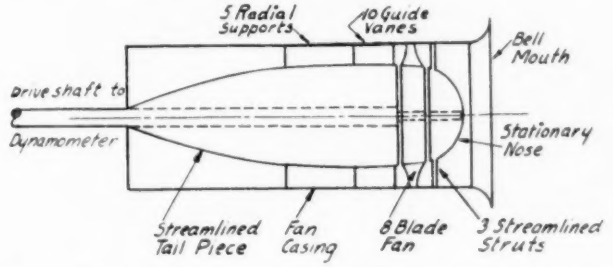

FIG. 6 FAN ASSEMBLY WITH STATIONARY NOSE AND TAIL PIECE IN ITS CASING

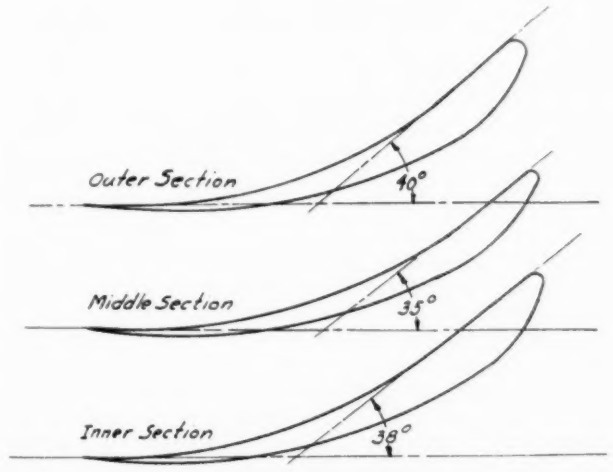

FIG. 7 GUIDE-VANE SECTIONS

DISCUSSION OF TEST RESULTS

It is interesting to make a comparison of the test results with those predictable from the cascade-test data given in Fig. 1. As a sample procedure utilizing these data, take the outside section with a diameter of 19.3 in.; a N.A.C.A. 6306 blade section as shown in Fig. 4; a volume of 4000 cfm; an entrance velocity V_f of 65 fps; a speed of 3600 rpm; and a section tangential velocity U of 303 fps.

Assume H_d = 520 ft of air.

From Equation [4], V_{u3} = 55.4 fps.

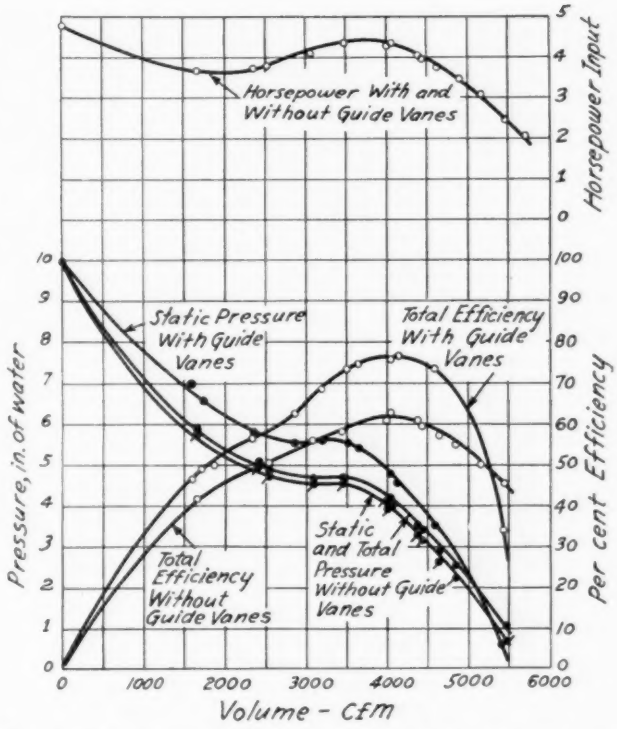

FIG. 8 PERFORMANCE CURVES OF AXIAL-FLOW FAN WITH AND WITHOUT GUIDE VANES

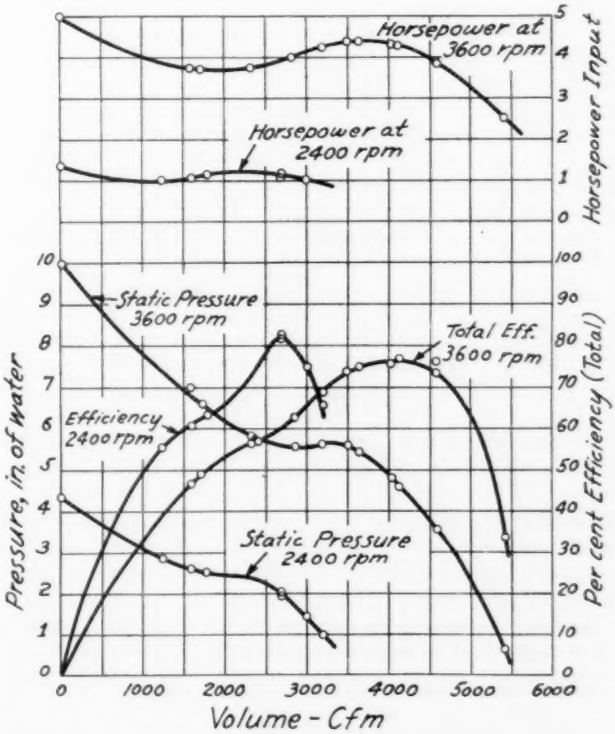

FIG. 9 PERFORMANCE CURVES OF AXIAL-FLOW FAN, WITH GUIDE VANES, AT 2400 AND 3600 RPM

From Equation [5], $\beta = 13$ deg 16 min, and since the blade pitch angle $(\beta + \alpha) = 15$ deg 30 min as seen from Fig. 5, $\alpha = 2$ deg 14 min.

From Fig. 4, $C_L = 0.775$ and $C_D = 0.0093$.

Interpolating in Fig. 1, the correction factor k for mutual blade interference is 0.610. The correction factor for C_D is negligible.

The lift coefficient normal to the long axis of the blade section

$$C_n = (kC_L \cos \alpha) + C_D \sin \alpha = 0.472.$$

The lift coefficient parallel with the axis of the fan

$$C_a = C_n[\cos (\beta + \alpha)] - C_t [\sin (\beta + \alpha)]$$

where $C_t = C_L \sin \alpha - C_D \cos \alpha = 0.455$

The velocity of the air stream relative to the blade section

$$V = \sqrt{[V_f^2 + (U - \tfrac{1}{2} V_{w3})^2]} = \sqrt{79{,}900} \text{ fps}$$

The thrust per blade $T = C_a \times V^2 \times d \times$ area of the blade lying between two cylindrical sections bordering closely the design section, where d is the density of the working fluid.

Multiplying T by the number of blades and distributing it over the area enclosed by the two bordering cylindrical sections

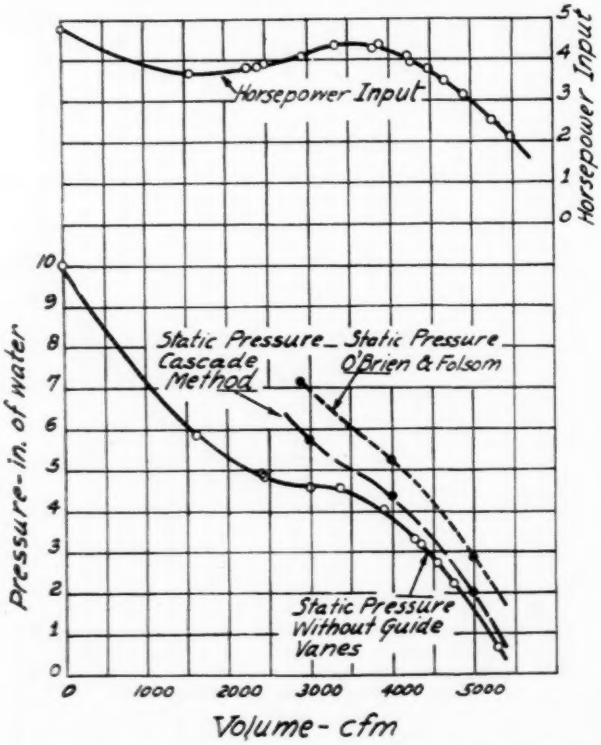

FIG. 10 STATIC PRESSURES OBTAINED IN A FAN WITHOUT GUIDE VANES COMPARED WITH THOSE PREDICTABLE BY TWO DESIGN METHODS

gives the developed head H_d, which for this particular case is found, after two more trial assumptions for H_d, to be 6.4 in. of water. The static head H_s is determined from Equation [2] and a weighted average is then obtained.

The static pressures as obtained by this procedure, together with those which were predicted from the O'Brien and Folsom formulations,[5] are shown in Fig. 10, the experimentally determined static pressures being given by the solid line. Both calculated curves show a strong similarity to the test curve but neither of them follows the shape of the test curve in the range of pressures above the point of inflection of that curve. For static pressures below the inflection point, the cascade method gives results which come very close to those of the test curve and the difference may well be ascribed to factors such as clearance and leakage losses, for which no corrections have been made.

It is interesting to note that the inflection in the test curve comes at a volume for which the angle of attack for all the blade sections is considerably below that at which break-off occurs,

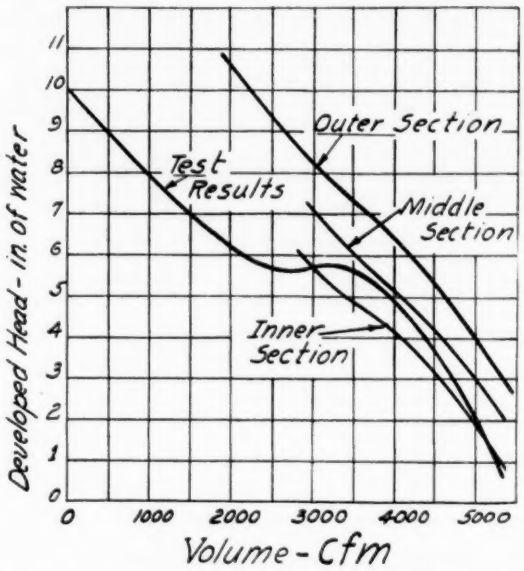

FIG. 11 DEVELOPED HEAD OBTAINED FROM TEST COMPARED WITH THEORETICAL VALUES AT THREE BLADE SECTIONS

and is at a point where the horsepower curve is falling. This would seem to preclude the interpretation of this phenomenon as the breakdown point of the various blade sections.

In Fig. 11 are given the values of the developed head H_d at the three design sections as calculated from the cascade-test data. The test results for total head are also shown. The calculated developed heads do not have the same value at the three design sections under any condition of operation. The sections were designed by the procedure given by O'Brien and Folsom[5] in order to have a common value of developed head at 2900 cfm. At the peak efficiency, the developed head is seen to be 6.4 in. of water and falls to 4.2 in. at the hub. Such a pressure difference would result in recirculation between the blades, and therefore indicates one method of improving the efficiency.

The air-discharge angles at the middle section of the blades, as calculated from the cascade tests, are in very close agreement with the measured angles, being better than 0.25 deg. As calculated by the O'Brien and Folsom method,[5] they are about 8 deg 30 min too large. Near the hub and the tip a comparison is useless, as the boundary effect is unknown.

The noise intensity of this fan was not measured, but it was comparatively low when operated at capacities down to the inflection point of the static-pressure curve (2900 cfm at 3600 rpm). Below this point a penetrating wailing noise developed suddenly and persisted down to the no-flow condition.

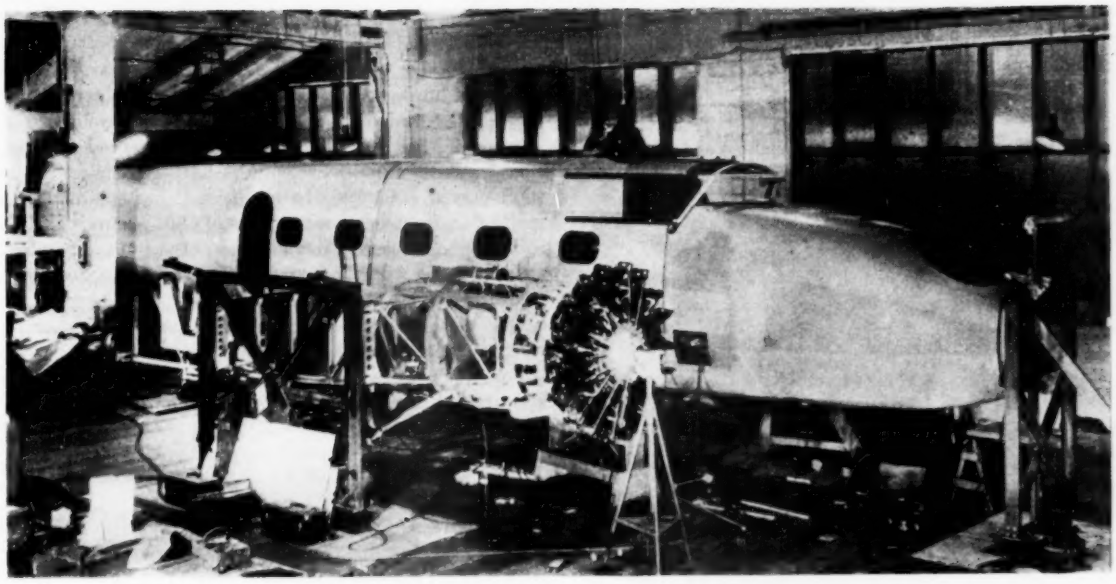

FIG. 1 ARC-WELDED ENGINE NACELLE ON BOEING TRANSPORT PLANE

Reliability of Aircraft Welds

BY N. F. WARD,[1] BERKELEY, CALIF.

This paper outlines the effects of fusion welding upon the dependability of structures in aircraft, due consideration being given to the existing conditions of welding practice found in this field. Obviously, the fusion welding of steel is of primary importance, since this is accepted practice. For the purposes of analysis, specimens prepared by experienced aircraft welders were subjected to physical tests and microscopic examination. With this information certain guiding principles in design for welding are outlined.

INTRODUCTION

ADEQUATELY designed airplanes, when fabricated by processes which produce safe carriers requiring a minimum of maintenance, represent the primary and substantial contribution to air transportation. The design of modern aircraft is guided largely by service requirements and economical fabrication processes which are consistent with structural stability.

The modern airplane is no simpler in structural form than its predecessor the tubular fuselage. In fact, the great variety of joints and fittings built in the all-metal airplane with prestressed covering, imposes additional fabrication costs which were absent in the welded airplanes of former years. Fusion welding, although contributing a reliable structural unit with favorable physical properties and the minimum of excess weight, is a fabrication process which is largely displaced by other methods with the advent of modern all-metal construction. The principal reason for the lessened emphasis on fusion welding is the vitiating effects of welding heats upon the alloys of thin section with further difficulties, in many instances, where low-melting-temperature alloys are required. Undoubtedly this field for structural application is inept for fusion welding, but entirely within the field of resistance welding. The successful use of resistance welding of thin sections in stainless-steel structures has been demonstrated by performance. Further extension of this type of welding to other metals is to be expected. However, fusion welding is utilized effectively from a structural and economical standpoint in the modern all-metal transport plane for such structural units as engine mountings, nacelles, shown in Fig. 1, fittings, and the landing gear.

Due to the complexity of structural units such as shown in Fig. 2, it is apparent that the usual fusion welding demands a precise skill during placement which only a manual operator can exercise. The degree of reliability in the weld is reduced to adequate training and experience of the welding personnel. At the present time, training is given at the aircraft manufacturing plants and only after successful welding of aircraft parts such as exhaust stacks, tanks, and fittings, is the experience recognized as sufficient to permit the operator to do structural welding. Through the efforts of the American Welding Society procedure

[1] Assistant Professor, University of California. Assoc-Mem. A.S.M.E. Professor Ward was graduated from Cornell University in 1921 with an M.E. degree and received his M.M.E. degree from the same University in 1927. From 1921 until 1927 he was employed as instructor in machine design and heat-power engineering at Cornell University, leaving that position to become assistant professor in mechanical engineering at the University of California. He also served as lecturer at the Boeing School of Aeronautics, Oakland, Calif., and consulting engineer for the American Tractor Equipment Company, Oakland, Calif.

Contributed by the Aeronautic Division and presented at the National Aeronautic-Hydraulic Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS at Berkeley, Calif., June 19, 20, and 21, 1934.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until December 10, 1935, for publication at a later date.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

in aircraft welding has been revised and improved on the basis of experience, so that if closely adhered to, it should produce welds as reliable as human experience can devise.

Significance of Static Test

A study of failure under static loading such as encountered in the standard hardness and tension tests, although not simulated

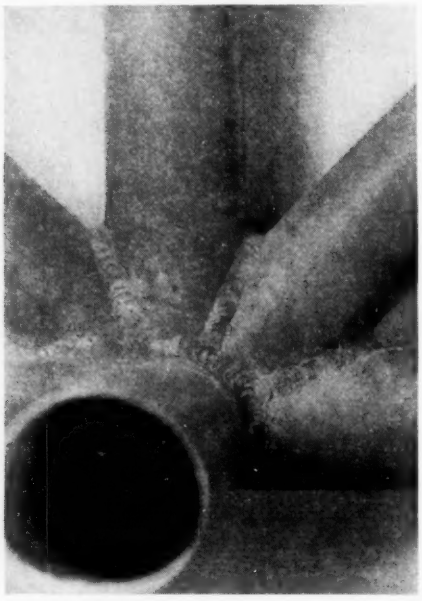

Fig. 2 Typical Gas-Welded Cluster Joint

in actual service, serves with the aid of microscopic examination to detect inherent characteristics of welded joints. When these qualities in the weld and its immediate vicinity are recognized, suitable application of this type of joint is assured.

For specific data in this connection, butt-welded tubes of cold-drawn chrome molybdenum S.A.E. 4130 steel were used. The tubes were 1 in. in diameter and 3 in. long, and had a wall thickness of 0.049 in. They were butt-welded with oxyacetylene torch and low-carbon-steel welding rod to form a specimen with an overall length of 6 ft. The welded tubes were fitted with steel plugs in both ends and inserted far enough to absorb the crushing load of the friction grips in the 30,000-lb Olsen Universal testing machine. The results of the commercial tests of the tubes, summarized in Table 1, are indicative of the reliability in static tension of the usual butt-type weld.

TABLE 2 COMPARISON OF HEAT-TREATED SPECIMENS OF BUTT-WELDED AND UNWELDED TUBES

	Ultimate stress, lb per sq in.	Ductility in 2 in. %	Remarks
Minimum.....	129,000	6.25	Broke in weld
Maximum.....	153,300	9.4	Broke in tube
Avg of six.....	142,400	7.3	....
Original tube as received.....	156,000	25.5	Broke at mid-section

After subjecting another group of butt-welded specimens to a combination of normalizing treatment at 1700 F hardening in water from 1700 F and tempering at 900 F, the results shown in Table 2 were obtained under static tension.

Prior to the tension tests and after the tubes were welded, a survey of hardness with a Rockwell hardness tester was made. The average values of three readings in the weld and at 1/4-in. intervals either side of the weld were observed as indicated in Fig. 3. After heat-treatment the butt-weld hardness increased to Rockwell B-82 and the hardness either side of the weld remained uniform at average values of C-6. These tests indicate a softening or annealing in the region of the outer envelope of the welding flame which produces sufficient heat to recrystallize the cold-drawn microstructure. In the heat-treated tubes the variation in hardness was adjusted with the exception of the weld, where an increase in hardness was evident.

For static tests the indentation of the hardness penetrator appears to have little or no effect on the tube strength. Yet for

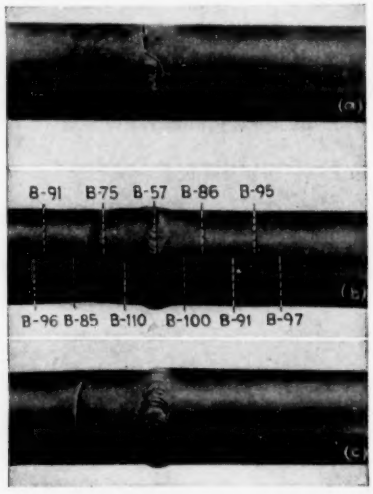

Fig. 3 Fractures in Tensile Specimen. Hardness Numbers at 1/4-In. Intervals Before Tensile Tests Are Shown on the Center Specimen

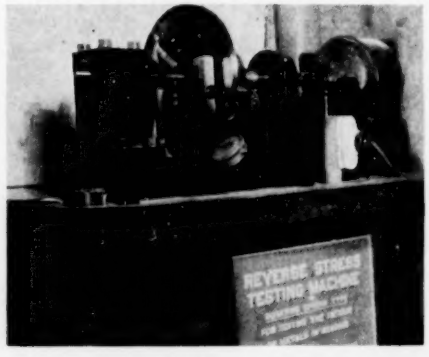

Fig. 4 Fatigue-Testing Machine for Tubes Under Bending Stress

the dynamical loading, encountered during fatigue tests, the indentation inhibits a weakness not already in the tube as welded. For this reason it was thought inadvisable to determine the hardness on fatigue specimens. Since the fatigue tests alter the physical structure of the metal, hardness determination after the test would be of little value. It remains for the microscopic examination to explain the allocation of the fracture as a result of the fatigue tests.

Fatigue Tests of Tubes

With usual service conditions inducing repeated stresses, the endurance of welded tubes under repeated loading is a logical test. Due to limitations of grip size on the fatigue-testing machine which was available, it was necessary to use 1/2-in. chrome-molybdenum S.A.E. 4130 tubes with 0.049-in. wall thickness. Since the smaller tubes are more difficult to weld accurately, the results should represent less favorable performance than the average. In other words, the minimum values for design are indicated by these tests.

The fatigue machine shown in Fig. 4 is of the cantilever type in which one end of the specimen is held rigidly while the other end is guided and loaded with an 80-lb indicator spring. The spring load deflects the specimen and induces the maximum stress at the inner side of a rigid clamp. In the tube tests, the maximum stress is in the region affected by the welding heats. The mounting of the tubular specimen requires the steel plug on the clamped end to prevent collapse of the tube under the grip pressure. A similar plug is inserted in the opposite end which engages the ball-bearing housing through which the spring load is applied.

Each heat-treated specimen, as welded with oxyacetylene flame, was tested for a given spring deflection which was measured on the dial gage shown in Fig. 4. By means of a direct-connected 1/4-hp motor, the single specimens were rotated at 1725 rpm until fractured. This was possible by subjecting each specimen to a different stress by proper spring adjustment. The results are plotted on the curves in Fig. 6. For maximum deflection the specimens fractured as low as 62,000 reversals. For stresses of low intensity some of the specimens did not break after 3,000,000 reversals. In every instance the specimens as welded broke adjacent to the weld bead as shown in Fig. 5. On which side of the weld bead failure would occur wasn ot predictable. Some failed on the side nearest to the rigid grip and an equal number of other specimens failed on the opposite side of the weld bead, as shown by comparing Fig. 5*c* with Fig. 5*b*. The fracture in the unwelded tube may be seen in Fig. 5*a*.

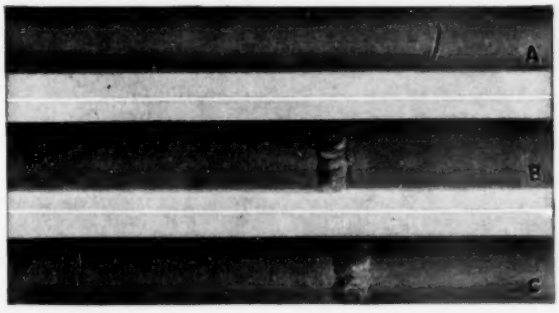

Fig. 5 Fatigue Failure of 1/2-In. Cr-Mo Steel Tubing
(*a*, tube as received; *b* and *c*, Oxyacetylene-welded tubes.)

Several observations for butt-welded tubes during these comparative tests show that loads inducing high stress are accompanied by failure during a wide variation of cyclic frequency.

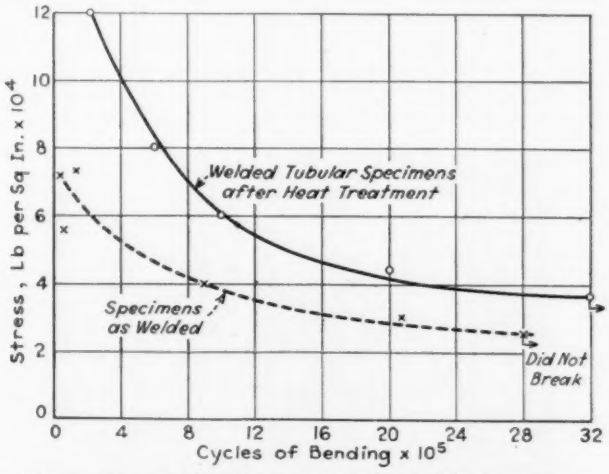

Fig. 6 Fatigue-Test Curves of 1/2-In. Cr-Mo Oxyacetylene-Welded Tubes With 0.049-In. Wall Thickness

The heat-treated specimens develop a more uniform response to fatigue in bending. Improvement of the endurance limit by heat-treatment of welded tubes in these tests amounted to approximately 40 per cent. The ratio of endurance strength to static tensile strength of the tubes as welded was 1/4, while for welded tubes after heat-treatment the ratio was 1/2.

Within probable errors of the test, this comparison between the tubes as welded and the welded tubes after heat-treatment maintains a close parity for the ratio of endurance limit to ultimate tensile strength. However, the fatigue failure in the butt-welded tube without subsequent heat-treatment has a tendency to localize failure in the immediate vicinity of the weld as indicated by the fractures in Fig. 5. The fatigue failure in the heat-treated tubes appeared most frequently at least the diameter of the tube from the weld. Obviously, the desire in service is to preserve these critical sections against concentration of load by any of several types of construction, such as gusseting or reinforcing with straps or telescoping the tubes or using a fishmouth joint.

Where these welds fail has been demonstrated by physical tests. Why the welds are more reliable in certain sections and vitiated in others is revealed in the microstructure of the weld and its vicinity.

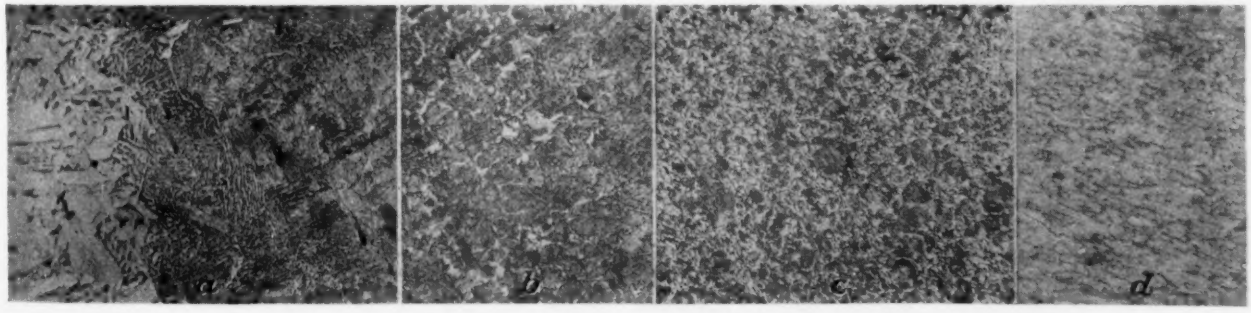

Fig. 7 Microstructure in Oxyacetylene-Weld (× 130)
(*a*, weld matrix at left with transition beginning at the right; *b*, transition; *c*, annealed section 1/2 in. and 3/4 in. from weld; *d*, original cold-drawn tube.

Influence of Welding Heats

Progressing from the weld outward toward the parent metal, the metallurgical changes in the weld may be seen in Fig. 7. The large areas of free ferrite are present with less carbon matrix than seen in the original tube in Fig. 7*d*. The weld metal is a typical structure found in low-carbon-steel castings cooled slowly from fusion temperatures. The precipitation of large ferritic masses accounts for the soft weld. The heat used in placing the weld has been moderate, since no excess of oxide and nitride contamination is evident. The avoidance of high temperature in placing the weld is essential to keep the gas (oxygen and nitro-

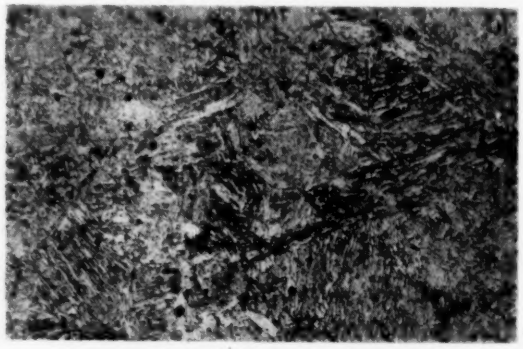

Fig. 8 Microstructure in Transition Zone of Heat-Treated Weld

gen from the air) content at a minimum. These gases develop a porosity and form oxides and nitrides which embrittle the weld if present in combination.

The transition zone from weld to tube appears in Figs. 7*a* and 7*b*. The microstructure is large grained and of tough consistency which is harder than the weld except at grain boundaries, which are soft ferrite. The growth of large-grain structure is a natural accompaniment of welding heats. The precipitation of tough constituents in this transition zone is largely due to rapid conductivity of heat from the weld to the cooler tube. The cross-section of a weld thus affected with the aircraft welding torches persists for $^1/_2$ in. either side of the welds in varying intensity, which depends upon the adjustment of the torch flame and its position. The larger grain of the weld in comparison with the transition zone represents a source of weakness with reversal of loading, since it yields more rapidly than the hard tough metal adjoining it in the transition zone.

Interposed for a distance between $^1/_2$ in. and $^3/_4$ in. between the transition zone Fig. 7*a*, *b* and the original plate 7*d* is found the recrystallized section Fig. 7*c* in which refinement of the grain has been produced by contact of a portion of the welding flame or the heat as conducted from the weld to the cooler plate or from both causes. The existence of this structure explains the fracture in this area for sound weld during static-tension tests, rather than in the weld. Briefly, the unit stress is least in the weld because of its greater section. The softened section (Figs. 3 and 7*c*) strain-hardens with the application of load but suffers a greater reduction in cross-sectional area than adjoining sections, thus developing greater stress intensity which persists under load until the ultimate stress is reached and pronounced reduction in cross-sectional area continues until fracture occurs.

Since the base or parent metals in aircraft structural members are cold-drawn or rolled, they reach their yield point at a greater load than for the annealed section. Where there is a weld fracture under static-tension load, the specimen has been misaligned or the weld has been overheated and consequently embrittled by contamination of oxides and "cold shuts."

Summary of Physical Changes in Oxyacetylene Weld

In tubing of chrome-molybdenum steel the welding heat is beneficial to certain sections and detrimental to others. Since chrome-molybdenum steel hardens as it cools in air from fusion temperatures, the static strength of the areas adjacent to the weld approaches or exceeds that of the cold-drawn sections. Use of mild-steel tubing for welded joints effectively prevents as wide a variation in hardness, but the strength averages half that of chrome-molybdenum steel. The fatigue resistance of the fused areas is reduced because of the large grain. Interposed between this zone and the cold-drawn section is an annealed section in which sound welds finally fracture under static loading.

Welded-tube sections which undergo proper heat-treatment, i.e., normalizing hardening and drawing, develop high ultimate strength, as is evident from the values in Table 2. This heat-treatment develops a welded structure as reliable as the original

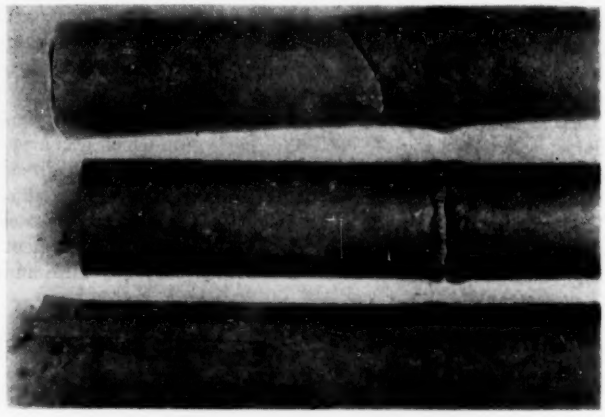

Fig. 9 Typical Failure of Oxyacetylene-Welded Tubes After Heat-Treatment

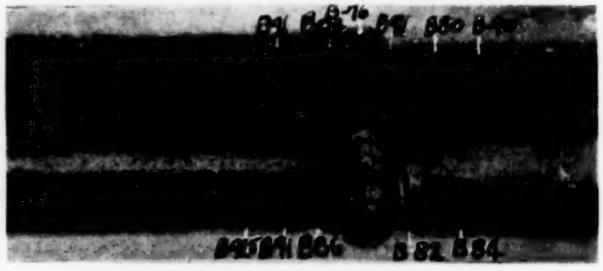

Fig. 10 Static-Tension Failure in Arc-Welded Tube. Hardness Values Taken at $^1/_8$-In. Intervals

by adjusting inequalities of the crystalline matrix and producing uniform strength and ductility. The microstructure changes at the weld zone resulting from this heat-treatment are shown in Fig. 8. The position and type of fracture for the static-tension tests is shown for selected specimens in Fig. 9.

Characteristics of Arc Welds

Metallic arc welding with direct current and low-carbon-steel electrode has had limited application in airplane structures. For adequate fusion of the tube or plate the bead deposit is greater than for oxyacetylene welding. The concentrated heat evolved from the arc localizes the critical zone in close proximity to the weld beads. The annealed section, which is less extensive than that for the oxyacetylene welds, develops within $^1/_4$ in. of the welds. The variation in hardness appears to be less marked

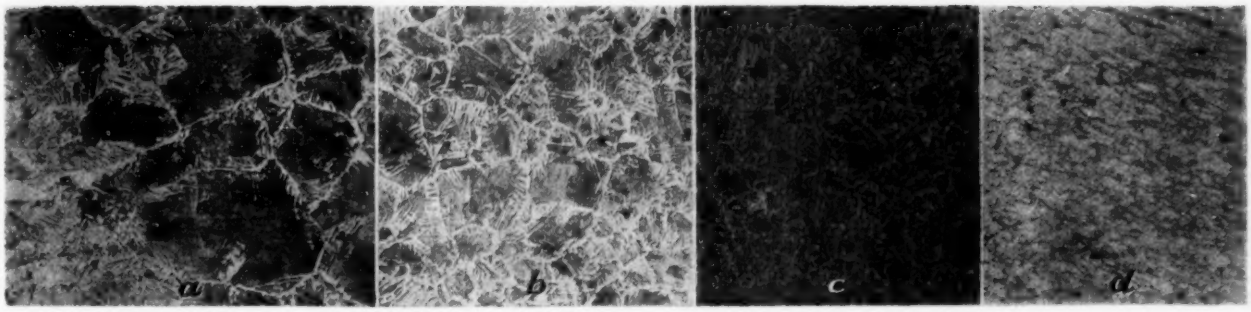

FIG. 11 TYPICAL MICROSTRUCTURE IN 1-IN. TUBE ARC WELDED WITH DIRECT CURRENT AND LOW-CARBON FILLER ROD (× 130)
(*a*, weld matrix showing on the right large-grained sorbite with ferrite boundaries; *b*, transition zone; *c*, partially annealed zone 1/16-in. from weld; *d*, original cold-drawn tube.)

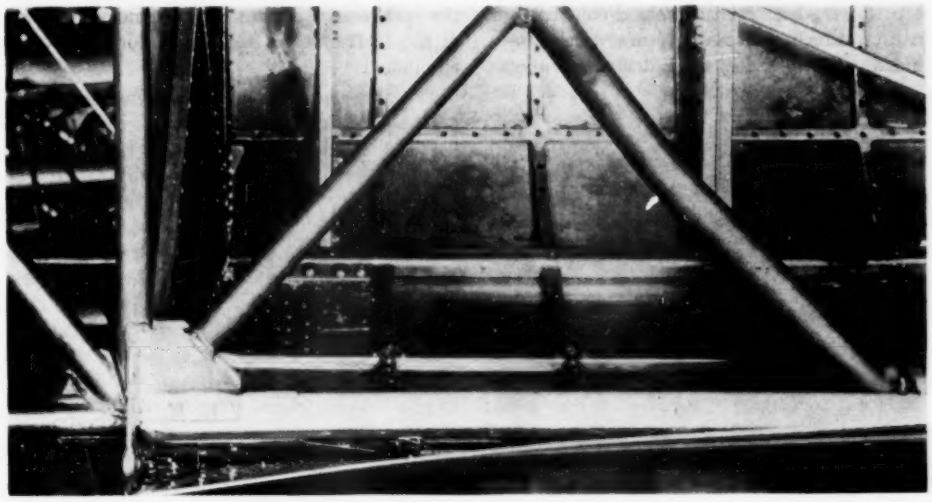

FIG. 12 STATIC FAILURE IN BEADING OF ARC-WELDED TUBE. LOAD FACTOR = 14½

than for the oxyacetylene-welded tube. Comparison of Rockwell hardness values for the electric arc weld is indicated at ⅛-in. intervals in Fig. 10. The failure under static-tension loading is evident from Fig. 10.

The transformations in the weld and tube for a representative arc-welded specimen are shown in Fig. 11. The weld structure at the left Fig. 11*a* is a typical steel matrix as cast, tapering into a sorbitic zone of large grain bounded by soft ferrite. The retention of high sorbitic content is probably due to the large temperature gradient between the weld and its environs which produces faster chilling than is present in oxyacetylene welding. There is evidence in Fig. 11 that grain diminishes in size until the annealing temperature is reached about ¼ in. from the fusion zone. Then the original cold-rolled structure is resumed with lowering of the temperature below that required for recrystallization. Fracture in static tension for the butt-welded tubes occurs in this annealed zone adjacent to the weld for reasons given under the discussion for oxyacetylene welding. The zones of fusion and transformation are very similar for both the oxyacetylene and direct-current arc welds.

The frequency with which failures occur outside of the weld when tested with the weld bead intact for a joint properly designed and welded, is evidence that the strength is not dependent upon the welds so much as the amount of weakening due to the welding process.

OTHER FACTORS AFFECTING RELIABILITY OF WELDED JOINTS

Temperature Stresses. There are many conditions arising from mechanical shrinkage as the welds cool. A brief for the solution of the problems encountered could not be attempted in this short treatise. The principal difficulty with shrinkage in welds during solidification is the adjustment of the residual stresses during cooling or immediately after the weld is placed. Usually the intensity of stress due to shrinkage is localized in the sections which cool unevenly. For example, the hotter areas are weak and the stress is transferred from the cool, stronger areas. Where the correct sequence of deposition of the weld bead and tack welding is used, the shrinkage is absorbed sufficiently so that subsequent normalizing, stress-relief annealing or peening adjusts the residual stresses in larger areas. In this way the stress intensity is distributed but never eliminated. Abrupt change of sections, such as heavy reinforcement in the weld bead, is undesirable not only because of the diminished fatigue resistance at the juncture of the bead and the tube, but also because of localization of shrinkage in this larger mass which retains its temperature during a longer period than the thin tube. Weld beads which are flush with the tube and rough or undercut are prone to weakness in fatigue and represent doubtful security in a structure.

Significance of Welding Knowledge for Design. The general conclusions which may be drawn from the foregoing facts about fusion welding in aircraft leads to the proportioning of the structural members so that stresses of a concentrated nature are not imposed at the critical section. By the critical section is meant that at which failure originates due to predisposition to structural weakness under repeated tension, compression, shear loading, or their combination. Clarifying examples may be cited.

The structural member or members in a fuselage are under tension, compression, and bending loads of varying intensity. The tube size, or plate thickness, is calculated for one or several predominant stresses. In a typical instance of a tube where a large ratio of length to diameter is used, the welds at the ends can safely develop the tube strength, unless the joints receive heat treatment; otherwise the crushing strength in the annealed section of the weld is reduced below that of the tube. This critical section requires suitable reinforcement, such as a strap or gusset. With adequate weld reinforcement the tube should bend in the center. Since the stress is seldom equally distributed in the final welded unit the probable failure occurs near the center section which, if very critical, transfers intensity to the tube ends. The static test on a fuselage shown in Fig. 12 indicates a collapse of the tube under a load factor of $14^1/_2$ with the end welds remaining intact.

Further extension of the analysis for the welded construction explains why application of heat unnecessarily near critical sections should be avoided. For instance, holes drilled for injecting lionoil to prevent internal corrosion of structural tubes are located usually beyond the first critical section and the drill holes are filled with screw plugs to avoid softening by flame or arc heat which produces areas susceptible to collapse near the critical section. Welding of telescoped tubes or fishmouth is preferred to butt-welded tubes because of the added stiffness and stability afforded in the joint. Deposition of relatively smooth concave weld beads is done where vibration is a predominant consideration. These show the place of accurate knowledge of weld performance as briefly outlined in the preceding discussion.

Acknowledgments

The Viscosity of Water and Superheated Steam[1]

By G. A. HAWKINS,[2] H. L. SOLBERG,[3] and A. A. POTTER,[4] LAFAYETTE, IND.

The authors present in this paper data on the viscosity of water and superheated steam at temperatures and pressures used in modern power-plant practice. The authors constructed an apparatus to measure the viscosity of water and superheated steam at pressures up to 3500 lb per sq in. abs and at temperatures up to the critical in the case of water and between 800 F and 1000 F for superheated steam. The apparatus is described and the results obtained with it are reported in this paper.

THE increasing use of dimensional analysis in correlating data and solving problems in the fields of heat transfer and fluid friction has made viscosity a very important physical property of fluids. In making a survey of the literature preparatory to an investigation of flow distribution in forced-circulation once-through steam generators (1),[5] the authors found that data on the viscosity of water and superheated steam are very meager or non-existent at the temperatures and pressures which are used in modern power-plant practice. The viscosity of water is known quite accurately at temperatures below 212 F and some determinations have been made at temperatures up to 320 F. von Hevesy (2) calculated the viscosity of water at elevated temperatures on the assumption that viscosity is a function of electrical conductivity, but this assumption has not been verified experimentally. M. DeHaas (3) used a capillary-tube viscometer for determining the coefficient of viscosity of water up to 153 C. The viscosity of superheated steam at atmospheric pressure is known with reasonable accuracy. Speyerer (4) has determined the effect of pressure on the viscosity of superheated steam at pressures up to a maximum of ten atmospheres.

In view of the absence of experimental data beyond the above limits, the authors decided to construct a suitable apparatus to measure the viscosity of water and superheated steam at pressures up to 3500 lb per sq in. abs and at temperatures up to the critical in the case of water and between 800 F and 1000 F for superheated steam. The results are reported in this paper.

Since this investigation was started Schiller (5) has published viscosity determinations. Schiller obtained the relation for calculating the viscosity of steam in terms of that of water, by observing the velocity at which the discharge coefficient of a nozzle shows an abrupt increase for water and steam and then equating the two Reynolds numbers. Schiller's curves show one test point at 30 atmospheres pressure, four test points at 25 atmospheres and other points at lower pressures with a maximum temperature of about 540 F.

Selection of Type of Viscometer[6]

In deciding upon the type of viscometer to be used in this investigation, where pressures of 3500 lb per sq in. and temperatures of 1000 F were contemplated, the matter of safety was given first consideration because of the high energy storage per unit of volume of hot compressed water. The apparatus had to be suitable for a wide range of viscosities and reasonable in cost. Adaptability to the use of automatic recording devices was desirable in order to reduce the human element in the collection of the more essential data. The high pressures involved, the effect of high temperatures on the elastic properties of suspensions, difficulties in measuring small pressure differences accurately, and of maintaining definite surfaces of separation between liquids and condensable vapors, resulted in discarding most of the types of viscometers which have been used for viscosity determinations.

The Lawaczeck (6) viscometer was selected as being the most suitable type for the range of conditions encountered in these tests. This viscometer was developed in 1919 and consists essentially of a metal weight falling in a tube closed at its lower end and having a diameter which is slightly greater than that of the weight. As the weight falls, the liquid is made to flow with streamline motion through the annular space between the weight and the tube. There are three distinct resistances to the fall of the weight through the liquid. The form of the streamlines causes a so-called "head resistance" which can be decreased to a minimum by using a long weight and a small clearance. As the liquid flows through the annular space, a pressure gradient is set up similar to the case of the flow of a fluid through an annular channel. This resistance is fixed by the area of the cross-section and the rate of fall of the weight. The third resistance is a viscous drag due to the relative movement of the two cylindrical walls. Neglecting the head resistance, the formula for this viscometer is

[6] The description of the development of the viscometer and the values for the viscosity of water are based on a thesis submitted by G. A. Hawkins in partial fulfillment of the requirements for the Ph.D. degree at Purdue University, June, 1935. The work on the viscosity of steam was completed subsequent to the submission of this thesis.

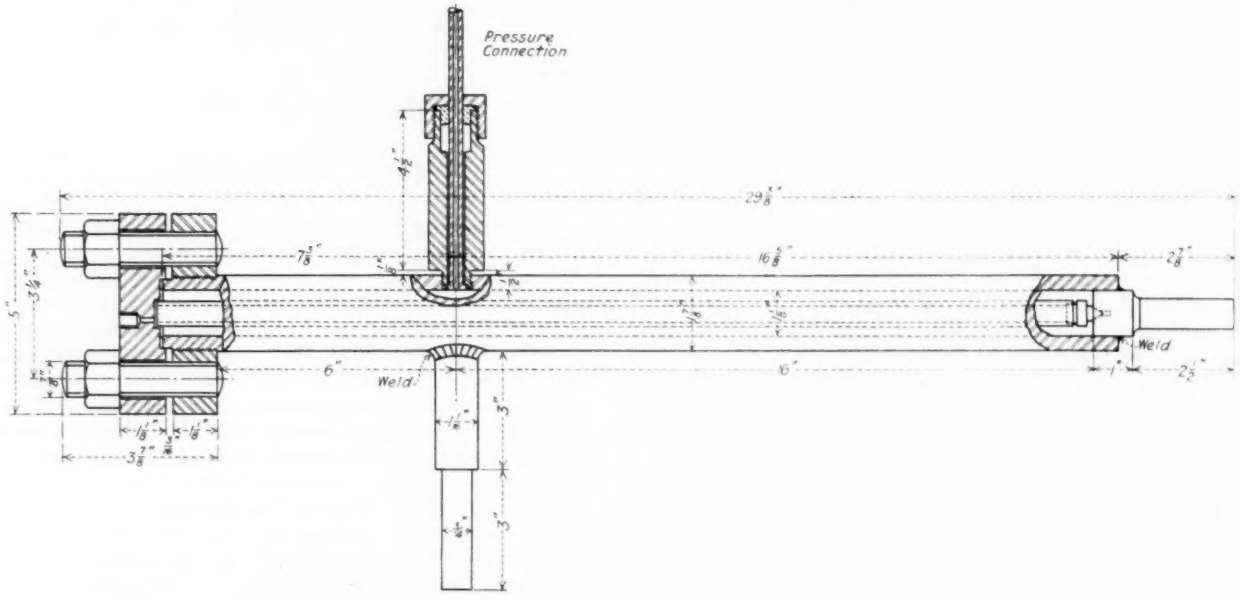

FIG. 1 DETAIL OF VISCOMETER AND PRESSURE CONNECTION

$$\mu = \frac{t}{s}(\sigma - \rho)\frac{\delta^3 d}{3(d + 2\delta)^2 - (2\delta)^2} \quad \ldots\ldots\ldots [1]$$

where μ is the absolute viscosity; σ is the density of the weight or fall-body; ρ is the density of the fluid; δ is the annular space between the fall-body and the tube; d is the diameter of the fall-body; s is the fixed distance through which the weight falls inside the tube; and t is the time required for the weight to fall the fixed distance s.

Because of the difficulty of measuring the dimensions accurately, the instrument is calibrated by using a fluid of known viscosity. Using a calibration constant C determined in this manner, Equation [1] is changed to the form

$$\mu = C(\sigma - \rho)t \quad \ldots\ldots\ldots [2]$$

Bridgman (7) in 1926 used a method similar to this for determining the viscosity of liquids at very high pressures but at low temperatures. In 1933, Stakelbeck (8) used a Lawaczeck viscometer for measuring the viscosity of carbon dioxide, ammonia, and sulphur dioxide, at the suggestion of R. Planck.

DESCRIPTION OF THE VISCOMETER

The viscometer, shown in Fig. 1, consists of an accurately bored, stainless-steel vertical tube through which a weight, or fall-body, of slightly smaller diameter is moved under the influence of gravity. The tube is placed concentrically within a seamless steel pipe capable of holding safely the maximum pressures to be used. This outer pipe or pressure vessel, hereafter called the container, was closed at the lower end by welding and was fitted with flanges at the upper end to allow for insertion of the tube and fall-bodies, and for periodic inspection. The top was closed with a blank flange and was provided with a $^1/_4$-in. vent valve. Two trunnions were secured to the container to serve as a support about which the apparatus could be rotated through an angle of 180 deg. One of the trunnions was provided with a packed pressure connection to which the pressure gage was attached. Distilled water was forced into the container by means of a hydraulic pump. The temperature of the fluid could be regulated by means of an electric heating coil which was wound around the container and thoroughly insulated. Fig. 2 shows the assembly

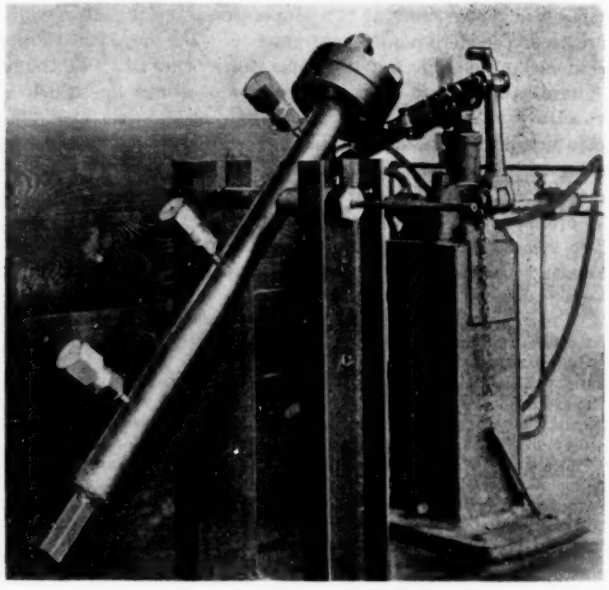

FIG. 2 VISCOMETER TEST ARRANGEMENT

of the container as mounted in its bearings. The three boxes for the electrical connections to the two timing coils are also shown. Three $^1/_8$-in. iron pipe taps were provided in the container, one at the center and one near each end, for the insertion of thermocouples.

The tube, 23 in. long and 0.658 in. outside diameter, was made by the Winchester Repeating Arms Company from a piece of Carpenter Steel Company No. 8 alloy containing 18 per cent chromium, 8 per cent nickel and a small percentage of selenium to facilitate machining. The bar was drilled, reamed four times and polished to 0.410 in. internal diameter with a high-speed lap coated with emery and oil. Periodic inspection of the tube has shown that it successfully resists corrosion and oxidation when in contact with steam and water at high temperatures. One end of the tube was threaded with a standard pipe tap and fitted

with a stainless-steel plug which centered it in a conical-shaped socket in the bottom of the container so as to insure coaxial alignment of the tube with the container when the two were assembled.

Details of the fall-bodies which were used in this investigation are shown in Fig. 3. They were drilled hollow to reduce their weight and the outside diameter is such that the Reynolds number of the fluid flowing into the annular space between the fall-body and the tube never exceeded 1300. The time required for a fall of 14 in. varied from 10 minutes to as low as 2 seconds, about 50 per cent of the tests involved a time of less than 1 minute. Fall-body No. 28 was used for determining the viscosity of water and this was checked by fall-bodies Nos. 30 and 31 in order to establish the fact that the results are independent of the shape of the ends of the fall-body. Fall-body No. 35 was used for determining the viscosity of superheated steam, which was checked by fall-body No. 33.

Pressures below 1500 lb per sq in. were measured by means of calibrated Bourdon gages. A Bailey self-loading, deadweight gage was used for higher pressures.

Temperatures were measured by iron-constantan thermocouples welded into the bottom of a steel well which was threaded to fit a $^1/_8$-in. pipe tap, as shown in Fig. 4. The thread on the thermocouple body was sufficiently long so that the hot junction was very close to the tube which contained the fall-body. Twenty thermocouples were made and calibrated in the physics laboratory of Purdue University against a platinum, platinum-rhodium thermocouple which had been checked by the National Bureau of Standards. Two of the three thermocouples were removed in rotating pairs at regular intervals and replaced by others, the third one being left in place as a check on the new one. Thermocouples were also checked periodically by boiling water in the viscometer with the vent valve open to the atmosphere. The thermocouples were connected to a very sensitive high-resistance Wilson-Maeulen millivoltmeter; the couple resistances were measured with a Wheatstone bridge.

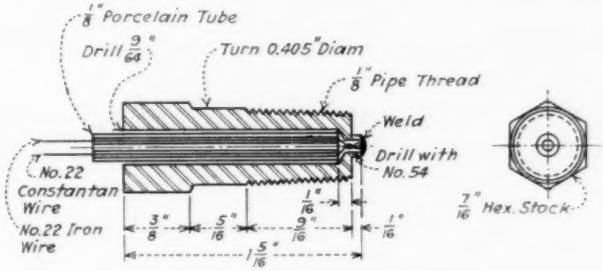

Fig. 4 Design of Thermocouples

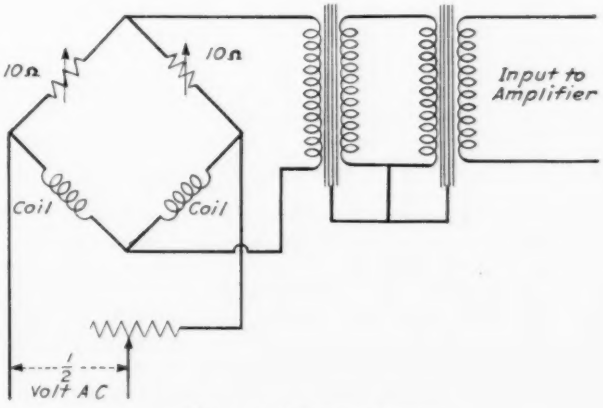

Fig. 5 A-C Bridge Circuit

Timing Equipment

The principal difficulty which was encountered in developing the viscometer was in devising an accurate means of timing the rate of fall of the body which was dropping through the tube. Among the schemes which were investigated and abandoned may be mentioned the use of an X-ray and Geiger-Müller counter, an X-ray and sensitive screen, and an oscillator, receiver, and oscillograph. An a-c bridge amplifier and recording milliammeter were finally selected as the most satisfactory solution to the problem.

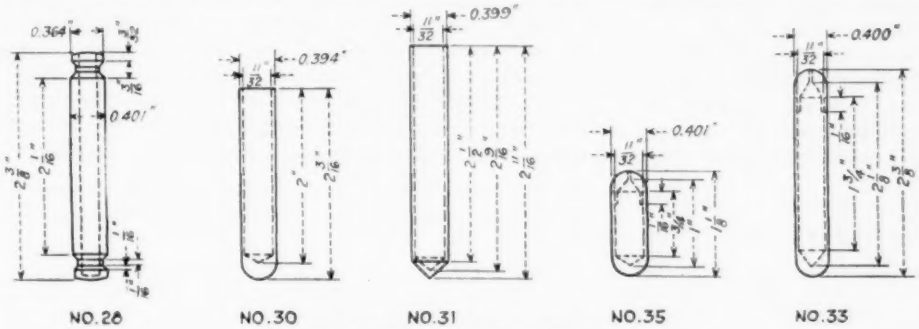

Fig. 3 Details of Fall-Bodies

The a-c bridge circuit is shown in Fig. 5. The two coils, indicated in the circuit diagram, were wound on the tube through which the fall-body dropped and were spaced about 14 in. apart. When the fall-body passed through either coil, the circuit was unbalanced sufficiently to swing a pen across a strip chart on the recording milliammeter. Each coil consisted of a single layer of 60 turns of copper wire wound on a sheet of mica rigidly held in place on the tube by two steel clamps which also served as terminals for the ends of the coils. Each turn was separated from the adjacent turn by a small asbestos thread. After winding, the coils were examined for defects with a magnifying glass. They were as nearly identical as it is possible to make them. The coils were connected in series and the three leads were brought out in asbestos tubing through the pressure connections shown in Fig. 2. Two identical 10-ohm rheostats were used for balancing the bridge. An objectionable 60-cycle disturbance which was being picked up by the bridge, was eliminated by connecting the output of the bridge to two transformers, as shown in Fig. 5. A constant voltage had to be impressed on the bridge in order to obtain satisfactory results.

Fig. 6 illustrates the circuit of the amplifier. It consisted of two 57 amplifiers and one 45 triode power-amplifier tube. In order to eliminate the d-c part of the power output of the amplifier, the leads of the output were connected to the primary of a small transformer. The secondary output, consisting of the a-c part of the amplifier output, was rectified by a small Rectox rectifier. The rectifier output was connected through a double-pole double-throw switch to an indicating milliammeter having a range of 0 to 100 ma and to an Esterline-Angus recording milliammeter having a range of 0 to 5 ma.

The recording-meter chart of the Esterline-Angus milliammeter

was driven by a synchronous motor from the power lines of the Public Service Company of Indiana. System frequency control in the case of this public utility is obtained from Chicago and is excellent as shown by the records from recording frequency meters in the electrical-engineering meter laboratory of Purdue University. The effect of any momentary variations in frequency was averaged out by taking from 5 to 40 readings at each test point. Chart speeds of 3/4, 1 1/2, 3, 6, and 12 in. per hr and per min were

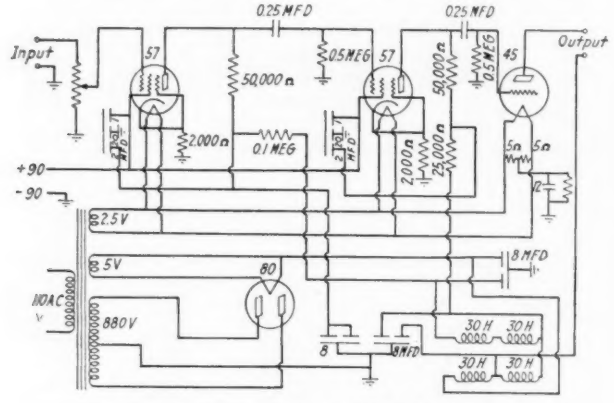

FIG. 6 CIRCUIT DIAGRAM OF THE AMPLIFIER

obtainable from the recorder. Charts were driven at 12 in. per min except where the time of fall exceeded five minutes when lower chart speeds were used. With a chart speed of 12 in. per min, it was possible to scale the time to about one-tenth of a second. The chart speed was checked periodically by recording with a stopwatch the time between two interruptions of the bridge circuit and scaling the distance on the chart.

Fig. 7 shows a typical chart. The two humps are due to the unbalance created in the bridge circuit as the fall-body passed through the coils. The time of fall was scaled from each chart at five different points such as *aa'*, *bb'*, etc. in Fig. 7. If any of the five time measurements differed from the average by more than 1 per cent, the test was discarded.

Some difficulty was experienced at first in securing symmetrical curves from the two coils because of unequal heating of the viscometer. A variation in temperature of 2 F between the two coils altered their resistances sufficiently to unbalance the circuit and destroy the symmetry of the curves. Proper arrangement of heating coils on the container solved this problem. No tests were made unless the readings of all three thermocouples agreed within 1 deg.

A fall-body was suspended from a chemical balance in one of the coils while the input to the bridge circuit was varied in order to check the possibility of these coils disturbing the rate of fall of the body. No deflection of the balance was obtained until the voltage impressed on the bridge circuit was 30 times that used in the test.

The coils were mounted 14 in. apart on the tube and far enough from each end of the tube so that the fall-body had accelerated to a uniform velocity before it entered the tube section which was surrounded by the coil.

CALIBRATION TESTS

A comparison of Equations [1] and [2] shows that the term C in Equation [2] is a function of the dimensions of the fall-body, tube, and distance between timing coils. These dimensions cannot be measured with sufficient accuracy and are also subject to variation with temperature. The effect of compression of the steel due to pressure was neglected as the error so introduced was less than 0.02 per cent at 3500 lb per sq in. The effect of temperature may be treated as a linear function of the temperature without introducing an error of more than 0.5 per cent at 1000 F. The term C for each fall-body was determined by timing the fall when a fluid of known density and viscosity was placed in the viscometer and heated to various temperatures. The results were expressed by an equation of the form

$$C = a + bt$$

where a and b are constants and t is the temperature of the fluid in degrees fahrenheit. These calibration constants for the various fall-bodies are given in Table 1.

TABLE 1 CALIBRATION CONSTANTS OF FALL-BODIES — $C^a = (a + bt)$

NOTE: t is in degrees F.

[a] See Equation [2].

Since fall-bodies Nos. 28, 30, and 31 were used to measure the viscosity of water, their constants were determined by using water at temperatures up to 212 F within which range the viscosity and density of water are known quite accurately. These values for viscosity were obtained from the International Critical Tables.[7] These calibration constants subsequently gave data on the viscosity of water which were identical for the three fall-bodies and which were in excellent agreement with the published

[7] International Critical Tables. Published for the National Research Council, McGraw Hill Book Company, New York, 1929, vol. 5, p. 10.

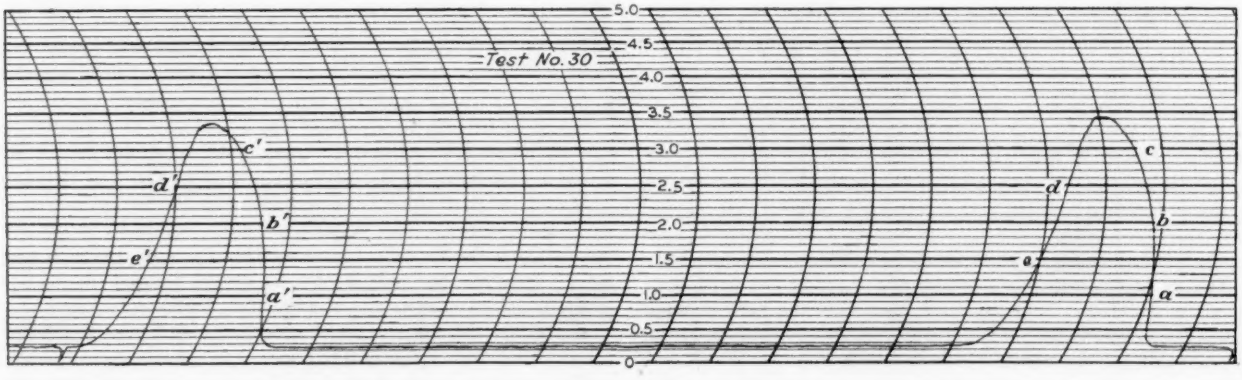

FIG. 7 RECORDING CHART FOR DETERMINING FALLING TIME OF THE WEIGHTS

results of other investigators up to 320 F, which is the upper limit of previous investigations.

The constants for fall-bodies Nos. 35 and 33 which were used in the superheated-steam tests were determined by using dry air at atmospheric pressure and temperatures up to 580 F the viscosity data for the above range having been obtained from the International Critical Tables.[8] Superheated steam up to 500 F at atmospheric pressure was also used for calibrating the constants. The range of pressures and temperatures investigated by the various fall-bodies overlapped sufficiently to obtain a check on the accuracy of the constants.

Test Procedure

In manipulating the apparatus, the fluid in the viscometer was heated to the desired temperature by controlling the electrical input to the heater and was maintained at the desired pressure by manipulating the vent valve or the hand-

operated pump. The switch in the heater circuit was opened and after conditions had reached equilibrium and the readings of the three thermocouples checked within 1 deg, the viscometer was rotated on its trunnions into the vertical position where it was held by a stop. The driving motor of the recording milliammeter was started and the time of fall was recorded automatically on the strip chart. The viscometer was then rotated through 180 deg to permit the fall-body to return to the starting position after which the process was repeated.

The Viscosity of Water

Using fall-body No. 28, the viscosity of saturated water was measured from room temperature to the critical temperature of 706 F. The results are tabulated in Table 2 and plotted in Fig. 8. The effect of pressure on the viscosity of compressed (sub-cooled) water was determined by increasing the pressure on the water and repeating the test procedure. The results are shown in Table 3. Each tabulated set of values in Tables 2 and 3 is the average of from 5 to 15 individual determinations. A typical set of test results for one pressure and temperature is shown in Table 4. The original data are too voluminous for presentation in this paper, but may be consulted in the office of the Engineering Experiment Station of Purdue University.

Check tests were made over the entire range of pressures and temperatures with fall-bodies Nos. 30 and 31. No difference in results was obtainable with the three fall-bodies.

Keenan's (9) values for the density of compressed water were used in calculating the results.

The viscosity of saturated water between 200 F and the critical temperature may be represented by the empirical equation

$$\mu = -2.185/(1 - 0.04012t - 0.0000051547t^2)$$

where μ is centipoises, and t is degrees F.

The results of this investigation show that at pressures up to 3500 lb per sq in. abs, the effect of pressure on the viscosity of water is negligible, but that viscosity depends upon the temperature.

The Viscosity of Superheated Steam

The viscosity of superheated steam was determined by filling the viscometer with distilled water, then boiling and discharging the excess liquid and vapor through the vent to the atmosphere until the desired pressure and temperature were attained. The instrument was then rotated into the vertical position and clamped, and the time of fall was recorded automatically.

Fall-body No. 35 was used to determine the viscosity of superheated steam for all of the test points while fall-body No. 33 was used to check a number of the previous tests.

The results of these tests are tabulated in Table 5. Each point is the average of from 5 to 40 separate determinations.

Figs. 9 and 10 show graphically the results of the investigation over the entire range of pressures and temperatures from atmospheric pressure to the upper limit of the Keenan steam tables. The authors believe that these results are sufficiently accurate so that they may be used with confidence in engineering calculations.

Stresses in Three-Dimensional Pipe Bends

By WILLIAM HOVGAARD,[1] NEW YORK, N. Y.

The paper presents first an algebraic method of calculating the couples, forces, and stresses in a three-dimensional pipe line fixed at the ends, consisting of straight parts at right angles to each other connected by quarter bends. The solution is complete in that it takes account of bending, torsion, compression, and shearing. It comprises a special discussion of the rotations and deflections of quarter bends when subjected to forces and couples acting normal to their plane, with particular application to the three-dimensional pipe line. The author also gives an analysis of the stresses at the terminal sections and in the bends, together with a discussion of the strength criteria and the permissible working stresses. A numerical example is given to illustrate the application of the formulas.

1—INTRODUCTION

IN a two-dimensional or plane pipe bend subjected to changes of temperature, the reactions at the anchorages are in the plane of the bend. The calculation of the couples and forces acting on any section of the pipe is relatively simple, and has been discussed by the author in four papers[2,3,4,5] published in the Journal of Mathematics and Physics of the Massachusetts Institute of Technology, and in two other papers.[6,7]

When a pipe is so shaped as to lie in three planes, even if at right angles to each other, the problem is more complicated, not only because three coordinates must be used instead of two, but also because torsional couples are produced and the curved parts deflect out of their plane. When the pipe is fixed at the ends, as here assumed, there are at each terminal three component reactions instead of two and three component couples instead of one. Torsional as well as bending stresses are produced and have to be combined with direct and shearing stresses.

When three-dimensional bends are not of simple geometrical form, it is necessary, as in the case of plane bends, to use graphical methods of solution, but when the pipe consists of straight parts and circular quadrants, and provided there are not too many bends and tangents, it is possible and, it is believed, preferable to use the algebraic method, which must always underlie all graphical solutions. It is the object of this paper to present a fairly rigorous solution for the simple case where the pipe has three straight parts and two quarter bends, all situated in three planes at right angles to each other. The method has been successfully applied in practice not only to this case, but also to a pipe having four straight parts and three quarter bends.

It is assumed that the curved parts of the pipe are bent to a radius of curvature not less than four or five times the diameter of the pipe, in which case it is unnecessary to take account of the fact that the neutral axis of a curved bar does not go exactly through the centroid of the section.

On the other hand, we include the effect of the flattening of the circular section which takes place when a curved pipe is bent in its own plane and which may cause a very marked increase in the angular deflection of the bend.[3] This flattening practically does not occur when a curved pipe is bent out of its plane nor is it produced by torsion, so that when calculating the deflections of a pipe bend under such actions, we can regard the pipe as a curved solid bar with the same axis as the pipe and with the same transverse and polar moments of inertia.

The Plane Bend

In developing the following formulas, the general method and notation adopted in the author's paper on deformation of plane pipes[3] are used, but it has been necessary or expedient in dealing with the curved parts of the pipe to extend the method considerably.

Referring first to Fig. 1, let

- M = a couple acting as indicated by a suffix
- R = radius of curvature of the axis of a pipe
- t = $2h$ = wall thickness of the pipe
- r_i = internal radius of the pipe
- r_o = external radius of the pipe
- r = $\frac{1}{2}(r_i + r_o)$ = radius of the middle surface of the pipe wall
- A = sectional area of the transverse section of pipe wall
- I = moment of inertia of the area of the transverse section about the neutral axis
- I_o = polar moment of inertia of the transverse section = $2I$
- E = modulus of elasticity
- G = modulus of rigidity. Taking Poisson's ratio as 0.30, we have: $G = E/2.6$ and $GI_o = EI/1.3$
- S = any point on the axis of the pipe
- ψ = angle between the radius to S and some fixed radius of reference

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until January 10, 1936, for publication at a later date.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

$d\psi$ = angle of a small element of the pipe axis comprised between two consecutive transverse sections

$\Delta d\psi$ = change in $d\psi$ caused by flexural strain

s = length or girth of axis from the point of reference to S

ds = $Rd\psi$

K = a coefficient applied to the angular deflection $\Delta d\psi/d\psi$ to allow for the flattening of the transverse section of a curved pipe

$$K = (48h^2R^2 + 10r^4)/(48h^2R^2 + r^4) \quad \ldots\ldots [1]$$

Writing

$$2hR/r^2 = \lambda \quad \ldots\ldots [2]$$

and substituting λ in Equation [1]

$$K = (12\lambda^2 + 10)/(12\lambda^2 + 1) \quad \ldots\ldots [1a]$$

Since the flexibility of a pipe bend is directly proportional to K, this coefficient shall be called the "flexibility factor."

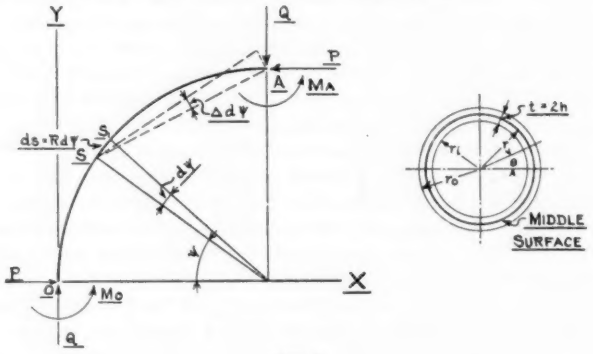

FIG. 1

For brevity, a direction parallel with the X-axis will be called the X-direction, and similarly, the rotation about an axis in the X-direction will be called an X-rotation; a couple with an axis in the X-direction will be called an X-couple; and a linear displacement in the X-direction will be called an X-displacement. Analogous terms are used in connection with the Y and Z axes, an XY-rotation being the rotation in which OX turns toward OY, the same as Z-rotation. The other rotations are similarly referred to. As seen from Fig. 6, a right-handed system of coordinates has been adopted in which the XY-, YZ-, and ZX-rotations are positive.

Axes of couples are indicated in the diagrams by arrows drawn so that when looking along the shaft toward the head, the rotation is clockwise. Thus an arrow drawn in the positive X-direction represents a positive couple and vice versa.

Before dealing with three-dimensional pipe bends, it is desirable first to analyze the case of plane circular quarter bends fixed at one end and subjected to terminal forces and couples acting normal to the plane of the bend at the other end. This problem occurs in three-dimensional bends, and in particular we wish to determine the rotations and the linear displacement normal to the plane of the bend at the free end. The analysis is here carried out in a simple and direct manner, disregarding the displacement of the free end in the plane of the bend, which is of the second order relative to that normal to the plane.

2—QUARTER BENDS UNDER THE ACTION OF FORCES OR COUPLES NORMAL TO THEIR PLANE

CASE I—QUARTER BEND FIXED AT ONE END AND LOADED WITH A FORCE NORMAL TO ITS PLANE AT THE FREE END

Referring to Fig. 2, the bend is represented by its axis, which forms a circular quadrant OA. The bend, which is spoken of as being in a horizontal plane, is fixed at O and loaded by an upward force F at its free end A.

Consider an element ds of the pipe at S. The radius CS forms an angle ψ with the X-axis. The force produces a bending

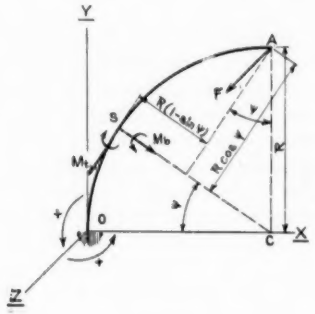

FIG. 2
(Case I.)

moment M_b with axis along the radius at S, and a twisting moment M_t with axis along the tangent at S. These moments can be expressed as

$$\left.\begin{aligned} M_b &= FR\cos\psi \\ M_t &= FR\,(1 - \sin\psi) \end{aligned}\right\} \quad \ldots\ldots [3]$$

The moment M_b produces rotation of the element in a vertica tangential plane so that

$$\Delta d\varphi_b = \frac{M_b}{EI}\,ds = \frac{M_bR}{EI}\,d\psi$$

The moment M_t produces a twist of the element

$$\Delta d\varphi_t = \frac{M_t}{GI_o}\,ds = 1.3\,\frac{M_tR}{EI}\,d\psi$$

By resolving these rotations along the X-direction, we obtain for the X-rotation of the element

$$\Delta d\varphi_{xs} = \left[\frac{M_b}{EI}\cos\psi - \frac{1.3\,M_t}{EI}\sin\psi\right] Rd\psi$$

Hence the total rotation at A in the YZ-plane becomes

$$\Delta\varphi_{xA} = \frac{FR^2}{EI}\left[\int^{\frac{\pi}{2}} \cos^2\psi\,d\psi - 1.3\int_0^{\frac{\pi}{2}} (1-\sin\psi)\sin\psi\,d\psi\right] = 0.506\,\frac{FR^2}{EI} \quad \ldots\ldots [4]$$

The Y-rotation of the element is

$$\Delta d\varphi_{ys} = -\left[\frac{M_b}{EI}\sin\psi + \frac{1.3M_t}{EI}\cos\psi\right] Rd\psi$$

and the total rotation of the pipe at A in the XZ-plane becomes

$$\Delta\varphi_{yA} = -\frac{FR^2}{EI}\left[\int_0^{\frac{\pi}{2}} \sin\psi\cos\psi\,d\psi + 1.3\int_0^{\frac{\pi}{2}} \cos\psi\,(1-\sin\psi)\,d\psi\right] = -1.150\,\frac{FR^2}{EI} \quad \ldots\ldots [5]$$

It will be noticed that we have here used the couples M_b and M_t and not M_x and M_y, although we wish to find the X-rotation

and Y-rotation. The reason for this is that it is simpler first to find the pure-bending rotation and the pure twist because the corresponding moments of inertia of the pipe section are easily determined. After that we obtain the desired rotations by resolving in the X-direction and the Y-direction. In other words, we resolve rotations instead of couples.

The linear vertical deflection Δz at A is determined as the algebraic sum of that due to M_b and that due to M_t. This deflection can be expressed as

$$\Delta z_A = \int_0^{\frac{\pi}{2}} \frac{M_b}{EI} R \cos\psi \, R d\psi + 1.3 \int_0^{\frac{\pi}{2}} \frac{M_t}{EI} R (1 - \sin\psi) \, R d\psi$$

$$= \frac{FR^3}{EI}\left[\int_0^{\frac{\pi}{2}} \cos^2\psi \, d\psi + 1.3 \int_0^{\frac{\pi}{2}} (1 - \sin\psi)^2 \, d\psi\right]$$

$$= +1.248 \frac{FR^3}{EI} \ldots\ldots [6]$$

where the positive sign indicates an upward displacement.

CASE II—QUARTER BEND FIXED AT ONE END AND SUBJECTED TO A TWISTING MOMENT M_z AT THE FREE END—FIG. 3

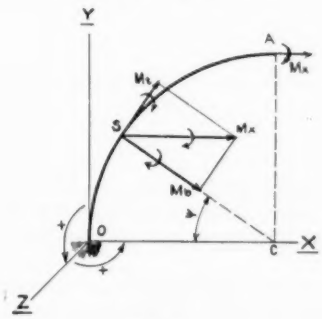

FIG. 3
(CASE II.)

From Fig. 3 it is seen that

$$\left.\begin{aligned} M_b &= M_z \cos\psi \\ M_t &= M_z \sin\psi \end{aligned}\right\} \ldots\ldots [7]$$

The X-rotation of the element is

$$\Delta d\varphi_{xs} = \left[\frac{M_b}{EI} \cos\psi + 1.3 \frac{M_t}{EI} \sin\psi\right] R d\psi$$

and

$$\Delta\varphi_{xA} = \frac{M_z R}{EI}\left[\int_0^{\frac{\pi}{2}} \cos^2\psi \, d\psi + 1.3 \int_0^{\frac{\pi}{2}} \sin^2\psi \, d\psi\right]$$

$$= +1.806 \frac{M_z R}{EI} \ldots\ldots [8]$$

The Y-rotation of the element is

$$\Delta d\varphi_{ys} = -\left[\frac{M_b}{EI} \sin\psi - 1.3 \frac{M_t}{EI} \cos\psi\right] R d\psi$$

and

$$\Delta\varphi_{yA} = -\frac{M_z R}{EI}\left[\int_0^{\frac{\pi}{2}} \sin\psi \cos\psi \, d\psi - 1.3 \int_0^{\frac{\pi}{2}} \sin\psi \cos\psi \, d\psi\right]$$

$$= +0.150 \frac{M_z R}{EI} \ldots\ldots [9]$$

It is seen that the major rotation is in the same direction as the acting couple. The Y-rotation is only about 8 per cent of the X-rotation.

The vertical deflection of the free end is

$$\Delta_{zA} = \int_0^{\frac{\pi}{2}} \frac{M_b}{EI} R \cos\psi \, R d\psi - 1.3 \int_0^{\frac{\pi}{2}} \frac{M_t}{EI} R(1 - \sin\psi) \, R d\psi$$

$$= \frac{M_z R^2}{EI}\left[\int_0^{\frac{\pi}{2}} \cos^2\psi \, d\psi - 1.3 \int_0^{\frac{\pi}{2}} (1 - \sin\psi) \sin\psi \, d\psi\right]$$

$$= +0.506 \frac{M_z R^2}{EI} \ldots\ldots [10]$$

where the positive sign again indicates an upward displacement.

CASE III—QUARTER BEND FIXED AT ONE END AND SUBJECTED TO A COUPLE M_y AT THE FREE END, HAVING ITS AXIS NORMAL TO THE TANGENT AT A—FIG. 4

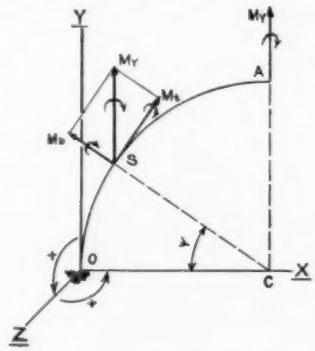

FIG. 4
(CASE III.)

It is seen from Fig. 4 that

$$\left.\begin{aligned} M_b &= M_y \sin\psi \\ M_t &= M_y \cos\psi \end{aligned}\right\} \ldots\ldots [11]$$

The rotation of the element in an X-direction at S is

$$\Delta d\varphi_{xs} = \left[-\frac{M_b}{EI} \cos\psi + 1.3 \frac{M_t}{EI} \sin\psi\right] R d\psi$$

and

$$\Delta\varphi_{xA} = -\frac{M_y R}{EI}\left[\int_0^{\frac{\pi}{2}} \sin\psi \cos\psi \, d\psi - 1.3 \int_0^{\frac{\pi}{2}} \sin\psi \cos\psi \, d\psi\right]$$

$$= +0.150 \frac{M_y R}{EI} \ldots\ldots [12]$$

Rotation of the element in a Y-direction at S is

$$\Delta d\varphi_{ys} = \left[\frac{M_b}{EI} \sin\psi + 1.3 \frac{M_t}{EI} \cos\psi\right] R d\psi$$

and

$$\Delta\varphi_{yA} = \frac{M_y R}{EI}\left[\int_0^{\frac{\pi}{2}} \sin^2\psi\, d\psi + 1.3\int_0^{\frac{\pi}{2}} \cos^2\psi\, d\psi\right] = +1.806\,\frac{M_y R}{EI} \quad [13]$$

These rotations are the same as found in case II, and we have again a major and minor rotation; but the X-axis and the Y-axis are interchanged.

The vertical deflection is

$$\Delta z_A = -\int_0^{\frac{\pi}{2}} \frac{M_b}{EI} R\cos\psi\, R d\psi - 1.3\int_0^{\frac{\pi}{2}} \frac{M_t}{EI} R\,(1-\sin\psi)\, R d\psi$$

$$= -\frac{M_y}{EI}\left[\int_0^{\frac{\pi}{2}} \sin\psi\cos\psi\, d\psi + 1.3\int_0^{\frac{\pi}{2}} (1-\sin\psi)\cos\psi\, d\psi\right] = -1.150\,\frac{M_y R^2}{EI} \quad [14]$$

Case IV—Quarter Bend Fixed at One End and Subjected at Any Point S to a Couple Equal to That Which Would Be Produced by a Force F Acting Normal to the Bend at O—Fig. 5

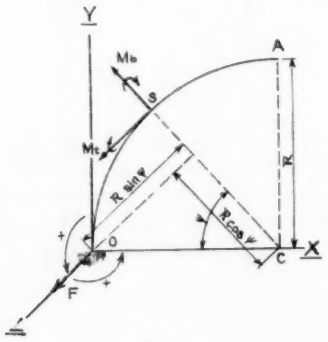

Fig. 5
(Case IV.)

The case is fictitious inasmuch as a force F applied at O would not actually produce a couple at S since O is fixed, but as will be explained later, it is here desired to determine the effect at A of a couple of just that magnitude at any point S. The result is the same as if F were acting downward at A in conjunction with a certain couple.

It is clear that the rotation at the A-end must be of the same amount as in case I, but since the force in case I was applied at the A end, $\Delta\varphi_{zA}$ becomes $\Delta\varphi_{yA}$ in case IV, and vice versa. Thus

$$\Delta\varphi_{zA} = -1.150\,\frac{FR^2}{EI} \quad [15]$$

$$\Delta\varphi_{yA} = +0.506\,\frac{FR^2}{EI} \quad [16]$$

Equation [15] gives the twist or X-rotation at A, while Equation [16] gives the Y-rotation at A.

The linear deflection at A normal to the plane will not be the same as in case I. In case IV, $M_b = FR\sin\psi$, and $M_t = FR(1-\cos\psi)$

$$\Delta z_A = -\int_0^{\frac{\pi}{2}} \frac{M_b}{EI} R\cos\psi\, R d\psi + 1.3\int_0^{\frac{\pi}{2}} \frac{M_t}{EI} R(1-\sin\psi)\, d\psi$$

$$= -\frac{FR^3}{EI}\left[\int_0^{\frac{\pi}{2}} \sin\psi\cos\psi\, d\psi - 1.3\int_0^{\frac{\pi}{2}} (1-\sin\psi)(1-\cos\psi)\, d\psi\right] = -0.408\,\frac{FR^3}{EI} \quad [17]$$

In cases I to IV, we have supposed the acting force and the axis of the acting couple to be in the positive X- or Y-direction and the axes of all the couples are so drawn as to make the rotation clockwise. The direction in which the arrows representing the couples M_b and M_t are to be drawn can thus be determined readily as can also the sign to be given to the rotations and the displacement at A. If the acting force or couple acts in the negative direction, all the rotations and all the displacements change sign, and we have only in the final results to substitute $-F$, $-M_z$, $-M_y$ for F, M_z, M_y, provided the coordinate axes are placed in the same position relative to the fixed and free ends of the quadrant. The orientation of the quadrant in space is indifferent, but if we change the name of the coordinate axes as in the second quarter bend of Fig. 6, we must realize clearly which end of the quadrant is assumed to be fixed and exactly how the acting force or couple is applied. This is indicated in Fig. 8.

3—Analysis of the Three-Dimensional Pipe Bend

General

Pipe bends are often attached to parts of the machinery which are anchored at points a certain distance from the terminals of the pipe, these parts of the machinery themselves being subject to heat expansion.

In such cases, linear displacements of the terminals will take place which must be added algebraically to those caused by heat expansion of the pipe itself.

Fig. 6 shows diagrammatically the general lay-out of such a pipe in the ideal case here considered, where all the bends are circular quadrants associated with straight tangents at right angles to each other. The ends O and A are regarded as fixed in direction and subject only to the displacements caused by the machinery parts to which they are attached. Thus, reaction forces and couples exist at those points, and it is the first object of the following analysis to determine these reactions.

Referring to Fig. 6, O is taken as the origin in a right-handed rectangular system of coordinates. The forces and couples (P, Q, N) and (M_{Ox}, M_{Oy}, M_{Oz}) at O, and ($-P$, $-Q$, $-N$) and (M_{Ax}, M_{Ay}, M_{Az}) at A are the reactions. The forces are considered positive when acting in the positive direction of the coordinate axes and the couples are considered positive when turning in the directions XY, YZ, and ZX. In Fig. 6, all the reaction couples are shown as being positive, but the forces at A, which are known to be equal and opposite to those at O, are shown as being negative.

The radius of the bends is R, and the straight lengths of pipe are L_y, L_z, and L_x, respectively. Also, $L_y + R = H$, $L_x + 2R = L$, and $L_z + R = T$.

The Y-direction shall be referred to as vertical, and the X- and Z-directions as horizontal.

At any section S (x, y, z), the couples acting on the part of the pipe farthest from the origin, but expressed in terms of the reactions at the origin, are

$$\left.\begin{aligned} M_x &= M_{Ox} + Qz - Ny \\ M_y &= M_{Oy} + Nx - Pz \\ M_z &= M_{Oz} + Py - Qx \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [18]$$

The couples acting at S on the part of the pipe nearest the origin, expressed in terms of the reactions at A, are of the form

$$M'_x = M_{Ax} + Q(T - z) - N(H - y) = M_{Ax} + QT - NH - Qz + Ny \ldots\ldots [18a]$$

which should be equal to M_x in magnitude, but of opposite sign.

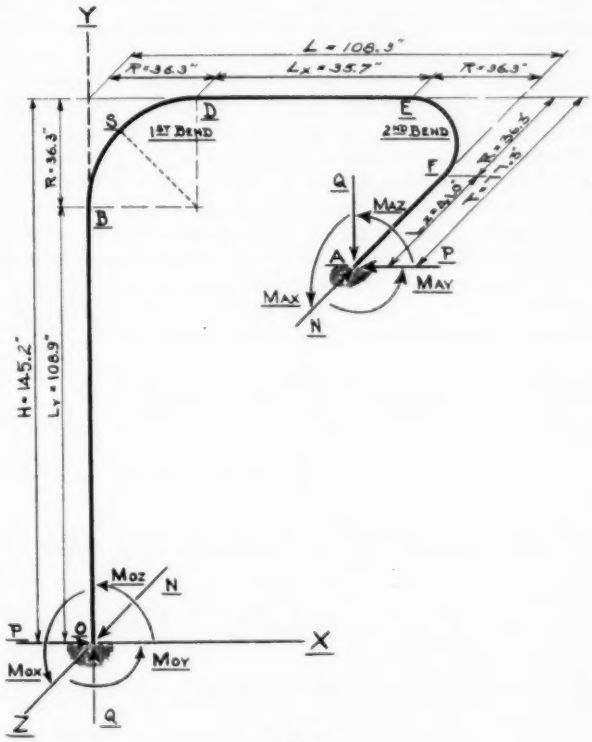

FIG. 6

Now, for equilibrium of the whole pipe taking moments about O, we must have,

$$M_{Ax} + QT - NH + M_{Ox} = 0$$

and substituting in Equation [18a] we get

$$M'_x = -M_{Ox} - Qz + Ny$$

which is equal to $-M_x$ according to the first of Equations [18]. Also M'_y and M'_z, expressed in terms of the reactions at A, are found to be equal to $-M_y$ and M_z, respectively, expressed in terms of the reactions at O.

In calculating the rotations and displacements of the A-end of the pipe, it would seem natural, as in cases I, II, and III, to find the deflections of the element at any point in terms of the reactions at A, that is, in terms of the couples (M'_x, M'_y, M'_z), but since the expressions for those couples, as given by Equation [18a], are more cumbersome than those for (M_x, M_y, M_z) in Equations [18], it is preferred in the following to substitute the latter, simply using $-M_x$, $-M_y$, and $-M_z$ instead of M'_x, M'_y, and M'_z. This consideration led to case IV.

There are six fundamental equations between the reactions and the deflections at each end of the pipe, three for the rotations and three for the linear displacements. Since both ends are assumed to be fixed in direction, the rotations of A relative to O are equal to zero and, therefore, the sign of the bending moments in the equations is indifferent, so that we can use the expressions in Equations [18] as they stand without changing their sign.

In forming the equations for the displacements, it must be borne in mind that the heat expansions at A do not actually take place; they are prevented by the reactions, which may be imagined to produce the displacements Δx_A, Δy_A, Δz_A in negative directions. Hence, while M_x, M_y, M_z must be entered with a negative sign, it is also necessary to enter Δx_A, Δy_A, Δz_A with a negative sign on the other side of the equations, and thus the minus signs cancel one another in this case. (Compare Equations [22] and [23] of this paper with the second and third Equations of [13′] on page 209 of the author's paper on the deformations of plane pipes.[3])

Since the pipe is assumed to be of uniform section and material, the product EI is constant and can be omitted in the equations for the rotations, each of which is equal to zero. In the displacement equations, EI has to be entered, and for the sake of simplicity, is placed as a factor of Δx_A, Δy_A, and Δz_A on the right-hand side of the equations.

It has been shown in case II that a pure or constant couple M_x, applied to a quarter bend, such as for instance the first bend, produces a major rotation (in that case a twist) of the free end in the X-direction, and a minor rotation in the Y-direction. Also, as shown in case III, M_y produces a major rotation in the Y-direction and a minor twist in the X-direction both having the same sign. The minor rotations will be neglected in the equations of rotation, where their inclusion would complicate the problem so as to make the solution impracticable. They can however be included without difficulty in the equations of displacement, and when on this basis the reaction forces and couples have been determined, a more accurate recalculation can be made, if necessary, by substituting these values in the small rotation terms and including them in the rotation equations.

We have seen in cases II and III that a constant couple acting on a quarter bend produces a displacement Δz as well as rotations of the free end. In connection with the three-dimensional pipe we shall refer to that displacement as "local," although the whole pipe beyond the bend partakes in it, but this term is adopted in order to distinguish it from the displacements of A produced by the rotations of the ends of the bends which act with a leverage on the end of the pipe.

Actually the couples, which act on the quarter bends, are not constant throughout the quadrant. Referring to Fig. 7, consider $M_x = M_{Ox} + Qz - Ny$ in the first quarter bend. Here $z = 0$ and $y = L_y + R \sin \psi$, so that M_x is composed of a constant couple $M_{Ox} - NL_y$ and a varying couple $-NR \sin \psi$. Also M_y furnishes a constant couple M_{Oy} and a varying couple $+NR(1 - \cos \psi)$. The effect of the two varying couples is the same as that of a force N acting in the Z-direction at B, since this gives $M_x =$

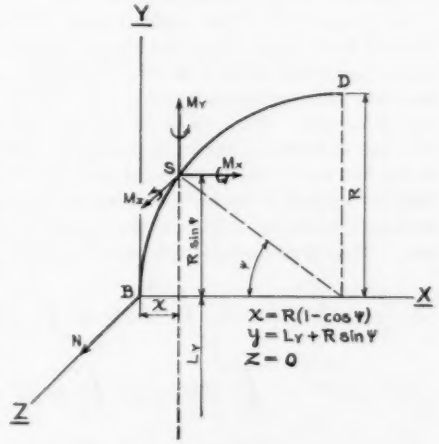

FIG. 7

(First bend, vertical projection.)

$NR \sin \psi$, and $M_y = + NR\ (1 - \cos \psi)$ and this is precisely the problem considered in case IV where F takes the place of N. We have then the rotations produced by the varying part of the couples M_x and M_y at the point D of the first bend, which are $-1.150\ NR^2$ in the X-direction, and $+0.506\ NR^2$ in the Y-direction.

The displacement Δz produced at D by the force N is, according to case IV, $-0.408NR^3$, which is in the negative Z-direction, and arises from the varying parts of both the M_x and M_y couples. Hence the varying parts, like the constant parts of these couples, produce a local displacement of the quarter bend at D and two rotations.

The M_z couple acts in the plane of the first bend and is dealt with as in a plane problem. Only rotations in the XY-plane are produced, and the displacements at A can be calculated directly by integrating the effect of each element ds as in plane bends.

All that has been said here about the first bend applies in principle to the second bend EF, Fig. 8, where M_y takes the place of

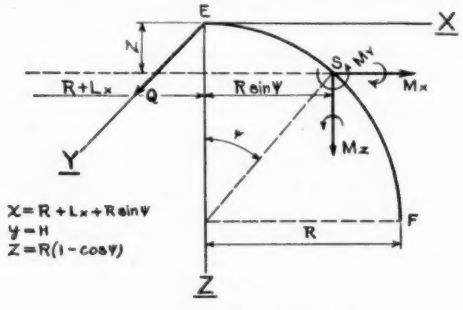

FIG. 8
(Second bend, horizontal projection.)

M_z, and M_z and M_x act in planes normal to the bend. The variable couple is here due to Q acting in the positive direction at E, which is regarded as fixed.

While the straight parts of the pipe can be dealt with by the same general method as used in plane bends, it is expedient to deal with each of the quarter bends separately. The local rotations at the endpoints D and F are determined from cases II, III, and IV and are simply added to the other terms in each of the equations of rotation. In the displacement equations we enter separately the local displacements normal to the plane of each bend and then the displacements caused at A by the rotations at the ends of the quarter bends. This somewhat complicated analysis will be explained in some detail.

In forming the three equations of rotation, the complete integral from O to A for the major component couple is first written, after which are added the integrals for the rotations about the same axis, produced in the quarter bends by the other component couples. While both M_y and M_z produce X-rotation in the first and second bends, respectively, and, therefore, appear in the first equation, M_z does not produce Y-rotation and hence does not appear in the second equation. Similarly M_y does not produce Z-rotation and is therefore absent from the third equation. Thus the equations of rotation become

$$\int_O^A M_x ds + \int_B^D M_y ds + \int_E^F M_z ds = 0 \ldots\ldots [19]$$

$$\int_O^A K M_y ds + \int_B^D M_x ds = 0 \ldots\ldots [20]$$

$$\int_O^A K M_z ds + \int_E^F M_x ds = 0 \ldots\ldots [21]$$

The integrations are with respect to ds, which in the straight parts of the pipe are equal to dx, dy, dz. In the bends $ds = Rd\psi$. The integrations follow the axis of the pipe.

It will be observed that the flexibility factor K is entered only under the integrals where the couple acts in the plane of one of the bends. In all other parts of the system, K is equal to unity. In the first bend, for instance, K is taken into account only in connection with M_z, in the second bend only in connection with M_y.

In forming the displacement equations consider first the X-direction. It is clear that M_x cannot produce any X-displacements in the straight parts and, as explained previously, in the bends except in the first bend where it produces a minor Y-rotation, which with a leverage T causes A to move in the positive X-direction. The couples M_z and M_y must be considered for the whole pipe. The couple M_z acting at any point S, causes the element at that point to rotate and, with a lever $(H - Y)$, to produce a negative X-displacement at A. The couple M_y rotates the element through an angle which, with a lever $(T - z)$, gives a positive X-displacement of A.

The algebraic sum of these displacements will be equal to the heat expansion Δx_A. The equations for the displacements in the Y- and Z-directions are formed in the same manner. Since M_x does not act in the plane of any of the bends, it does not carry the K-factor. The algebraic sums of the displacements are

$$-\int_O^A K(H - y) M_z ds + \int_O^A K(T - z) M_y ds + T \int_B^D M_x ds = EI\, \Delta x_A \ldots\ldots [22]$$

$$\int_O^A K(L - x) M_z ds - \int_O^A (T - z) M_x ds - T \int_B^D M_y ds - L_z \int_E^F M_x ds = EI\, \Delta y_A \ldots\ldots [23]$$

$$\int_O^A (H - y) M_x ds - \int_O^A K(L - x) M_y ds - (L_z + R) \int_B^D M_x ds = EI\, \Delta z_A \ldots\ldots [24]$$

X-ROTATION

The rotation in the YZ-plane is caused chiefly by the first term in Equation [19], containing M_z, which affects all parts of the pipe. The second and third terms of Equation [19], containing M_y and M_z, can produce no rotation in the X-direction in the straight parts of the pipe, and in the bends only where they act normal to the plane of the bends.

Substituting Equations [18] in Equation [19], we obtain

$$\int_O^A (M_{Oz} + Qz - Ny)\, ds + \int_0^{\pi/2} [M_{Oy} + NR\,(1 - \cos \psi)]\, Rd\psi + \int_0^{\pi/2} [M_{Oz} + PH - Q(R + L_z + R \sin \psi)]\, Rd\psi \ldots\ldots [19a]$$

since $z = 0$ and $x = R(1 - \cos \psi)$ in the first bend, and $y = H$, and $x = (R + L_z + R \sin \psi)$ in the second bend.

For the straight part of the pipe OB, where $z = 0$, we obtain

$$\int_0^{L_y} (M_{Oz} - Ny) dy$$

For the first bend, Fig. 7, where $y = L_y + R \sin \psi$, and $x = R\,(1 - \cos \psi)$, we obtain

$$\int_0^{\pi/2} [M_{Oz} - NL_y - NR\sin\psi]\,Rd\psi + \int_0^{\pi/2} [M_{Oy} + NR(1-\cos\psi)]\,Rd\psi$$

From case II we know that the constant couple $(M_{Oz} - NL_y)$ produces an X-rotation at A of $+1.806\ (M_{Oz} - NL_y)R$, and from case III, that the couple M_{Oy} produces an X-rotation of $+0.150\ M_{Oy}R$, but as previously stated, the latter will be neglected, at least preliminarily.

There remain the terms

$$-\int_0^{\pi/2} NR^2\sin\psi\,d\psi + \int_0^{\pi/2} NR^2(1-\cos\psi)\,d\psi$$

which are such as would arise from a force N acting normal to the bend at B. This is easily recognized as case IV, where a force F acting at O in Fig. 5 produces an X-rotation at the point A of $-1.150\ FR^2/EI$. Hence we obtain here for the point D a term $-1.150\ NR^2$,

For the straight length $L_x = DE$, extending from $x = R$ to $x = R + L_x$, we still have $z = 0$, but $y = H$. Thus M_x which in this instance is torsional, becomes $(M_{Ox} - NH)$ and we obtain a term

$$+1.30\int_R^{R+L_x} (M_{Ox} - NH)dx$$

The second bend, Fig. 8, is in a horizontal plane and only the first and third integrals in Equation [19a] need to be considered. Here $y = H$, $x = R + L_x + R\sin\psi$, $z = R(1-\cos\psi)$ and we get the terms

$$\int_0^{\frac{\pi}{2}} [M_{Oz} + QR(1-\cos\psi) - NH]Rd\psi + \int_0^{\frac{\pi}{2}} [M_{Ox} + PH - Q(R+L_x) - QR\sin\psi]\,Rd\psi$$

For the constant part of the M_x-couple $(M_{Oz} - NH)$, we get according to case III a major term $+1.806\ (M_{Oz} - NH)R$, and for the constant part of the M_x-couple according to case II a minor X-rotation, $+0.150\ [M_{Ox} + PH - Q(R + L_x)]R$, which again is neglected in the preliminary calculations.

The variable terms in Q give

$$\int_0^{\frac{\pi}{2}} QR^2(1-\cos\psi)\,d\psi - \int_0^{\frac{\pi}{2}} QR^2\sin\psi\,d\psi$$

which are recognized as expressing the effect of a force Q acting upward at E in the same way as F acts at O in case IV, in which $\Delta\varphi_{yA} = +0.506\ FR^2/EI$. Since OY in case IV corresponds to OX in the present case, we get an X-rotation of $+0.506\ QR^2$.

For the length $L_z = FA$, extending from $z = R$ to $z = R + L_z = T$, where again $y = H$, we obtain from the first term in Equation [19a]

$$\int_R^T (M_{Ox} + QZ - NH)dz$$

We can now write Equation [19a] as

$$\int_0^{L_y} (M_{Oz} - Ny)dy + 1.806\ (M_{Oz} - NL_y)R - 1.150\ NR^2 + 1.30\int_R^{R+L_x} (M_{Oz} - NH)dx + 1.806\ (M_{Oz} - NH)R + 0.506\ QR^2 + \int_R^T (M_{Ox} + Qz - NH)dz = 0 \ldots [19b]$$

Carrying out the integrations and arranging the terms, we obtain the final equation for the X-rotation

$$[3.612R + 1.30L_x + L_y + L_z]\ M_{Oz} + \tfrac{1}{2}\ T^2Q - [\tfrac{1}{2}\ L_y^2 + 1.806\ (L_y + H)\ R + 1.150R^2 + (1.30L_x + L_z)H]N = 0 \ldots [25]$$

If it is desired to allow for the minor rotations caused by M_y and M_z in an eventual recalculation, the following terms

$$0.150\ M_{Oy}\ R + 0.150\ R\ [M_{Ox} + PH - Q(R + L_x)]$$

should be added to the left-hand side of Equation [25]. Substitute the numerical values of M_{Oy}, M_{Ox}, P, and Q as determined by the calculations before these corrections were made; this means simply an addition of a numerical quantity.

Y-Rotation

From Equations [18] and [20] we have

$$\int_O^A K\ (M_{Oy} + Nx - Pz)ds + \int_0^{\frac{\pi}{2}} [M_{Ox} - N\ (L_y + R\sin\psi)]\ Rd\psi = 0 \ldots [20a]$$

and applying this to the various parts of the pipe we find that

$$1.3\int_0^{L_y} M_{Oy}\,dy + 1.806\ M_{Oy}\ R + 0.506\ NR^2 + \int_R^{R+L_x} (M_{Oy} + Nx)dx + KR\int_0^{\frac{\pi}{2}} [M_{Oy} + N(R + L_x + R\sin\psi) - PR(1-\cos\psi)]\,d\psi + \int_R^T (M_{Oy} + NL - Pz)dz = 0 \ldots [20b]$$

The flexibility factor is entered only for the second bend where M_y acts in the plane of the bend.

After integration and transformation Equation [20b] becomes

$$[1.806\ R + 1.571\ KR + L_x + 1.30L_y + Lz]\ M_{Oy} - [0.571\ KR^2 + \tfrac{1}{2}\ T^2 - \tfrac{1}{2}\ R^2]P + [0.506\ R^2 + 2.571\ KR^2 + RL_x + 1.571\ KRL_x + \tfrac{1}{2}\ L_x^2 + LL_x]N = 0 \ldots [26]$$

In a recalculation, the numerical value of a term $+\ 0.150R\ (M_{Ox} - NL_y)$ should be added to allow for the action of M_x on the first bend (case II).

Z-Rotation

From Equations [18] and [21] we derive the equation

$$\int_O^A K\ (M_{Ox} + Py - Ox)\ ds + \int_0^{\frac{\pi}{2}} [M_{Oz} + QR(1-\cos\psi) - NH]\ Rd\psi = 0 \ldots [21a]$$

from which we obtain

$$\int_0^{L_y} (M_{Ox} + Py)dy + KR\int_0^{\frac{\pi}{2}} [M_{Ox} + P\ (L_y + R\sin\psi)]\ d\psi + \int_R^{R+L_x} (M_{Ox} + PH - Qx)dx + 1.806\ [M_{Ox} + PH - Q(R + L_x)]\ R - 1.150\ QR^2 + 1.30\int_R^T (M_{Ox} + PH - QL)dz = 0 \ldots [21b]$$

The factor K appears in the integral for the first bend, where M_z acts in the plane of the bend. The term $-1.150\,QR^2$ is caused by Q in M_z and M_x in accordance with case IV, where the X-rotation corresponds to the Z-rotation in the present case.

Carrying out the integrations and transposing, we obtain for the Y-rotation

$$(1.806\,R + 1.571\,KR + L_x + L_y + 1.30\,L_z)\,M_{Oz} + (KR^2 + 1.571\,KRL_y + 1.806\,RH + \tfrac{1}{2}\,L_y^2 + HL_x + 1.30\,HL_z)P - (2.956\,R^2 + 2.806\,RL_x + \tfrac{1}{2}\,L_x^2 + 1.30\,LL_z)Q = 0 \ldots [27]$$

In a recalculation, a term $+\,0.150R\,(M_{Ox} - NH)$ must be added to the left-hand side in order to allow for the action of M_x on the second bend (case III). This is the only term caused by the second integral in Equation [21a].

X-Displacement

Here again the various terms obtained successively from Equation [22] for all the different parts of the pipe are to be added algebraically in order to obtain the displacement of the A-end. From Equations [18] and [22] we obtain

$$-\int_O^A K(H-y)\,(M_{Oz} + Py - Qx)ds + \int_O^A K(T-z)\,(M_{Oy} + Nx - Pz)\,ds + T\int_0^{\frac{\pi}{2}} [M_{Ox} - N(L_y + R\sin\psi)]\,Rd\psi = EI\,\Delta x_A \ldots [22a]$$

where the last integral represents the displacement due to a minor Y-rotation of the first bend caused by M_x.

The first and second integrals of Equation [22a] run through the whole length of the pipe, but, as explained previously, the bends are treated as independent parts.

In the vertical stem OB, displacements in the X-direction are produced by M_z. At every point, the rotation of an element acts on A with a lever $(H - y)$, giving the term $-\int_0^{L_y} (H-y)\,(M_{Oz} + Py)dy$. At the same time, M_y produces a torsion in OB which at B acts with a lever T relative to the point A, giving a displacement $1.30\,M_{Oy}\,L_y\,T$.

The straight part DE does not produce any X-displacement, but the part FA is bent by M_y and gives a term $+\int_R^T (T-z)\,M_y\,dz$.

The first bend is subjected to M_z and the second bend to M_y acting in their respective planes, and give rise to two terms, obtained by multiplying the corresponding rotation terms in Equations [21b] and [20b], respectively, with $R\,(1 - \sin\psi)$ and $(T - z)$ under the integral signs. Both terms carry the coefficient K. See Figs. 7 and 8.

In the first bend, the Y-rotation $+\,1.806\,M_{Oy}\,R$ given in Equation [20b] acts with a lever T. The minor Y-rotation caused by M_z in the third integral of Equation [22a] acts with the same lever.

From the second and third integrals in Equation [22a] there results for the first bend a term which is $+0.506\,NR^2T$. This expresses the effect of the rotation called $\Delta\varphi_{yA}$ in case IV, given in the third term of Equation [20b]. It acts on A with a leverage T.

Thus Equation [22a] becomes

$$-\int_0^{L_y} (H-y)\,(M_{Oz} + Py)\,dy + 1.30\,M_{Oy}\,L_y\,T + \int_R^T (T-z)\,(M_{Oy} + NL - Pz)dz - KR^2\int_0^{\frac{\pi}{2}} (1-\sin\psi)\,[M_{Oz} + P(L_y + R\sin\psi) - QR\,(1-\cos\psi)]\,d\psi + KR\int_0^{\frac{\pi}{2}} (L_z + R\cos\psi)\,[M_{Oy} + N(R + L_x + R\sin\psi) - PR(1-\cos\psi)]\,d\psi + 1.806\,M_{Oy}\,RT + 0.506\,NR^2\,T + 0.150\,(M_{Ox} - NL_y)\,RT = EI\,\Delta x_A \ldots [22b]$$

Carrying out the integrations and rearranging the terms, we obtain for the X-displacement

$$0.150\,RTM_{Ox} + (1.30\,L_yT + 1.806\,RT + 1.571\,KL_zR + KR^2 + \tfrac{1}{2}\,L_z^2)\,M_{Oy} - (HL_y + 0.571\,KR^2 - \tfrac{1}{2}\,L_y^2)\,M_{Oz} - (\tfrac{1}{2}\,HL_y^2 + 0.571\,KL_yR^2 + 0.430\,KR^3 + \tfrac{1}{6}\,T^3 + \tfrac{1}{3}\,R^3 + 0.571\,KL_zR^2 - \tfrac{1}{3}\,L_y^3 - \tfrac{1}{2}\,TR^2)P + (0.506\,R^2T + 2.571\,KL_zR^2 + 1.50\,KR^3 + KL_xR^2 + 1.571\,KL_xL_zR + \tfrac{1}{2}\,LL_z^2 - 0.150\,RT)\,N = EI\,\Delta x_A \ldots [28]$$

Y-Displacement

From Equations [18] and [23] we can derive

$$\int_O^A K(L-x)\,(M_{Oz} + Py - Qx)ds - \int_O^A K(T-z)\,(M_{Ox} + Qz - Ny)ds - T\int_0^{\frac{\pi}{2}} [M_{Oy} + NR\,(1-\cos\psi)]\,Rd\psi - L_z\int_0^{\frac{\pi}{2}} [M_{Oz} + PH - Q(R + L_x + R\sin\psi)]Rd\psi = EI\,\Delta y_A \ldots [23a]$$

The first and second integrals of Equation [23a] run through the whole length of the pipe. The third and fourth integrals provide for M_y in the first bend and M_z in the second bend, respectively, which couples act normal to the plane of the bends in both cases.

The displacements caused by the deflections of the straight parts are obtained by applying the proper leverages to the respective X- and Z-rotations as given in Equations [19b] and [21b].

The first bend is subject to Z-rotation in its own plane, acting with a leverage $[L - R(1 - \cos\psi)]$, and causing a Y-displacement at A.

The permanent couples $(M_{Oz} - NL_y)$ in the first bend and $(M_{Oz} - NH)$ in the second bend, which come from the second integral in Equation [23a], cause major rotations in the bends at D and F, respectively, and, as explained in cases II and III, carry the factor 1.806. They act on A with a leverage T and L_z, respectively, causing a negative Y-displacement.

The permanent couples also produce local displacements in the second bend at F. The couple $(M_{Oz} - NH)$, which corresponds to M_y in case III, causes a local Y-displacement of $-1.150\,(M_{Oz} - NH)R^2$, and the couple $(M_{Oz} + PH)$, which corresponds to M_x in case II, causes a local displacement at F of $+0.506\,(M_{Oz} + PH)R^2$.

In the third integral of Equation [23a], M_y causes a minor X-rotation of the first bend, giving a negative term $-0.150RTM_{Oy}$ In the fourth integral, M_z causes a minor X-rotation of the second bend, giving a negative term $-0.150\,RLz\,[M_{Oz} + PH - Q(R + L_x)]$.

The second and third integrals of Equation [23a] give together an X-rotation of the first bend due to the force N acting at B. According to case IV, this rotation is $-1.150\,NR^2$, as given in Equation [19b], and acting at A with a lever T, it gives an upward Y-displacement equal to $+1.150\,NR^2T$.

Similarly the second and fourth integrals of Equation [23a] give together an X-rotation of the second bend at F due to Q acting at E. According to case IV, and as given in Equation [19b], this rotation is equal to $+0.506\,QR^2$, which gives a downward displacement at A equal to $-0.506\,QR^2L_z$. These two integrals also, according to case IV, due to the action of Q, cause a local Y-displacement at F equal to $-0.408\,QR^3$.

We thus arrive at the following equation for the Y-displacement

$$L\int_0^{L_y}(M_{Oz}+Py)dy - T\int_0^{L_y}(M_{Oz}-Ny)dy - 1.30\,L_xT(M_{Oz} - NH) - \int_R^T(T-z)\,(M_{Oz}+Qz-NH)\,dz + \int_R^{R+L_x}(L-x)\,(M_{Oz} + PH - Qx)dx + KR\int_0^{\pi/2}[L-R\,(1-\cos\psi)]\,[M_{Oz} + P(L_y+R\sin\psi) - QR(1-\cos\psi)]d\psi - 1.806\,(M_{Oz} - NL_y)RT - 1.806\,(M_{Oz}-NH)RL_z - 1.150\,(M_{Oz} - NH)R^2 + 0.506\,(M_{Oz}+PH)R^2 + 1.150\,NR^2T - 0.506\,QR^2L_z - 0.408\,QR^3 - 0.150\,RL_z\,[M_{Oz}+PH - Q(R+L_x)] - 0.150\,RTM_{Oy} = EI\,\Delta y_A \quad [23b]$$

After integration and transformation we obtain

$$-(TL_y + 3.612\,L_xR + 2.956\,R^2 + 1.30\,TL_x + \tfrac{1}{2}\,L_x^2)M_{Oz} - 0.150\,RTM_{Oy} + (LL_y + \tfrac{1}{2}\,LL_x + 1.571\,KRL + 0.506\,R^2 - 0.571\,KR^2 - 0.150\,RL_x)\,M_{Oz} + [\tfrac{1}{2}\,LL_y^2 + \tfrac{1}{2}\,HL_x^2 + HLR_x + 1.571\,KRLL_y + KLR^2 - 0.150\,HRL_x - \tfrac{1}{2}\,(K-1)HR^2]P - (\tfrac{1}{6}\,L_x^3 + 0.850\,R^2L_x + 0.850\,RL_x^2 + 0.571\,KLR^2 + 0.408\,R^3 + \tfrac{1}{6}\,L_x^3 + 0.506\,R^2L_x + \tfrac{1}{2}\,RL_x^2 - 0.355\,KR^3)Q + [\tfrac{1}{2}\,TL_y^2 + 1.806\,TRL_y + 1.150\,R^2\,(T+H) + 1.806\,RHL_x + 1.30\,THL_x + \tfrac{1}{2}\,HL_x^2]N = EI\,\Delta y_A \quad [29]$$

Z-Displacement

From Equations [18] and [24] we can derive

$$\int_O^1(H-y)\,(M_{Oz}+Qz-Ny)ds - \int_O^A K(L-x)\,(M_{Oy}+Nx - Pz)ds - (L_z+R)\int_B^D[M_{Oz}-N(L_y+R\sin\psi)]\,Rd\psi = EI\,\Delta z_A \quad [24a]$$

The straight parts OB and DE give rise to the first three terms in Equation [24b], and do not require any explanation.

The couple M_y, acting in the plane of the second bend with a leverage equal to $R\,(1-\sin\psi)$, carries the factor K. No other Z-displacements are caused by the second bend as can be seen from Fig. 8.

The first bend is acted upon by a permanent couple $(M_{Oz} - NL_y)$ and a varying couple $-NR\sin\psi$. It is also acted upon by a permanent couple M_{Oy} and a varying couple $NR\,(1-\cos\psi)$. The first permanent couple produces a local displacement at D, which according to case II is equal to $+0.506\,(M_{Oz} - NL_y)R^2$. It also produces a Y-rotation acting with a leverage $(L_z+R) = (L-R)$ as given in the third integral of Equation [24a], giving a term $-0.150\,(M_{Oz} - NL_y)\,(L-R)R$. The second permanent couple M_{Oy} gives according to case III a local displacement at D equal to $-1.150M_{Oy}R^2$, and a Y-rotation with leverage $(L_z+R) = (L-R)$, giving a term $-1.806\,RM_{Oy}\,(L-R)$.

Finally the two varying couples, containing N, give, according to case IV, a local displacement at D equal to $-0.408NR^3$, and since they cause a Y-rotation equal to $+0.506\,NR^2$, they give moreover a negative displacement at A equal to $-0.506\,NR^2\,(L-R)$.

Thus Equation [24a] becomes

$$\int_0^{L_y}(H-y)\,(M_{Oz}-Ny)dy - 1.3\,M_{Oy}\,L_yL - \int_R^{R+L_x}(L-x)\,(M_{Oy}+Nx)dx - KR^2\int_0^{\pi/2}(1-\sin\psi)\,[M_{Oy} + N(R+L_x+R\sin\psi) - PR(1-\cos\psi)]\,d\psi + 0.506\,(M_{Oz} - NL_y)R^2 - 0.150\,(M_{Oz}-NL_y)\,(L-R)R - 1.150\,M_{Oy}R^2 - 1.806\,M_{Oy}R(L-R) - 0.408\,NR^3 - 0.506\,NR^2\,(L-R) = EI\,\Delta z_A \quad [24b]$$

After integration and transformation Equation [24b] becomes

$$(HL_y + 0.356\,R^2 - \tfrac{1}{2}\,L_y^2 - 0.150\,L_xR)M_{Oz} - (1.30\,LL_y + 2.956\,R^2 + 2.806\,RL_x + \tfrac{1}{2}\,L_x^2 + 0.571\,KR^2)M_{Oy} - (\tfrac{1}{2}\,HL_y^2 + 0.914\,R^3 + \tfrac{1}{2}\,LL_x^2 + 1.506\,R^2L_x + 0.785\,KR^3 + 0.571\,KR^2L_x + 0.656\,L_yR^2 - 1/3\,L_x^3 - 1/3\,L_y^3 - 0.150\,LL_yR)N = EI\,\Delta z_A \quad [30]$$

Solution of the Equations

The fundamental equations can be written in the following forms

$$A_1M_{Oz} + A_5Q + A_6N = 0 \quad [31]$$

$$B_2M_{Oy} + B_4P + B_6N = 0 \quad [32]$$

$$C_3M_{Ox} + C_4P + C_5Q = 0 \quad [33]$$

$$D_1M_{Oz} + D_2M_{Oy} + D_3M_{Ox} + D_4P + D_6N = EI\,\Delta x_A \quad [34]$$

$$E_1M_{Oz} + E_2M_{Oy} + E_3M_{Ox} + E_4P + E_5Q + E_6N = EI\,\Delta y_A \quad [35]$$

$$F_1M_{Oz} + F_2M_{Oy} + F_6N = EI\,\Delta z_A \quad [36]$$

where the composition of the coefficients A to F with suffixes can be obtained from Equations [25] to [30], inclusive. For a given lay-out of the pipe line, all the quantities that enter into the coefficients are known and their numerical values can be computed.

The solution for the unknown forces P, Q, and N, and for the unknown couples M_{Oz}, M_{Oy}, and M_{Ox} is best obtained by first eliminating the couples. Determine the value of each of the couples from Equations [31], [32], and [33], and substitute the values of the couples in Equations [34], [35], and [36]. This will result in three equations of the form given in the following Equations [37].

$$\left.\begin{aligned}\alpha_1P + \beta_1Q + \gamma_1N &= EI\,\Delta x_A\\ \alpha_2P + \beta_2Q + \gamma_2N &= EI\,\Delta y_A\\ \alpha_3P + \beta_3Q + \gamma_3N &= EI\,\Delta z_A\end{aligned}\right\} \quad [37]$$

from which the unknown forces, P, Q, and N, can be determined.

If these values of the forces so obtained are substituted in Equations [31], [32], and [33], the couples acting at O can be found.

We are now able to determine the couples acting at any point (x, y, or z) of the pipe by substituting the values of the component couples and forces acting at O in Equations [18]. Thus, the couples at the A-end can be found by putting x, y, and z in Equations [18] equal to L, H, and T, respectively. When reversing their sign we have the reaction couples

$$\left.\begin{aligned} M_{Ax} &= -(M_{Ox} + QT - NH) \\ M_{Ay} &= -(M_{Oy} + NL - PT) \\ M_{Az} &= -(M_{Oz} + PH - QL) \end{aligned}\right\} \quad [38]$$

It is necessary to examine separately the conditions in the bends in order to determine the maximum stresses in these parts. At any point of a bend, one of the three component couples M_x, M_y, M_z acts in the plane of the bend, and stresses caused thereby require the use of the flexibility factor K for their determination. The two other component couples are resolved into one couple M_b with axis in the radius of the bend, causing bending of the pipe. Another couple M_t, with axis tangent to the pipe at the point, constitutes a twisting couple. By means of these couples the bending and torsional stresses can be determined since the corresponding moments of inertia of the section, I and I_o, are readily found.

In the first bend where M_z is acting in the plane of the bend, Fig. 6, the expression for the couple is

$$M_z = M_{Oz} + P\,(L_y + R\sin\psi) - QR(1 - \cos\psi) \quad [39]$$

Differentiating with respect to ψ, this couple is found to be a maximum when

$$\tan\psi_{max} = P/Q \quad [40]$$

Since P and Q are positive, M_z becomes a maximum somewhere within the bend. The maximum value of this couple can be found by substituting from Equation [40] into Equation [39], whence

$$M_{z\,max} = M_{Oz} + PL_y + R\left[\sqrt{(P^2 + Q^2)} - Q\right] \quad [39a]$$

The maximum M_z, however, depending on the sign of M_{Oz}, may be smaller numerically than the couples M_{Bz} and M_{Dz} acting at the points B and D, respectively. The value of M_{Bz} at B where $\psi = 0$ is

$$M_{Bz} = M_{Oz} + PL_y$$

while at D, where $\psi = \pi/2$

$$M_{Dz} = M_{Oz} + PL_y + R(P - Q)$$

It is necessary in all cases to ascertain the value of $M_{z\,max}$. The bending couple normal to the plane of the bend is

$$M_b = M_x\cos\psi - M_y\sin\psi = [M_{Ox} - N(L_y + R\sin\psi)]\cos\psi - [M_{Oy} + NR\,(1 - \cos\psi)]\sin\psi$$

Therefore

$$M_b = (M_{Ox} - NL_y)\cos\psi - (M_{Oy} + NR)\sin\psi \quad [41]$$

The maximum value of M_b occurs when

$$\tan\psi_{b\,max} = -\frac{M_{Oy} + NR}{M_{Ox} - NL_y}$$

The twisting couple is

$$M_t = M_x\sin\psi + M_y\cos\psi = (M_{Ox} - NL_y)\sin\psi_{max} + (M_{Oy} + NR)\cos\psi_{max} - NR \quad [42]$$

the maximum value of which occurs when

$$\tan\psi_{b\,max} = \frac{M_{Ox} - NL_y}{M_{Oy} + NR} = -\frac{1}{\tan\psi_b}$$

showing that M_t has its maximum in a plane at right angles to M_b. Hence, one of these maxima falls outside the quadrant.

The forces P, Q, and N, acting at any section, are best resolved in directions normal and tangential to the transverse section. They produce direct compression and shear, where

$$F_N = P\sin\psi + Q\cos\psi$$

$$F_s = \sqrt{(P\cos\psi - Q\sin\psi)^2 + N^2}$$

Again it is necessary to determine the maximum values, which for F_N occurs at the same section as that of M_z, while F_s has its greatest value at B and D.

Similar equations can be established for the second bend, where M_y acts in the plane of the bend, and M_x and M_z act at right angles to it.

4—THE STRESSES

Stresses at the Terminal Sections O and A

The greatest stresses are found in the terminal sections and in the bends. The longitudinal bending stress p_{1b} at the O-end of the pipe is generally the most important. This stress is caused by the resultant couple of M_{Ox} and M_{Oz}, here denoted by M_O, where

$$M_O = \sqrt{(M_{Ox}^2 + M_{Oz}^2)} \quad [45]$$

Since there is no flattening effect, the flexibility factor K is equal to unity, and the corresponding maximum stress is

$$p_{1b} = M_O r_o/I \quad [46]$$

where r_o is the radius to the outer surface of the pipe.

The steam pressure P produces a longitudinal stress, which is assumed to be uniformly distributed over the section of the pipe wall. This stress is approximately

$$p_{1s} = Pr_i/2t \quad [47]$$

where r_i is the internal radius of the pipe. This equation is given on page 336 of the author's paper "Tests on High-Pressure Pipe Bends."[5]

Finally, there is a uniform longitudinal stress due to the compressive reaction Q which can be expressed as

$$p_{1c} = Q/A \quad [48]$$

but which is generally small and can be neglected in many cases.

Thus, the total longitudinal stress becomes

$$p_1 = p_{1b} + p_{1s} + p_{1c} \quad [49]$$

which has its maximum value at the outer surface in the plane of M_O.

The steam pressure also produces a transverse or "hoop" stress which is assumed to be uniformly distributed over the section of the pipe wall. This stress can be expressed as

$$p_{2s} = Pr_i/t \quad [50]$$

Where the pipe is straight, as it is at O, no other transverse

stresses exist, so that, denoting the total transverse stress by p_2, we have $p_{2s} = p_2$ in this case.

The torsional couple M_{Oy} produces a shearing stress which has its maximum value in the outer surface. It acts in the plane of the section and is directed everywhere normal to the radius. This stress

$$q_t = M_{Oy} r_o / 2I \quad \ldots\ldots [51]$$

A shearing stress q_f is also produced by the resultant of the forces P and N where

$$q_f = \frac{\sqrt{(P^2 + N^2)}}{A} \quad \ldots\ldots [52]$$

This stress acts in the same plane as q_t and is added directly to it at the point where the two stresses act in the same direction. It is generally small and can be neglected in many cases. The sum of the shearing stresses produced by the torsional couple M_{Oy} and the resultant of the forces P and N is

$$q_t + q_f = q$$

The stresses at the A-end of the pipe are determined in the same manner.

In addition to the stresses here enumerated, bending and shearing stresses are produced by the deadweight of the piping between hangers and supports. These stresses are to be included in the p_1-stresses and the q-stresses of Equations [49], [51], and [52]. Their values depend on the arrangement of the points of support and are determined by usual methods. With proper design these stresses are generally small and in order not to lengthen the paper they are omitted in the present analysis.

Stresses in the Bends

The curved parts of the pipe require special treatment. The component couple acting in the plane of a bend produces a flattening of the section, causing a peculiar distribution of the longitudinal stresses and the introduction of relatively high transverse stresses. The component couples normal to the plane of a bend produce twisting as well as bending, as previously described in cases I to IV.

In the first bend, that is, the bend nearest the origin, the couple M_s acts in the plane of the bend and has its maximum value as given by Equation [39a] in the section determined by Equation [40]. The stress in the middle surface of the section so determined is generally a maximum, not at the top and bottom of the section, but at points the radius of which forms an angle θ with the neutral axis of the section as shown in Fig. 1. As explained on page 328 of the author's paper "Tests on High-Pressure Pipe Bends,"[5] the maximum value is found by applying a factor β to the ordinary expression for the longitudinal stress, thus

$$p_{1b\max} = \beta(M_{s\max} r/I) \quad \ldots\ldots [53]$$

where

$$\left.\begin{aligned} \beta &= 2/3\ K \sqrt{\ } [(6\lambda^2 + 5)/18] \quad \text{when } \lambda < 1.472 \\ \beta &= (12\lambda^2 - 2)/(12\lambda^2 + 1) \quad \text{when } \lambda \gtrless 1.472 \end{aligned}\right\} \ldots [54]$$

The value of λ is given in Equation [2], while the value of K is given in Equation [1a].

Usually $\lambda < 1.472$ and the maximum stress occurs at an angle θ from the neutral axis, such that

$$\sin\theta = \sqrt{[(6\lambda^2 + 5)/18]} \quad \ldots\ldots [55]$$

and hence

$$\beta = 2/3\ K \sin\theta \quad \ldots\ldots [54a]$$

When $\lambda \gtrless 1.472$, the maximum value of p_{1b} occurs at the top and bottom of the section.

The value of β varies little from unity except in thin-walled bends of sharp curvature, but θ may be far from a right angle.

The longitudinal bending stresses due to M_b, given by Equation [41], which act in a plane normal to that of the bend, have their maxima at the points which are in the neutral axis relative to M_s, and since $p_{1b\max}$ due to $M_{s\max}$ rarely falls at points less than 45 deg from the neutral axis, these maxima can be considered separately.

The steam pressure produces a longitudinal stress as given by Equation [47], while the reactions P and Q cause a normal stress on the transverse section

$$p_{1c} = (P \sin\psi + Q \cos\psi)/A \quad \ldots\ldots [48a]$$

The transverse stress due to the steam pressure is p_{2s} as given by Equation [50], but in addition there is a transverse bending stress p_{2b} due to the flattening of the section with a maximum at $\theta = 0$ deg, and $\theta = 90$ deg, as explained on page 340 of the author's paper "Tests on High-Pressure Pipe Bends."[5] This latter stress is

$$p_{2b} = \frac{18\ M_s \lambda r}{I(12\lambda^2 + 1)} \quad \ldots\ldots [56]$$

In the outer surface this is a tensile stress, while at the inner surface at the neutral axis for M_s it is a compressive stress, and is reversed in sign at the top and bottom of the section. Compared with the longitudinal stresses in the bend as given by Equation [53], the transverse stresses are very high, and bear a definite ratio to them. If μ be that ratio, then

$$\mu = \frac{p_{2b}}{p_{1b\max}} = \frac{81\ \lambda}{(6\lambda^2 + 5)^{3/2}\sqrt{2}} \quad \ldots\ldots [57]$$

For ordinary values of λ, between 0.5 and 1.2, this ratio varies from 1.80 to 1.36, so that the transverse bending stress is on the average 60 per cent greater than the longitudinal bending stress.

There is also a smaller compressive stress in the neutral axis due to the flattening of the section which reduces the tensile stress at the outer surface. It is expressed by

$$p_{2c} = \frac{2Mr^2}{RI} \frac{(6\lambda^2 + 1)}{(12\lambda^2 + 1)} \quad \ldots\ldots [58]$$

This equation is the same as Equation [25] on page 83 of the author's paper "The Elastic Deformation of Pipe Bends."[2]

Combining these stresses, the total transverse stress, which will generally be a maximum at the outer surface in the neutral axis, is

$$p_2 = p_{2b} + p_{2s} + p_{2c} \quad \ldots\ldots [59]$$

The twisting moment M_s, given by Equation [42], causes a stress, which at the outer surface is given by Equation [51]. The shearing force F_s causes a small shearing stress which generally can be neglected.

The stresses in the second bend are analyzed in the same manner.

Strength Criteria and Working Stresses

Strength criteria and working stresses are among the most important and the most difficult of the pipe-line problems. The difficulty is enhanced by the recent increase in steam pressures and temperatures and by the use of new alloys of steel, with which experience is still very limited. The higher steam pressures produce hoop stresses which can no longer be neglected. At high temperatures the modulus of elasticity and the stress at the yield point are reduced considerably and this, as well as the peculiar nature of each particular alloy, must be taken into account in determining the working stress.

All the stresses so far discussed act in a plane tangential to the cylindrical surface through the point under consideration, and, in combining the stresses, we consider a small element in that plane. If there is no load on the element normal to its plane, we have the first order of a simple case of plane stresses. Referring to Fig. 9, p_1 acts in the X-direction, p_2 in the Y-direction, and the shearing stress q acts on the sides of the element.

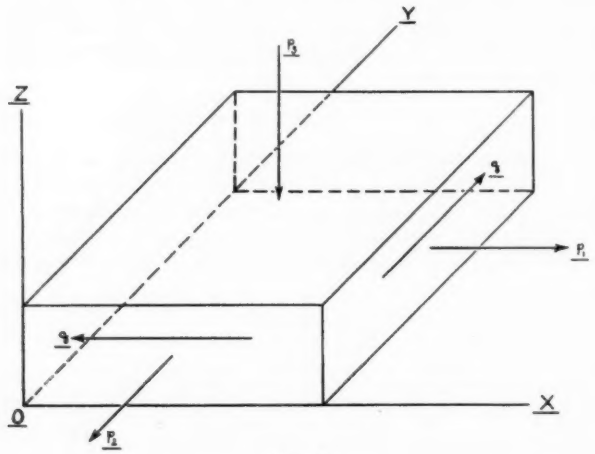

FIG. 9

If we take into account the radial stress p_3, produced by the steam pressure P, we have three-dimensional stress. Actually p_3 is small, being equal to P at the inner surface and decreasing to zero at the outer surface of the pipe wall, but since it has been taken into account by some investigators, it will be included in the following discussion.

For a state of combined stress several strength criteria have been proposed, but we shall only consider the maximum-shear theory and the strain-energy theory,[8] of which the latter appears to be the most rational. Either theory leads to a certain function of the component stresses, so determined that when it is equal in magnitude to the yield point of the material, plastic flow is supposed to occur. This function is referred to as the equivalent stress, which will be noted by p_{eq}. It may or may not represent an actually existing stress, but it is clear that under working conditions the equivalent stress should be smaller than the stress at the yield point of the material.

The Maximum-Shear Theory. According to this theory plastic flow of the material begins to take place when the maximum shearing stress reaches a certain magnitude, regardless of the state of stress. Hence, this stress, must have the same magnitude in the most general case as in the simple case when a straight bar, subject to uniaxial stress, reaches the yield point.

In a state of plane stress, that is, when $p_3 = 0$, or when p_3 is very small, the maximum shearing stress, expressed in terms of the ordinary component stresses, is in the general case

$$q_{max} = \tfrac{1}{2}\sqrt{[4q^2 + (p_1 - p_2)^2]} \quad [60]$$

In a straight bar subject to a simple tension, $q = 0$, $p_2 = 0$, and therefore $q_{max} = p_1/2$.

When p_1 reaches the yield point p_0,

$$q_{max} = p_0/2 \quad [60a]$$

Equating the expressions for q_{max} as given in Equations [60] and [60a], we obtain

$$p_0 = \sqrt{[4q^2 + (p_1 - p_2)^2]} \quad [61]$$

The expression on the right-hand side of Equation [61] is the equivalent stress, and is expressed as

$$p_{eq} = \sqrt{[4q^2 + (p_1 - p_2)^2]} \quad [62]$$

which, if adopted as the working stress, should then be smaller than p_0.

If we take p_3 into account, we have three-dimensional stress and it is known that in such a case the maximum shearing stress is equal to one-half the difference between the greatest and the smallest of the three principal stress, denoted here by σ_1, σ_2, and σ_3. Let $\sigma_1 > \sigma_2 > \sigma_3$, then

$$q_{max} = (\sigma_1 - \sigma_3)/2 \quad [63]$$

Since there are no shearing stresses parallel with the plane of the element, p_3 is a principal stress, and therefore $p_3 = \sigma_3$. The two other principal stresses are found from the formula

$$\left.\begin{matrix}\sigma_1\\ \sigma_2\end{matrix}\right\} = \tfrac{1}{2}(p_1 + p_2) \pm \tfrac{1}{2}\sqrt{[4q^2 + (p_1 - p_2)^2]} \quad [64]$$

The value of q_{max} from Equation [63] is now equated to its value expressed by Equation [60a] in order to obtain for the equivalent stress

$$p_{eq} = \sigma_1 - \sigma_3 = \tfrac{1}{2}(p_1 + p_2) + \tfrac{1}{2}\sqrt{[4q^2 + (p_1 - p_2)^2]} - p_3 \quad [65]$$

This value of the equivalent stress must be smaller than p_0. At the outer surface of the pipe $\sigma_3 = p_3 = 0$, and $p_{eq} = \sigma_1$ which may be greater than p_{eq} as given by Equation [62] for plane stress.

The Strain-Energy Theory. According to this theory, plastic flow occurs when the energy of pure deformation reaches a certain limit, excluding the energy due to change of volume, regardless of the state of stress. Where plane stress occurs, assuming $p_3 = 0$, the energy of deformation per unit volume can be expressed as

$$w = (1/12G)[(p_1 - p_2)^2 + p_1^2 + p_2^2] + (1/2G)q^2$$

where p_1, p_2, and q are the total longitudinal, transverse, and shearing stresses, respectively, and G is the modulus of rigidity. Since w must be equal to the energy at the plastic limit under all conditions, it must also be equal to the energy in a bar under simple tension when the yield point is reached. Under these conditions $p_2 = 0$, $q = 0$, and $p_1 = p_0$. Therefore

$$w = p_0^2/6G$$

Equating these expressions for w, the yield point is found to be reached when

$$p_0 = \sqrt{(p_1^2 + p_2^2 - p_1p_2 + 3q^2)}$$

Thus the equivalent stress in this case is

$$p_{eq} = \sqrt{(p_1^2 + p_2^2 - p_1p_2 + 3q^2)} \quad [66]$$

which, in order to avoid plastic flow, must be smaller than p_0.

If we can disregard q as being insignificant, p_1 and p_2 become principal stresses and Equation [66] takes the form

$$p_{eq} = \sqrt{(p_1^2 + p_2^2 - p_1p_2)} \quad [66a]$$

If the transverse stress p_2 can also be disregarded, we have the case of a simple longitudinal stress, where $p_{eq} = p_1$, and therefore $p_1 < p_0$.

In three-dimensional stress, plastic flow will occur according to the strain-energy theory when

$$(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2 = 2p_0^2$$

[8] "Zur Theorie plastiche Deformation und der hierdurch im Material hervorgerufenen Nach spannungen," by H. Hencky, *Zeitschrift fur angewandte Mathematik und Mechanik*, vol. 4, no. 4, 1924, pp. 323–334.

Hence

$$p_{eq} = \sqrt{(\sigma_1^2 + \sigma_2^2 + \sigma_3^2 - \sigma_1\sigma_2 - \sigma_2\sigma_3 - \sigma_1\sigma_3)} \quad [67]$$

which should be made smaller than p_0. Here $\sigma_3 = p_3$, while σ_1 and σ_2 can be found from Equation [64].

If σ_3 is neglected

$$p_{eq} = \sqrt{(\sigma_1^2 + \sigma_2^2 - \sigma_1\sigma_2)}$$

which is identical with Equation [66*a*], as it should be, since in that equation $p_1 = \sigma_1$, and $p_2 = \sigma_2$.

The Working Stress. The yield point of the material will be used in this paper as the standard of reference, and it is suggested that under working conditions the equivalent stress determined by the strain-energy method as given by Equations [66] or [67] should be not greater than about one-half of the stress at the yield point, that is

$$p_{eq} \leqq \tfrac{1}{2}\, p_0 \quad [68]$$

In the author's paper "Tests on High-Pressure Pipe Bends," page 344, it was recommended, on the basis of a number of full-scale tests with pipe bends, to use the longitudinal stress at the middle surface of the pipe wall as strength criterion in the curved parts. It was suggested also that this stress, p_1 in Equation [49] should not be allowed to exceed 16,000 lb per sq in. This means that p_{1b}, the stress due to bending alone, should not be greater than $16{,}000 - (p_{1s} - p_{1c})$, but as previously shown, the transverse bending stresses due to flattening of the bends is much higher than $p_1 b$ and might thus become excessive. It was argued, however, that these high stresses were strictly a local phenomenon; they occurred only within very limited regions of the inner and outer surfaces of the pipe wall, and did not seem to affect the general behavior of the pipe. Although that rule led to results which were in accordance with good engineering practice, it appears advisable under more modern conditions of pressure and temperature in all cases to use the equivalent stress as the strength criterion, as recommended previously. If this is done, the transverse stresses will be taken into account, not only in the straight parts of the pipe, but also in the bends. Possibly a somewhat higher working stress may be allowed in the bends than in the straight parts.

These rules are believed to be conservative, but in view of recent rapid developments they must be regarded as suggestions. Before an accurate and fully reliable basis of design can be established, covering all modern conditions, there is required further practical experience over extended periods, and correlated with a theoretical analysis of the stresses. In any case it seems justifiable, in determining the working stress, to take advantage of the higher yield point in alloy steels, while at the same time due account must be taken of the reduction in the stress at the yield point and in the modulus of elasticity at higher temperatures.

5—NUMERICAL EXAMPLE

The numerical analysis for a three-dimensional three-arm pipe, in which the arms are at right angles to each other and connected by right-angle bends, as shown in Fig. 6, is here given to illustrate the application of the formulas presented in this paper. Both ends of the pipe are fixed in position and direction, and when steam is admitted, expansion takes place, not only of the pipe itself but also of certain parts of the machinery to which the ends of the pipe are attached.

The pipe is made of alloy steel, has a modulus of elasticity of 24×10^6 lb per sq in. at 850 F, and a yield point of approximately 39,000 lb per sq in. at 800 F. The temperature rise in the pipe is assumed to be 850 F, at which the expansion of the pipe per inch of length $\delta = 0.006083$ in. Other data are: Working pressure $P =$ 400 lb per sq in.; outer radius of pipe $r_o = 3.644$ in.; inner radius of pipe $r_i = 3.403$ in.; radius of middle surface $r = 3.523$ in.; thickness of pipe wall $2h = t = 0.241$ in.; sectional area of pipe wall $A = 5.33$ sq in.; moment of inertia of A about a diameter $I = 33.14$ in.^{4}; and the radius of pipe bend $R = 36.3$ in. From these data it is found that

$$\lambda = tR/r^2 = 0.705$$

and that

$$K = (12\lambda^2 + 10)/(12\lambda^2 + 1) = 2.29$$

From the dimensions given in Fig. 6, it is observed that $H = 145.2$ in.; $L_y = 108.9$ in.; $L_x = 35.7$ in.; $L = 108.3$ in.; $L_z = 41.0$ in.; and $T = 77.3$ in.

The dimensions for expansion are: $H_e = 156.1$ in.; $L_e = 96.8$ in.; and $T_e = 82.2$ in. Further, $EI\,\Delta x_A = 468.4$; $EI\,\Delta y_A = 755.3$; and $EI\,\Delta z_A = 397.8$.

The coefficients A to F in Equations [31] to [36] are computed from the expressions in Equations [25] to [30].

A sample calculation of the A-coefficients in Equation [25] gives

$3.612\,R = 131.2$	$\tfrac{1}{2}L_y^2 = 5930$
$1.30\,L_x = 46.4$	$1.806\,(L_y + H)R = 16{,}670$
$L_y = 108.9$	$1.150\,R^2 = 1515$
$L_z = 41.0$	$1.30\,L_x H = 6740$
	$L_e H = 5955$

$A_1 = 327.5 \quad A_3 = \tfrac{1}{2}T^2 = 2988 \quad A_4 = -36{,}810$

The other coefficients are found in the same manner from Equations [26] to [30], inclusive, finally furnishing equations, for this illustration, in which the numerical values of the coefficients replace the algebraic coefficients. The fundamental Equations [31] to [36], inclusive, for this numerical example can now be written with numerical coefficients, which are

$$327.5\,M_{Ox} + 2988\,Q - 36{,}810\,N = 0 \quad [31]$$

$$427.5\,M_{Oy} - 4223\,P + 20{,}700\,N = 0 \quad [32]$$

$$407.1\,M_{Oz} + 47{,}330\,P - 13{,}940\,Q = 0 \quad [33]$$

$$421.0\,M_{Ox} + 26{,}060\,M_{Oy} - 11{,}780\,M_{Oz} - 808{,}000\,P + 956{,}300\,N = 468.4 \times 10^6 \quad [34]$$

$$-22{,}110\,M_{Ox} - 421.6\,M_{Oy} + 27{,}820\,M_{Oz} + 2{,}798{,}000\,P - 336{,}500\,Q + 2{,}382{,}000\,N = 755.2 \times 10^6 \quad [35]$$

$$10{,}150\,M_{Ox} - 25{,}390\,M_{Oy} - 791{,}000\,N = 397.8 \times 10^6 \quad [36]$$

From Equations [31], [32], and [33], the couples can be expressed in terms of the forces, and substituting these values in Equations [34], [35], and [36], we obtain Equations [37] with numerical coefficients, which are

$$\left.\begin{aligned} 817.7\,P - 407.3\,Q - 257.7\,N &= 468.4 \times 10^3 \\ -439.1\,P + 817.8\,Q - 83.1\,N &= 755.3 \times 10^3 \\ -2507\,P - 92.6\,Q + 157.9\,N &= 397.8 \times 10^3 \end{aligned}\right\} \quad [37]$$

from which the reaction forces $P = 1729$ lb, $Q = 1916$ lb, and $N = 640$ lb, are obtained.

Substituting these values of P, Q, and N in Equations [31], [32], and [33] and solving for the couples, we obtain $M_{Ox} = +54{,}410$ in-lb, $M_{Oy} = -13{,}800$ in-lb, and $M_{Oz} = -135{,}400$ in-lb.

The reaction couples at A as determined from Equation [38] are

$$M_{Ax} = -(M_{Ox} + QT - NH) = -109{,}590 \text{ in-lb}$$

$$M_{Ay} = -(M_{Oy} + NL - PT) = +78{,}280 \text{ in-lb}$$

$$M_{Az} = -(M_{Oz} + PH - QL) = +91{,}900 \text{ in-lb}$$

A corrective calculation was carried out by substituting the values of the forces and couples at O just determined in the expressions for the minor terms omitted in the rotation equations and adding the numerical quantities so found as constants on the left-hand side of these equations. Equations [34], [35], and [36] for the displacements were left unaltered, the minor terms having been included already. The solution of the six equations could now be obtained and were found to give values for the reaction forces and couples which differed from those previously obtained by less than 1 per cent, except that M_{Oz} was —134,670 in-lb, instead of —135,400 in-lb, i.e., about 2 per cent smaller.

Another calculation was made by which the minor terms were omitted in all six fundamental Equations [31] to [36], inclusive, and again the results were practically the same. However, it is recommended to follow the method applied above, by which the minor terms are omitted in the rotation equations but included in the displacement equations.

Determination of Stresses at the O-End

From Equation [45]

$$M_O = \sqrt{(M_{Ox}^2 + M_{Oz}^2)} = \sqrt{(54{,}410^2 + 135{,}400^2)} = 145{,}900 \text{ in-lb}$$

The longitudinal stress at the outer surface due to bending is obtained from Equation [46]

$$p_{1b} = (M_O r_o/I) = (145{,}900 \times 3.644)/33.14 = \pm 16{,}040 \text{ lb per sq in.}$$

The longitudinal stress due to the steam pressure, from Equation [47], is

$p_{1s} = Pr_i/2t = (400 \times 3.403)/(2 \times 0.241) = +2825$ lb per sq in.

From Equation [48] is obtained the longitudinal stress due to end reaction, which is

$$p_{1c} = Q/A = -1916/5.33 = -359 \text{ lb per sq in.}$$

Hence, the total maximum longitudinal stress at the outer surface, found by applying Equation [49], is

$$p_1 = p_{1b} + p_{1s} + p_{1c} = 16{,}000 + 2825 - 359 = 18{,}500 \text{ lb per sq in.}$$

The hoop stress due to steam pressure, from Equation [51], is

$$p_{2s} = p_2 = Pr_i/t = 400 \times 3.403/0.241 = 5650 \text{ lb per sq in.}$$

The shearing stress due to twisting moment, from Equation [51] is

$$q_t = \frac{M_{Oy} r_o}{2I} = \frac{13{,}880 \times 3.644}{2 \times 33.14} = 763 \text{ lb per sq in.}$$

According to Equation [52], the shearing stress due to the reaction forces P and N are

$$q_f = \frac{\sqrt{(P^2 + N^2)}}{A} = \frac{\sqrt{(1729^2 + 640^2)}}{5.33} = 346 \text{ lb per sq in.}$$

Hence,

$$q = q_t + q_f = 763 + 346 = 1109 \text{ lb per sq in.}$$

The equivalent stress, according to the strain-energy theory is then found by applying Equation [66], where

$$p_{eq} = \sqrt{(p_1^2 + p_2^2 - p_1 p_2 + 3q^2)} = \sqrt{[18{,}500^2 + 5650^2 - (18{,}500 \times 5650) + (3 \times 1109)^2]} = 16{,}530 \text{ lb per sq in.}$$

According to the maximum-shear theory, Equation [62], the equivalent stress is $p_{eq} = 13{,}040$ lb per sq in.

Stresses at the A-End

The resultant couple of M_{Ax} and M_{Ay} here denoted by M_A, is

$$M_A = \sqrt{M_{Ax}^2 + M_{Ay}^2} = \sqrt{(109{,}590^2 + 78280^2)} = 134{,}700 \text{ in-lb}$$

The corresponding maximum stress is

$$p_{1b} = M_A r_o/I = 134{,}700 \times 3.644/33.14 = 14{,}810 \text{ lb per sq in.}$$

The longitudinal stress due to steam pressure is the same as at O, which is 2825 lb per sq in. The uniform longitudinal stress due to the compressive reaction N is

$$p_{1c} = N/A = -640/5.33 = -120 \text{ lb per sq in.}$$

Therefore

$$p_1 = 14{,}810 + 2825 - 120 = 17{,}500 \text{ lb per sq in.}$$

We have again

$$p_2 = p_{2s} = 5650 \text{ lb per sq in.}$$

The shearing stress due to the twisting moment is

$$q_t = \frac{M_{Ax} r_o}{2I} = \frac{91{,}900 \times 3.644}{2 \times 33.14} = 5052 \text{ lb per sq in.}$$

While the shearing stress due to the reaction forces at A is

$$q_f = \frac{\sqrt{(P^2 + Q^2)}}{A} = \frac{\sqrt{(1729^2 + 1916^2)}}{5.33} = 484 \text{ lb per sq in.}$$

Therefore

$$q_A = q_t + q_f = 5052 + 484 = 5540 \text{ lb per sq in.}$$

and the equivalent stress, according to the strain-energy theory, Equation [66] becomes

$$p_{eq} = \sqrt{[17{,}500^2 + 5650^2 - (17{,}500 \times 5650) + (3 \times 5540^2)]} = 18{,}200 \text{ lb per sq in.}$$

This still falls below one-half the stress at the yield point, $\frac{1}{2}p_0 = 19{,}500$ lb per sq in.

According to the maximum-shear theory, Equation [62] $p_{eq} = 16{,}200$ lb per sq in., which is again appreciably lower than according to the strain-energy theory.

In most cases the direct stress p_{1c} and the shearing stress q_f can be safely neglected as being inside the limits of accuracy of the computations.

The stresses at O and A are greater than anywhere else in the straight parts of the pipe as can be ascertained by means of Equations [18], so that it remains only to investigate the stresses in the bends.

Stress in the First Bend

In the first bend M_s acts in the plane of the bend and is a maximum when

$$\tan \psi_{max} = P/Q = 1729/1916 = 0.902$$

Therefore $\psi = 42$ deg 3 min.

The maximum value of M_s as obtained from Equation [39a] is

$$M_{s\max} = M_{Oz} + PL_y + R[\sqrt{(P^2 + Q^2)} - Q] = 135{,}400 + (1729 \times 108.9) + 36.3\,[\sqrt{(1729^2 + 1916^2)} - 1916] = 77{,}000 \text{ in-lb}$$

The bending moment normal to the plane of the bend at any point S as obtained from Equation [41] is

$$M_b = (M_{Ox} - NL_y)\cos\psi - (M_{Oy} + NR)\sin\psi$$

which is a maximum when

$$\tan\psi_{b\max} = -\frac{M_{Oy} + NR}{M_{Ox} - NL_y} = -\frac{-13{,}880 + (640 \times 36.3)}{54{,}410 - (640 \times 108.9)} = 0.613$$

Substituting this value in Equation [41] we find

$$M_{b\max} = (-15{,}280 \times 0.852) - (9360 \times 0.523) = -17{,}900 \text{ in-lb}$$

The twisting moment at S, according to Equation [42], is

$$M_t = (M_{Ox} - NL_y)\sin\psi + (M_{Oy} + NR)\cos\psi - NR$$

which is a maximum when

$$\tan\psi_{t\max} = -1/\tan\psi_{b\max}$$

This places the maximum outside the quadrant and we have to determine the value of M_t where $\psi = 0$, and $\psi = \pi/2$. It is found that for $\psi = 0$, $M_t = M_{Oy} = -13{,}880$ in-lb, and for $\psi = \pi/2$, $M_t = 38{,}520$ in-lb. Hence, M_t has its greatest value at D, and since M_s has its maximum at $\psi = 42$ deg, and M_b at $31\frac{1}{2}$ deg, and since they are all small or moderate as compared with the couples at A and O, it is unnecessary to consider any combination of the three couples. It is of interest, however, to investigate the stress caused by $M_{s\max}$, which is found from Equation [53].

The maximum stress occurs at a point in the section, the radius of which forms a certain angle θ with the neutral axis. This angle can be found from Equation [55], in which $\lambda = 0.705$. Therefore

$$\sin\theta = \sqrt{[(2.982 + 5)/18]} = 0.666$$

and since $K = 2.29$, the value of β can be found from Equation [54a], where

$$\beta = 2/3\ K\sin\theta = 2/3 \times 2.29 \times 0.666 = 1.017$$

The maximum stress can now be determined from Equation [53], where

$$p_{1b\max} = (1.017 \times 77{,}000 \times 3.523)/33.14 = 8320 \text{ lb per sq in.}$$

It is unnecessary further to peruse the study of the longitudinal stress in this case, since it is known to be much smaller than the transverse stress. From Equation [56] we have at the outer surface in the neutral axis

$$p_{2b} = \frac{18\,M_s\lambda r}{I\,(12\lambda^2 + 1)} = \frac{18 \times 77000 \times 0.705 \times 3.523}{33.14\,(12 \times 0.497 + 1)} = 14{,}930 \text{ lb per sq in.}$$

The hoop stress p_{2s} due to steam pressure was found previously to be 5650 lb per sq in. The transverse compressive stress due to flattening, applying Equation [58], is

$$p_{2c} = \frac{2M_s r^2}{RI}\,\frac{(6\lambda^2 + 1)}{(12\lambda^2 + 1)} = \frac{2 \times 77000 \times 12.41}{36.3 \times 33.14} \times \frac{3.982}{6.964} = 910 \text{ lb per sq in.}$$

Hence, from Equation [59] the total transverse stress in the neutral axis is

$$p_2 = 14{,}930 + 5650 - 910 = 19{,}670 \text{ lb per sq in.}$$

At the section where $M_{s\max}$ is acting, there is a twisting moment as given by Equation [42]. With $\psi_{\max} = 42$ deg 3 min, we find after applying Equation [42] that $M_t = 26{,}520$ in-lb. Hence, a shearing stress is produced at the outer surface which, according to Equation [51], is found to be

$$q_t = \frac{M_t r_o}{2I} = \frac{(26{,}520 \times 3.644)}{(2 \times 33.14)} = 1460 \text{ lb per sq in.}$$

The equivalent stress in the neutral axis with $p_1 = 0$ and neglecting p_3, from Equation [66] is

$$p_{eq} = \sqrt{(p_2^2 + 3q^2)} = \sqrt{[19{,}670^2 + (3 \times 1460^2)]} = 19{,}900 \text{ lb per sq in.}$$

which is a little more than one-half the stress at the yield point.

The investigation of the stresses in the second bend are made in the same manner.

6—ACKNOWLEDGMENT

The author wishes to express his indebtedness to Henry C. E. Meyer, chief engineer of Gibbs and Cox Inc. for his advice in the preparation of this paper; in particular, the discussion of the permissible working stress. His thanks are due also to Horace L. Bickford of Gibbs and Cox Inc. for his assistance in the preparation of the diagrams as well as in working out the numerical example.

An Airfoil-Type Propeller Blower for Ventilating Electrical Machines

By C. E. PECK[1] and M. D. ROSS,[2] EAST PITTSBURGH, PA.

The authors discuss the development of an airfoil-type propeller blower, the design of which was influenced by space limitations in connection with the motor-driven blower equipment for a 165,000-kw turbine-generator unit installed at the Richmond station of the Philadelphia Electric Company. After the fan was designed, a model was built and tested before the full-size equipment was constructed. The authors present performance data for both the model and the full-size blower.

NEW types of apparatus of improved design and performance are frequently developed as a result of an effort to overcome certain difficulties in a particular commercial application. Space limitations in connection with the motor-driven blower equipment for a large turbine-generator unit brought about the development of the blower described in this paper. When the latest addition to Richmond station of the Philadelphia Electric Company was planned, it was decided to add a 165,000-kw turbine-generator unit. As the turbine-room structure was already in existence with space originally designed for four 50,000-kw units, it will be seen that the design of a 165,000-kw unit to go in the space originally occupied by a 50,000-kw unit involved a careful use of all the available space. The specifications called for all blowers, air coolers, and air ducts to be located below the generator. The height of the space available for this equipment was fixed by the height of the existing turbine-floor level which was 28 ft 6 in. above the condenser-floor level. The width of the space was limited on one side by a circulating pump and on the other by an elevated track. Space had to be provided to permit ready removal of air-cooler tubes. The specifications called for four motor-driven blowers, one of which was to be a spare unit. The generator required a maximum volume of 170,000 cfm. The calculated pressure drop in the generator air coolers and ducts was 12 in. of water. Therefore, the volume rating of each blower was to be 57,000 cfm.

A study of the space available under the generator soon indicated that the usual types of blowers available would occupy too much space and would not fit in with any reasonable system of air ducts. Having had considerable experience with propeller blowers built on the shafts of turbine generators, it was decided to undertake the development of a propeller-type blower of high speed and small dimensions to suit this application.

Another requirement to be met by these blowers was that they were to be suitable for full-voltage starting control for the induction motors driving them. As the generator would operate at all times with two or three blowers running in parallel, the blower characteristics had to be such that good parallel operation would be obtained. As the blowers were to be part of a closed ventilating system in which the air was returned to the generator after being cooled in finned-tube coolers, it was necessary to provide them with suitable intake ducts. Air leaving the generator and entering the blower may reach a temperature of 150 F and some means had to be provided in the design to avoid excessive heating of the blower bearings with this high-temperature air adjacent to them. The speeds available for the blowers corresponded to the standard speeds for 60-cycle induction motors. The speed adopted was 3550 rpm.

Description of Full-Size Blower

The design of the full-size blower is shown in section in Fig. 1. The fan runner consists of eight aluminum-alloy blades dovetailed into a forged-steel hub. The fan runner is overhung on two sleeve bearings mounted in a common rigid cast-iron pedestal as shown in Fig. 2. The shaft and bearings were designed on the premise that no serious damage would occur to these parts in the event of losing one blower blade at full speed. The provision of a rigid shaft and pedestal contributed largely to the smooth running of the unit as a whole as found by test. The thrust varies with the back pressures against which the blower is working. In order to take care of the highest thrust obtained, a two-shoe Kingsbury thrust bearing was incorporated in the same housing as the journal bearing adjacent to the motor coupling.

As the blower bearing losses amounted to something over 1 kw, a small centrifugal fan was mounted on the blower shaft to force a stream of air through passages under the oil chamber in the pedestal, thus cooling the lubricating oil. This cooling air discharges into the space between the pedestal and the blower casing and effectively prevents heat from the casing affecting the pedestal. To provide circulation of the lubricating oil, a small oil pump is mounted on the outboard-motor bracket and connected to the blower pedestal by brass piping.

Air from the generator enters the blower casing from the top through a hand-operated damper which can be closed when a blower is shut down with other blowers in operation. The blower casing is constructed of welded-steel plate sufficiently rigid to support the guide-vane and diffuser structure which is bolted with a flanged joint to the casing. Air enters the blower through a spun-aluminum intake nozzle, passes through the blower and then through the stationary guide vanes in the diffuser. The guide vanes are built up of aluminum castings.

Theoretical Design of the Fan

The fan without guide vanes and diffuser was designed on the basis of the theory outlined in a paper by Dr. O. G. Tietjens.[3] Within certain empirical limits the proportions of the fan itself,

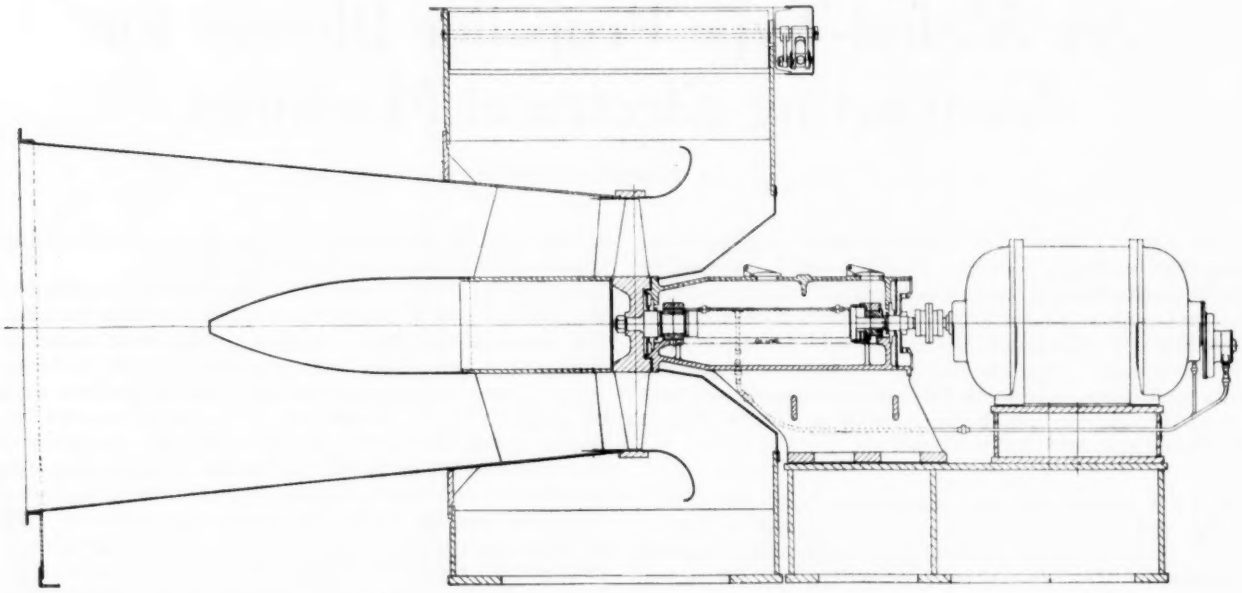

FIG. 1 CROSS-SECTION ASSEMBLY OF THE FULL-SIZE UNIT

without guide vanes or diffuser, can be accurately predetermined for a given pressure and volume. Certain empirical limits applied to the theoretical design had been found by means of considerable experimental investigation performed by H. C. Werner of the Westinghouse Research Laboratories on several different fans of the air-foil type. The guide vanes and diffuser add considerably to the capacity and efficiency of the fan. As a result, the theoretical design of the fan itself was based on 90 per cent of the required volume of 57,000 cfm per fan and 85 per cent of the required static pressure of 12 in. of water, which is approximately 25 per cent lower than the required capacity. It was assumed that the diffuser would recover between 70 and 80 per cent of the dynamic energy created by the fan in a direction parallel with the axis of rotation. In addition, it was assumed that the guide vanes would recover about 50 per cent of the rotational energy at the discharge side of the fan. How closely the tests verified these assumptions is discussed later.

The fan blade has an airfoil cross-section of varying profile from hub to tip. The general shape is that of a cross-section of an airplane wing having a flat side and well-rounded leading edge which is stable for large angles of attack. The blade width and angle with respect to a vertical plane gradually decrease from hub to tip. The fan contains eight blades so spaced at the hub that no overlapping exists. Mutual interference of one blade upon another was found to be very small with this spacing.

In line with the theory outlined in Tietjens' paper,[3] the following is a brief analysis of the factors to be considered in the theoretical design: In designing a propeller fan the total pressure generated by the fan multiplied by the volume rate of flow represents a certain power output. The volume rate of flow is equal to the fan area times the axial velocity through the fan. Hence, the power output is

$$Ap_t w = Tw \quad \ldots\ldots [1]$$

where A is the fan area, w is the axial velocity through the fan, p_t is the total pressure (static plus dynamic), and T is the total force acting on the fan area and is called the thrust. In general, the problem reduces to that of designing a fan which will produce the total thrust corresponding to the required total pressure.

From airfoil and propeller theory, the thrust depends on the magnitude and distribution of the aerodynamic circulation around the blade. This may be given by the relation

$$dT = (n\rho\ \Gamma\ r\omega)\ dr \quad \ldots\ldots [2]$$

where dT is the incremental thrust at a point corresponding to radius r on the blade, Γ is the circulation, ω is the angular velocity of the fan, n is the number of blades, and ρ is the air

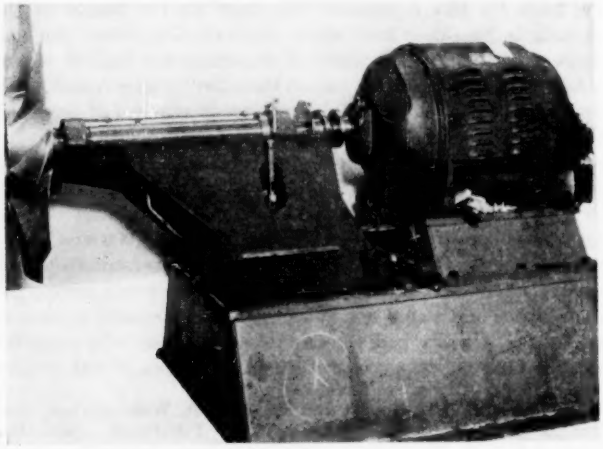

FIG. 2 FAN RUNNER AND BEARING OF THE AIRFOIL BLOWER

density. It has been shown theoretically that the pressure rise through a propeller fan and, hence, the thrust, can only be obtained by the creation of a rotational-velocity component which can be clearly observed at the discharge side of the fan. The circulation and rotation are related to the blade dimensions at radius r by the equation

$$\Gamma = C_L\ bv/2 \quad \ldots\ldots [3]$$

in which C_L is the coefficient of lift of the blade at the air-foil cross-section corresponding to the radius r; b is the width of the blade; and v is the velocity of air relative to the blade. The relation between v and the axial velocity through the fan and the peripheral

speed at the radius r and the rotational component at the radius r is shown geometrically in Fig. 3. The angle of attack α is necessary to produce the required lift at radius r, and $\alpha + \beta$ is the angle at which the blade is located on the hub.

The fundamental definition of the term circulation is given by the relation of the quantities defined in Equation [3]. Physically, the circulation is an idealized component of the actual flow around an airfoil which can be represented by the streamlines completely traversing the airfoil in a rotating manner. A detailed explanation of the meaning of circulation is given by Prandtl-Tietjens.[4]

If the circulation were assumed constant over the entire blade area in Equation [2], the thrust would vary directly with the radius only, and the total thrust could be obtained by analytical integration of Equation [2]. However, with constant circulation the portions of the blade at the smaller radii are worked at relatively high outputs and the rotation losses become much higher than if the circulation were decreased with decreasing blade radius. It is possible to have constant circulation over the blade area without large rotation losses if the hub diameter is made large relative to the outside diameter, which has the effect of increasing the outside diameter. For a given required total thrust, a compromise is reached between the size of hub relative to outside diameter.

The circulation distribution is decreased toward the hub in such a way that rotation losses are reduced to a value consistent with high efficiency. The fan considered in this paper would have had 45 per cent more rotation loss if the circulation had been constant over the blade area, which is equivalent to a reduction of 5 per cent in the fan efficiency. The ratio of hub diameter to outside diameter was 0.4. This rotation loss is the component of energy at the fan discharge which lies in a plane perpendicular to the axis of rotation of the fan. The dynamic energy is the axial component of the energy at the fan discharge.

Table 1 gives the important constants of the fan referred to in these tests. The volume and pressure are for the fan itself without guide vanes or diffuser at the calculated design point which is also the point of maximum efficiency.

TABLE 1 PRINCIPAL CONSTANTS OF THE AIRFOIL PROPELLER BLOWER

Air density, lb per cu ft	0.0749
Volume, cfm	52,500
Static pressure, in. of water	10.2
Speed, rpm	3600
Outside diameter, in.	38.31
Inside diameter, in.	14.50
Fan area, sq ft	6.87
Constant axial velocity through fan, cfm	7650
Dynamic pressure head, in. of water	3.55
Total head, in. of water	13.75
Ratio of dynamic to total head	0.258
Number of blades	8

The ratio of dynamic head to total head is an important constant for the propeller-type fan because if this value is made too low, such as 0.10 to 0.15, the application of airfoil theory to the fan design begins to become inaccurate because the nature of the flow around the blades is changing due to centrifugal effects caused by the air rotating much faster at the lower-volume points. Values of the ratio between 0.20 and 0.30 have been found satisfactory from the standpoint of performance and efficiency.

Description of Model-Test Set-Up

The model was built about one-quarter size and geometrically similar to the proposed full-size application in all the important details including the inlet box, inlet guides, and diffuser. The best proportions of such parts as the guide vanes and diffuser as determined from the model tests were incorporated in the final full-size unit with exact geometric similarity.

A schematic diagram of the model-test set-up is shown in Fig. 4. The fan draws air through a long gradually diverging inlet duct at the entrance of which is located a flow nozzle for measurement of air volumes. The inlet duct is fastened to the side of the inlet box of the fan. The fan discharges air directly to the room or into the diffuser and guide-vane arrangement. The fan shaft extends through the inlet box and is coupled to a $^1/_2$-hp electric dynamometer used to measure the power input to the fan and also drive the fan. The duct ahead of the flow nozzle was provided with a well-rounded entrance in the form of a one-piece smooth spun-copper ring. Between this ring and the duct

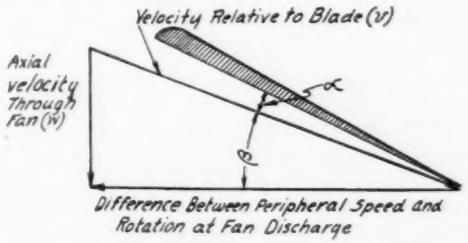

Fig. 3 Air Velocity Relative to the Blade

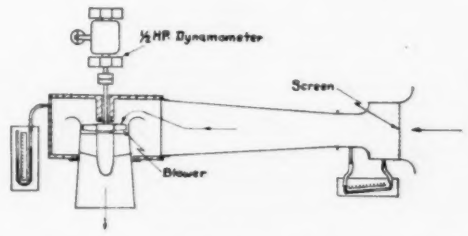

Fig. 4 Diagram of Test Arrangement for the Model Blower

flange, screens were placed in order to vary the pressure-volume delivery of the fan.

Measurements

The volume of air was measured by means of a flown ozzle made of smooth spun copper. The proportions of the nozzle were similar to one of those built by the Bureau of Standards and calibrated for use in calibrating orifices.[5] An average nozzle coefficient of 0.980 was used. The pressure drop across the nozzle was measured by means of eight accurately constructed static-pressure taps on the inlet and discharge sides of the flow nozzle. The pressure drops were measured on an inclined manometer the scale of which was such that errors were within $^1/_4$ per cent for normal fan delivery.

The static pressure developed by the fan was measured by means of taps in the top corners of the inlet box. The average velocity to the inlet box was about 500 fpm which is low enough to introduce negligible error in the measurement of static pressures from $^1/_2$ to 2.5 in. of water found in the model tests.

The power input was measured by means of a dynamometer arrangement consisting of a $^1/_2$-hp direct-current motor used to drive the fan. The stator of the dynamometer was suspended in ball bearings and equipped with a lever arm and scale pan. The torque reaction was measured by balancing it against weights

[4] "Applied Hydro- and Aeromechanics," by O. G. Tietjens, based on lectures of L. Prandtl, McGraw-Hill Book Company, Inc., New York, 1934.

[5] "Discharge Coefficients of Square Edged Orifice for Measuring the Flow of Air," by H. S. Bean, E. Buckingham, and P. S. Murphy, *Bureau of Standards Journal of Research*, March, 1929, pp. 568–652.

placed in the scale pan mounted on the lever arm. Speed was maintained at a given value by using current supplied from a separately excited direct-current generator driven by a single-phase alternating-current motor. The sensitivity of the suspension was such that the average input of $^1/_4$ to $^1/_3$ hp could be checked within 1 per cent. Extreme care was exercised to obtain accurate results. Checks were obtained by means of repeat runs after a considerable time interval. All data were corrected to the standard air density of 0.07488 lb per cu ft. On repeat runs, the pressure multiplied by the volume and divided by the power input which measures the fan efficiency could be checked within 2 per cent.

Model Tests and Test Results

Tests on Fan Itself. In all of the model tests made, the intake box was in place. All of the model data have been expressed in terms of the values for the full-size unit. The results of the tests of the fan itself without guide vanes or diffuser are shown in Fig. 5. The test-performance curve checks closely with the working point for which the fan was designed. The static efficiency of 56 per cent at the working point is the approximate maximum static efficiency. The total efficiency of the fan itself without guide vanes or diffuser is about 75.8 per cent and is based on the static pressure plus the dynamic pressure corresponding to the average axial-velocity component of the air at the fan-discharge area. The difference between 100 per cent and the total efficiency

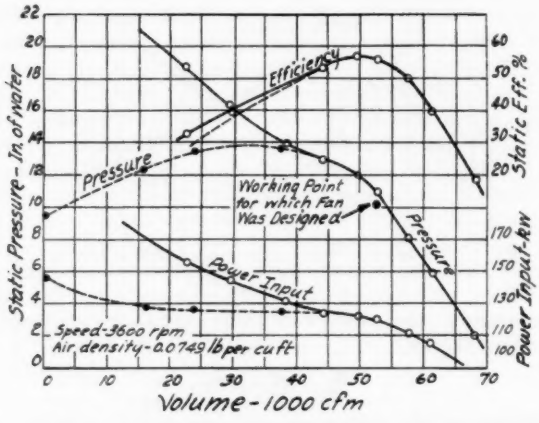

Fig. 5 Performance Curves of the Fan Alone

(Performance with inlet-box baffles removed is shown by dashed lines while performance with baffles in the inlet box is shown by solid lines.)

is a measure of the sum of the fan losses expressed in terms of per cent efficiency. A detail discussion of the magnitude and distribution of these losses is given later.

The solid curve in Fig. 5 represents the performance with the intake box in which were placed two vertical baffle plates diametrically opposite. These plates were fitted around the curved inlet guide which is part of the fan housing. With these plates in place, the pressure characteristic was rising with decreasing volume which is a necessary property for satisfactory operation of two or more fans in parallel. When the plates were omitted from the intake box, the pressure characteristic assumed the "hump" shape which is represented by the dashed line in Fig. 5. This shape is not suitable for parallel operation. The performance with and without the plates was the same at the higher-volume points and in the region of the desired working point. The "hump" shape is caused by the air whirl induced in the inlet box which becomes large enough in magnitude at the lower volumes to reduce the static pressure considerably below the values obtained when no such whirl is present.

The flat portion on the fan curve is characteristic of the propeller-type fan. From a theoretical standpoint, this sudden change in the slope of the pressure characteristic is caused by too large an angle of attack on the blade section. From airfoil theory, as the angle of attack increases, a point is reached at which the lift becomes a maximum and any further increase in angle of attack results in a sudden decrease in the lift, the flow conditions around the blade becoming unstable. In the propeller fan, as the axial velocity through the fan decreases the angle of attack at a

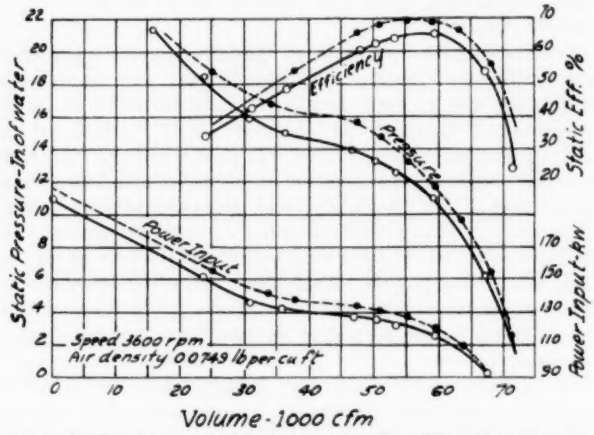

Fig. 6 Performance Curves of the Fan With Diffuser Only

(Performance with very close clearance between the housing and fan is shown by dashed lines while the performance with a clearance of 1.25 per cent of the fan housing is shown by solid lines.)

given point on the blade section increases until a point is reached where the angle of attack has reached a value corresponding to the maximum lift. Beyond this point the decrease in lift which takes place on a wing section is replaced in the propeller-fan blade by centrifugal action. Thus, at the point where the pressure characteristic flattens out, the airfoil theory no longer holds.

Tests With Diffuser and No Guide Vanes. The performance curves for the fan with diffuser and no guide vanes are shown in Fig. 6. A large gain in efficiency results when the diffuser alone is used. In this particular fan, a reasonably large gain using a diffuser alone may be expected because approximately 20 per cent of the fan power input is necessary to create the axial component of the dynamic energy present at the fan-discharge area. Of this 20 per cent, 3.2 per cent represents the axial component of the dynamic energy at the discharge area of the diffuser. The change in static efficiency of the fan from 56 to 66 per cent with the diffuser and same housing clearance in each case indicates that the diffuser recovered about 60 per cent of the available dynamic energy between the entrance and exit of the diffuser. Since no guide vanes were present to straighten the rotating air, the 80 per cent conversion of axial dynamic energy to static energy which is to be expected with a good diffuser could not be obtained. A test made with the center cone of the diffuser removed reduced the static efficiency from 66 per cent to 64 per cent.

Guide-Vane Model Tests. The proportions and angles of the guide vanes were determined by a set of tests. It was found that flat-plate vanes twisted so that the angle varied from the hub to tip gave but a small increase in static efficiency. The plate shape is much more sensitive to the direction at which the air leaving the fan strikes the vane than the blunt-nose airfoil-shaped vane. The air leaving the fan strikes the airfoil vane at a certain angle of attack. With the blunt-nose airfoil-shaped vane, the angle of attack may vary as much as 10 to 12 deg before the air flowing around the vane tends to "break" away from the vane

surface. At the "break" point the vane no longer acts as a guide to straighten the air flow from the rotational direction to the axial direction, but acts instead as an obstruction. The approximate angles at which the air was discharged from the fan were measured from hub to tip by means of a thread and protractor. From these

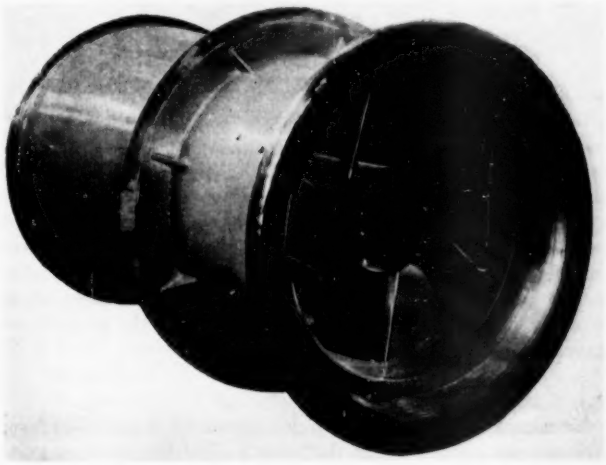

FIG. 7 THE DIFFUSER AND GUIDE VANES OF THE BLOWER

data several sets of airfoil-shaped vanes with various angles of twist were made and tested. It was found that the vane which gave the largest increase in static efficiency near the desired fan working point was set within about 5 to 8 deg of the theoretical discharge angle corresponding to the calculated rotation of the fan.

The number of guide vanes was varied and it was found that when less than six vanes were used the gains in efficiency were reduced, probably due to the lack of sufficiently close spacing between vanes to provide the required guiding action. Both the six-vane and eight-vane arrangements gave about the same efficiency. The six-vane arrangement was used on the final full-size unit. The guide vanes mounted in the diffuser are shown in Fig. 7.

FULL SIZE TESTS AND RESULTS

Description of Test Set-Up and Method of Test. The full-size unit assembled with inlet box and diffuser is shown in Fig. 8. A large discharge box was built at the discharge of the diffuser. A portion of this box can be seen in Fig. 8. On the roof of the discharge box, five stacks, each with a different discharge area, were constructed and used as flow nozzles. Various volume points on the performance curve of the fan were obtained by closing different combinations of the stack openings.

The air enters the inlet box from above and passes through the fan and diffuser to the discharge box. A large screen with a cheese-cloth covering is located in the discharge box just beyond the diffuser outlet. This serves to break up the velocity head of the air leaving the diffuser and thus provides uniform inlet conditions to the nozzles.

The air volume was measured by making a pitot-tube traverse at the exit of each nozzle. In order to investigate the air distribution in each nozzle and obtain an accurate average, a large number of pitot-tube readings were taken. The air distribution was found to be reasonably uniform and the direction of the air was essentially parallel with the axis of the nozzle. These conditions made it possible to measure the air volume very accurately. The use of the large discharge box and screens eliminated any errors which might be present due to pulsating flow conditions.

The static pressure generated by the fan was measured in the discharge box after the air had passed through the screen. At this point the air velocity was very low and thus an accurate measurement of static pressure could be obtained.

The fan is driven by a 3600-rpm induction motor. The power output of the motor was accurately obtained by means of a special calorimeter-test method which will not be described here. This method of test eliminated the uncertainty of the magnitude of the load loss which in this case was enough to affect the fan efficiency by approximately 2 per cent.

Test Results. The results of the test on the full-size fan with guide vanes and diffuser are given in Fig. 9. The performance includes the effect of the inlet box. The power input to the fan includes the loss in the thrust bearing which is of the order of 1.5 kw. The model tests with similar guide vanes and diffuser checked the full-size performance closely. The maximum static efficiency on the model was 77 per cent. The maximum static

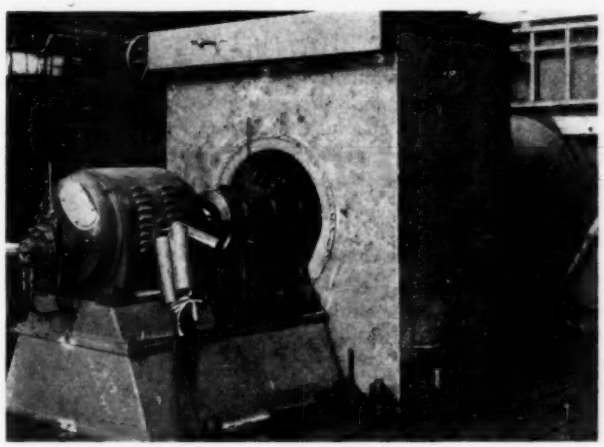

FIG. 8 TEST ARRANGEMENT OF THE ASSEMBLED FULL-SIZE BLOWER UNIT

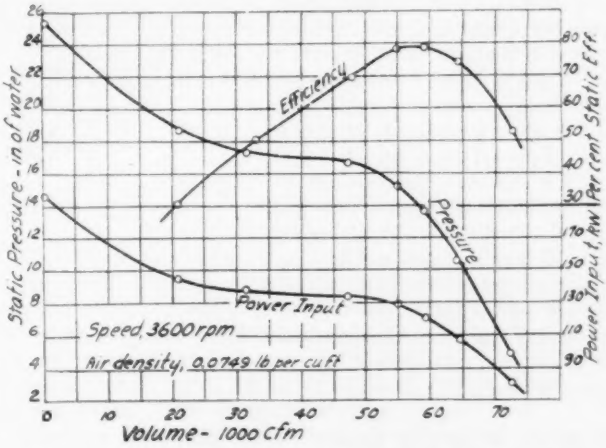

FIG. 9 PERFORMANCE CURVES OF THE FULL-SIZE UNIT WITH GUIDE VANES AND DIFFUSER

efficiency on the full-size unit was 78.5 per cent, including the loss due to the fan thrust bearing. The close check between the tests of the model and full-size unit indicated that the different methods of test used on the model and the full-size unit were satisfactory. The total efficiency of the unit with guide vanes and diffuser based on the static pressure plus the axial dynamic pressure at the diffuser discharge is 82.5 per cent, including the effect of the inlet-box and thrust-bearing loss.

Clearance Between Fan and Housing. The model tests demonstrated the importance of the clearance space between the outside fan diameter and the surrounding housing. Fig. 6 shows performances ascertained from two tests, one with a clearance between fan and housing of 1.25 per cent of fan radius, and the other with a very small clearance obtained on the model by molding a layer of modeling clay to the inside of the housing and scraping the excess off by running the fan in the housing. With this type of fan, an appreciable gain in efficiency results when clearances are close. The axial width of the eight-bladed fan at the blade tip is about 24 per cent of the radial height of the blade. The small axial width compared to the blade height may be linked with the sensitivity to clearance. The clearance between the blade tip and housing for the full-size unit is 0.163 per cent of the outside fan radius. In the test shown in Fig. 5, the efficiency of the fan itself was raised from 57 per cent to 61 per cent when an extremely small clearance was used.

Calculated Losses and Efficiencies Compared to Tests

The losses in a propeller fan may be classed under the two headings of recoverable and non-recoverable losses. The non-recoverable losses are those which originate in the fan itself and are called the drag losses. It is equivalent to the drag loss on an airfoil and is due to the fact that each blade element in producing a certain lift must overcome a certain drag due to friction and the nature of the flow around the airfoil.

The recoverable losses consist of the energy in the air at the discharge side of the fan. This energy is conveniently resolved into two components, namely, the rotational-velocity component which lies in a place perpendicular to the axis of rotation, and the axial-velocity component which is parallel with the axis of rotation of the fan.

Table 2 gives the magnitude of these various losses expressed as per cent of energy input to fan at working point of fan itself. (For point of maximum efficiency see Fig. 5.) Table 2 shows which losses limit the efficiency of the fan. The agreement between the calculated and test values of static efficiency indicates that the magnitude and relative apportionment of the total losses into their various parts is approximately correct.

A study of Table 2 makes the following points worthy of note.

TABLE 2 CALCULATED LOSSES AND EFFICIENCIES, PER CENT OF FAN INPUT

Item	Fan alone	Fan with guide vanes and diffuser
(*a*) Drag loss, not recoverable	13.3	13.3
(*b*) Rotational-loss component	9.3	3.7[a]
(*c*) Axial dynamic-energy component	20.0	3.4[b]
(*d*) Energy at diffuser exit, not recoverable	0	3.2
(*e*) Total losses, Items *a* + *d*, not recoverable	13.3	16.5
(*f*) Total losses, Items *b* + *c*, recoverable	29.3	7.1
(*g*) Total losses, Items *a* + *b* + *c* + *d*	42.6	23.6
Calculated static efficiency (100 — Item *g*)	57.4	76.4
Test static efficiency	56.5	78.5[c]

[a] Assumed 60 per cent recovered.
[b] Assumed 80 per cent recovered.
[c] Approximately 1 per cent low because of bearing loss.

If all of the recoverable losses were recovered, the maximum efficiency of the fan would be 86.7 per cent. The approximate percentage of losses recovered by means of the guide vanes and diffuser amounts to 75 per cent of the recoverable losses. The largest component of loss is the axial dynamic component which explains in part why the diffuser alone without the guide vanes gave a large increase in the static efficiency.

Noise

No complete investigations of noise levels were made but some comparisons indicated that the noise level of the fan would add little, if any, to the general noise level of the power station. These comparisons are based on the fan operating on the test floor where the intakes were open, but in the actual application the fan is part of a completely enclosed system.

Summary

The results of designing, building, and testing a fan of this type bring out the following possible advantages:

1 Within certain limits the performance and design proportions can be predetermined accurately.

2 From a mechanical standpoint, the propeller is particularly adaptable for high speeds.

3 The intake box has little effect on the fan performance.

4 For the pressures and volumes used in this application, the size of the unit is reasonably small.

5 The fan efficiency is high.

Progress Report on Cavitation Research at Massachusetts Institute of Technology

By J. C. HUNSAKER,[1] CAMBRIDGE, MASS.

This paper, a second progress report on the study of the nature of hydraulic cavitation being conducted at M.I.T., is continued along the lines reported in the first paper published in *Mechanical Engineering*, April, 1935, and discusses information obtained regarding the relation between frequency of vapor collapse and the controlling variables. The current work tends to confirm that previously reported. A new method for the study of resistance to cavitation attack is described.

IN THE present work on hydraulic cavitation it is found that the coefficient fL/V remains substantially constant, not only for geometrically similar venturi-type nozzles but also for all nozzles having the same exit flare. In the coefficient term fL/V, f is the frequency of collapse, L is the length of cavitation volume, and V is the velocity at the nozzle throat. Reynolds' number does not appear to control matters, possibly because the range for variation of Reynolds' number in the tests is not very great, but more probably because the flow is inherently turbulent and viscosity effect cannot be important. However, the relation fL/V can only be determined when cavitation is well developed and L is of substantial magnitude.

Further work has confirmed the opinion that the damage to surfaces caused by cavitation is severe only when the collapse is noisy, violent, and regular. For such fully developed cavitation the frequency of collapse is regular. When cavitation is not well developed and L is but one or two throat diameters, the frequency observed is highly irregular, severe shocks are infrequent or absent, and damage to walls is very slight.

FIG. 1 LEAD DISK $^5/_8$ IN. DIAMETER AFTER 0.5-MIN OSCILLATION IN CALCIUM-CHLORIDE SOLUTION

Wall damage also appears to depend on the abolute size of the nozzle used, or the energy available in the cavitation volume, since tests with small nozzles, geometrically similar to large ones produced little or no damage even when cavitation conditions appeared to be similar.

When the exit flare varies more or less from 21 deg, the frequency of cavitation collapse is irregular, severe shocks infrequent or absent, and damage slight regardless of the length of cavitation volume for equal throat velocities.

The conclusion from the current work is that cavitation of a type to cause severe damage requires, probably, some unique combination of variables, of which exit flare or profile shape appears to be important. Therefore, a technique for the quantitative measure of the severity of cavitation damage is required. In this connection exposure of test medallions of metal has proved of interest. The determination of weight loss against time of exposure, however, does not give a suitable numerical measure of the severity in a reasonable time. Lead, for example, may be severely damaged without showing appreciable loss of weight. However, it is found that properly cured cement will progressively lose weight under cavitation attack and it is planned to report tests of various cavitation conditions in terms of a scale based on loss of weight of cement.

The severity of cavitation not only depends on the type of cavitation but must also depend on the liquid, and especially its density and vapor pressure. However, it is impractical to repeat the hydraulic experiments with other liquids.

It is known, however, that high-frequency vibration of a submerged diaphram, such as is used in submarine signaling, can produce cavitation and damage. An apparatus, similar to that described by Gaines[2] for oscillating a nickel tube at high frequency by magnetostriction effect was used to oscillate $^5/_8$-in. disks of lead and cement with a frequency of about 8500 cycles per sec through an amplitude of about 0.01 mm.

Tests are being made with a number of common liquids of widely different physical properties. Tests of lead disks in water or in a calcium-chloride solution show vastly more damage than when tested in alcohol or in carbon tetrachloride. Presumably the high vapor pressure of the latter liquids accounts for this. The appearance of the damaged surface of the lead is identical

[1] Head of Mechanical Engineering Department, Massachusetts Institute of Technology. Mem. A.S.M.E. Dr. Hunsaker was graduated from the United States Naval Academy in 1908 and received his M.S. degree from M.I.T. in 1912 and D.Sc. degree in 1916. From 1909 to 1926 he was an officer in the U. S. Navy, but during this period served as instructor of aeronautic engineering at M.I.T. from 1912 to 1916. From 1916 to 1923 he was in the Navy Department, Washington, D. C., in charge of aircraft design. From 1923 to 1926 he was Assistant Naval Attaché at London, Paris, Berlin, and Rome. He was appointed assistant vice-president of the Bell Telephone Laboratories in 1923 which position he held until 1926 when he became vice-president of the Goodyear-Zeppelin Corporation. He assumed his present duties in 1933.

Contributed by the Hydraulic Division for presentation at the Annual Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS to be held in New York, N. Y., December 2 to 6, 1935.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until January 10, 1936, for publication at a later date.

[2] "A Magnetostriction Oscillator Producing Intense Audible Sound and Some Effects Obtained," by N. Gaines, *Physics*, vol. 3, no. 5, 1932, pp. 209–229.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

FIG. 2 LEAD DISK 5/8 IN. DIAMETER AFTER 6 MIN OSCILLATION IN CALCIUM-CHLORIDE SOLUTION

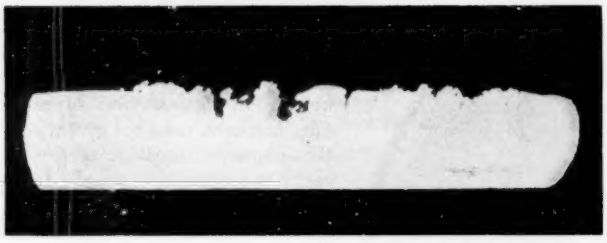

FIG. 3 CROSS-SECTION OF THE DISK SHOWN IN FIG. 2

with that observed on lead exposed to hydraulic cavitation in the original apparatus. However, the damage to lead is not consistently measured by loss of weight and the tests are being repeated with cement disks. The results of these tests will be reported later.

It is found that either with lead or with cement, appreciable damage is done in one minute and a test can be completed in less than 10 minutes. Fig. 1 shows the surface of a lead disk after oscillation of one-half minute duration in saturated calcium-chloride solution. Figs. 2 and 3, the latter a cross-section of the disk in Fig. 2, show a disk similar to the one in Fig. 1 after six-minutes exposure. It will be noted that material on the surface is displaced plastically and not lost. On the other hand, a cement surface is not displaced plastically and damaged particles are washed away. Fig. 4 shows the appearance of a cement disk after 1.2 min exposure to oscillation in water.

FIG. 4 CEMENT DISK 5/8 IN. DIAMETER AFTER 1.2 MIN OSCILLATION IN WATER

This new method of high-frequency oscillation permits a rapid estimation of the relative resistance to cavitation damage of various materials of construction. Likewise the method lends itself to a fundamental study of the influence of the properties of the liquid on cavitation damage. To oscillate a sample in a beaker of fluid for a few minutes is much cheaper and quicker than to run hydraulic cavitation tests.

Progress in Cavitation Research at Princeton University

By LEWIS F. MOODY[1] and ALFRED E. SORENSON,[2] PRINCETON, N. J.

The authors describe test apparatus and an experimental method used to determine the critical point of cavitation, or cavitation limit, of liquids flowing in a closed system as caused by the formation of vapor-filled cavities in the system. The experiments here described were directed to determine the cavitation limit, at which cavitation begins, and not to ascertain the consequences of maintained cavitation. The authors show that the experiments give results entirely consistent with the cavitation principle as now generally applied.

The Problem of Determining the Cavitation Limit

As THE effective head causing flow through a hydraulic apparatus is increased, the velocity head at any point in the system increases correspondingly and this increase in velocity head entails a compensating reduction in pressure head. This relation holds until the absolute pressure at some point in the system reaches the vapor pressure of the liquid, below which it cannot go while liquid remains present. Any further increase in the effective head merely produces boiling, the conversion of part of the liquid into vapor. When this occurs the principle of continuity of flow then fails to apply and a marked change in the performance of the apparatus occurs. The production of vapor-filled cavities in the flowing liquid is what is meant by the term *cavitation*. The consequences are an interconnected pressure pulsation and condensation and reevaporation of the vapor pockets constituting a series of explosions, or more strictly implosions, with resulting mechanical vibration and pitting of the conduit walls. The experiments here described were directed to determine the critical point or cavitation limit, at which cavitation begins, and not to ascertain the consequences of maintained cavitation.

The principles governing the incidence of cavitation in hydraulic machines such as turbines and pumps were analyzed and formulated by one of the authors at the Hydroelectric Conferences of 1922[3] and 1925[4] in Philadelphia and by D. Thoma at the First World Power Conference in 1924 at London,[5] and need not be repeated here. The use of Dr. Thoma's simple and convenient expression for the criterion of cavitation has become well standardized and will be adopted here. The relation is $\sigma = (H_b - H_s)/H$, in which H is the effective head producing flow through the system; H_b is the height of a water barometer or the atmospheric head minus the vapor-pressure head, that is, $H_b = H_a - H_{vp}$; H_s is the elevation of the point where cavitation begins above the free-water surface under static conditions such as the tail-water surface in the case of a turbine or pump; and σ is a coefficient which is a constant for a given apparatus. The relation is not limited in application to machines having moving parts, but is equally applicable to stationary conduits.

Questions have been raised as to the validity of this relation, and it has been stated by J. C. Hunsaker[6] in reporting on experiments on a special profile that "Experience with the profile shows that cavitation commences at pressures much higher than the true vapor pressure." (The authors suggest that the pressure here referred to may not have been that at the point of lowest pressure; also, that separation of air may be distinguished from true cavitation due to separation of condensable vapor.) It must be admitted that although the derivation appears to be based on logical deduction and its use in turbine practice seems to be satisfactory, nevertheless it is desirable to obtain direct experimental evidence of its validity or non-validity.

In the experiments here described, the formula was applied to a stationary conduit of simple form, namely a small venturi meter, in which the throat section can be relied upon to give good velocity distribution without curvature of the flow lines and to provide a piezometer location which may reasonably be expected to record the lowest pressure in the system. To avoid a varying elevation of the region of cavitation the conduit was kept horizontal. The entrance and discharge diameters were the same, so that the effective head producing flow was merely the difference in pressure heads, requiring no velocity-head corrections.

The Method Applied

As an indication of the performance of the apparatus, the authors used a ratio of heads representing the efficiency of conversion of velocity head into pressure head in the diffuser, or enlarging tapered section; that is

$$e = (h_{p3} - h_{p2})/(h_{p1} - h_{p2})$$

in which h_{p1}, h_{p2}, and h_{p3} are the pressure heads at entrance,

throat, and discharge, respectively, expressed as heights of water column above the centerline of the conduit, and e is the efficiency of the diffuser based on pressure heads (without introducing the small velocity heads at entrance and discharge). This ratio was used as an indicator because the deceleration process may be expected to be particularly sensitive to change of flow pattern. The tests were run to determine whether the point of

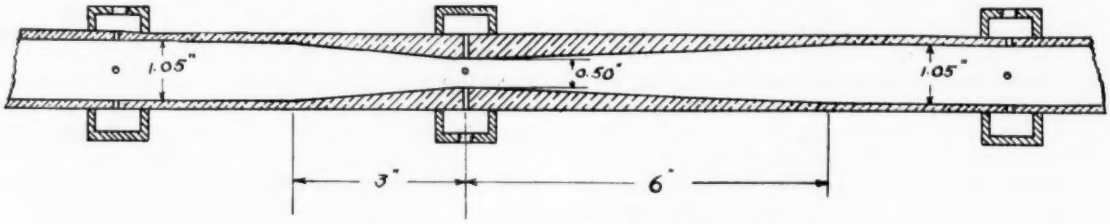

FIG. 1 CROSS-SECTION OF VENTURI METER

cavitation as evidenced by a sudden dropping-off in efficiency or discontinuity in the efficiency curve would coincide with the reaching of the vapor pressure at the throat of the conduit. The difference in pressure heads between discharge and throat is dependent on the velocity head and may be expressed as a coefficient σ multiplied by the effective head producing flow or

$$h_{p3} - h_{p2} = \sigma H$$

The absolute pressure at the throat is

$$H_{p2} = h_{p2} + H_a = h_{p3} + H_a - \sigma H$$

in which H_a is the atmospheric pressure head. As H is increased, H_{p2} decreases until it reaches the limit H_{vp}, the head corresponding to the vapor pressure. This according to the theory is the cavitation point, and the corresponding σ can be found from the equation

$$\sigma = (h_{p3} + H_a - H_{vp})/H = (H_b + h_{p3})/H$$

in which H_b is the barometric head $H_a - H_{vp}$.

If the pressure at discharge is lower than atmospheric, and the top of the water column is H_s ft below the elevation of the throat, then h_{p3} becomes $-H_s$, and $\sigma = (H_b - H_s)/H$, the form used for turbines or pumps.

By plotting the efficiency of the diffuser e versus σ, a point of discontinuity in the curve will indicate a change in the mode of flow such as would be caused by the formation of a vapor pocket. If the theory is correct this point should coincide with the point where the absolute throat pressure just reaches the vapor pressure of the water.

Finally, the results were plotted, as shown in Figs. 4 and 5, from which it will be seen that the break in the curve of efficiency versus σ, Fig. 5, coincides exactly with the reaching of the vapor pressure at throat as shown by Fig. 4. The corresponding values of the throat pressure are also shown in Fig. 5 for various values of σ, to show this coincidence more clearly. The slight slope of the efficiency curves in the region of no cavitation reflects the changing Reynolds number. The two curves for different ranges of back-pressure show agreement with the theory in each case.

APPARATUS AND PROCEDURE

The work described in this paper was conducted in the hydraulic laboratory of the Princeton University School of Engineering with the apparatus layout shown in Figs. 1 and 2. The venturi meter used was of brass, manufactured in the shop at the University. Before the tests were made, the instrument was carefully cleaned and the piezometer openings smoothed off with fine emery cloth. The throat diameter was 0.50 in. and the upstream and downstream sections measured 1.05 in. in diameter.

The water for these experiments was pumped from the laboratory sump to a tank on the top floor of the building from which it flowed by gravity through $1^1/_2$-in. piping to the venturi meter. The water was then discharged through $1^1/_2$-in. piping into a

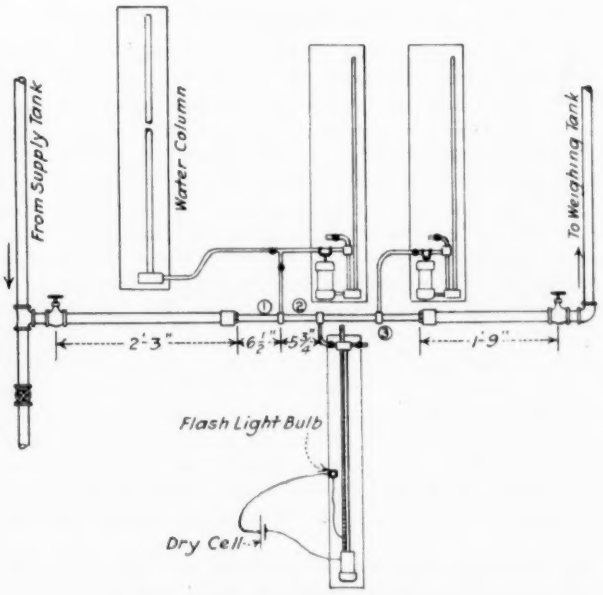

FIG. 2 GENERAL LAYOUT OF APPARATUS

pair of weighing tanks which were not used in this series of experiments.

Many types of gages were used before suitable instruments were obtained. There was so much oscillation in the plain U-tube manometer that it had to be modified for use in this connection. The gages for measuring the pressures at points 1 and 3 in Fig. 2 were made as shown by using a 2-in. pipe nipple capped on both ends, as a mercury pot. The pot was connected by a $^1/_8$-in. nipple to a cast-iron header which held the gage glasses. The gage glasses were $^3/_8$-in. outside diameter and $^1/_4$-in. inside diameter and were held in the header by means of rubber stoppers. Meter sticks graduated in millimeters were used as scales on all gages. The gage for recording the pressure at the throat of the meter had to be made differently because of the vacuum at this point. The gage which was finally successful was similar to a barometer but the scale was adjustable and was fitted with a strip of stainless steel set at its exact zero mark. The strip was connected through a dry cell to a flashlight bulb, so that when the point touched the mercury level in the pot, the circuit was completed and the bulb would light. It was found that this arrangement was very sensitive and gave excellent results.

The top of the gage glass was connected by means of a cast-iron header to the throat of the venturi. This header had to be made extremely tight and was boiled in paraffin to close all pores. As finally used, this gage was able to hold a 28-in. vacuum overnight. Connections to all gages were made with $^1/_4$-in. copper tubing and Dole compression fittings. Valves and vent valves on the gages were $^1/_8$-in. Dole needle valves. A water column 10 ft high made of $^1/_2$-in. glass tubing was used as a calibrating device for the gages.

The specific gravity of the mercury was first checked by finding the deflection of the mercury manometers as compared to a given height of water column. This varied slightly from day to day due to changes in temperature.

The downstream valve was opened up as wide as possible and the flow regulated by the valve upstream. It was found that as the quantity of water passing through the meter increased, the absolute pressure at the throat of the meter decreased to a certain point when it became constant no matter how much the velocity of the water at the throat was increased. This then should be the vapor pressure of the water. However, this pressure was always between 2 and 3 in. of water lower than the vapor pressure shown by the steam tables for water at the temperature used in the tests.

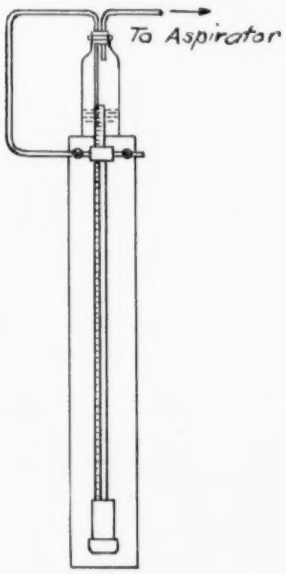

FIG. 3 APPARATUS FOR FINDING VAPOR PRESSURE

The water used in the tests was obtained from a well and it was found to be fairly hard. It was decided then to find the vapor pressure of the water. This was done by means of a static water column connected to a bottle and connected in turn to an aspirator, as shown in Fig. 3, forming a water barometer. This procedure gave a vapor pressure for the water which corresponded exactly with the minimum pressure found in the venturi meter. In order to check this method of determining vapor pressure, distilled water was placed in the bottle and gage connections, and the experiment repeated. The vapor pressure found in this way agreed with the value given in the steam tables for water at the temperature which was being used.

A series of runs was made with the discharge valve wide open and a second series with this valve partly throttled. For each series of runs, the pressure at the throat of the meter was progressively lowered by adjusting the inlet valve, runs being taken at suitable intervals. As many points as possible were taken just before cavitation took place and also just after it had occurred. Also a number of runs were taken beyond the cavitation point. For each run, the pressures at the entrance to the meter, the throat of the venturi, and the exit from the instrument were read as nearly as possible at the same time. Since cavitation should begin at the upper wall of the throat rather than at the centerline, the heads were corrected to correspond to this point as a datum elevation. The observed data taken during the runs and the results of the tests are given in the appendix of the paper. Before the meter was cleaned out, no noticeable noise was produced when cavitation occurred, but after the greasy deposit on the walls had been removed, cavitation caused a continual noise with periodic major disturbances causing a considerable variation in pressure at points 1 and 3, Fig. 2. This sound effect gives secondary evidence of the beginning of cavitation.

CONCLUSIONS

While the authors have no basis for asserting that the cavitation formula will satisfy all conceivable arrangements and conditions, these experiments appear to answer the question of its validity, for the apparatus and conditions adopted, by confirming it. This was true for two different values of back pressure, showing that σ remains constant and independent of the back pressure, in accordance with the theory. It was found that when dealing with hard waters, heavily charged with salts, the vapor pressure may be appreciably higher than that given for distilled water in the steam tables, and when applying the formula to unknown waters a small allowance should be provided in the value of H_b to cover this factor. At least when using ordinary run-of-laboratory water free from abnormal air content, the formula appears to be perfectly satisfactory, without modification.

In brief, these experiments give results entirely consistent with the cavitation principle as now generally applied.

The Measurement of Air Flow in Fan Inlet and Discharge Ducts

By LIONEL S. MARKS,[1] CAMBRIDGE, MASS.

This paper is devoted to a proposed method for determining the volume of air handled by any fan which is provided with either inlet or discharge ducts. The proposal is to use pitot tubes for capacities near the wide-open condition and square-edged inlet or discharge orifices for lower capacities down to the no-flow condition. To make the pitot-tube measurements accurate, a standard form of pitot tube is suggested, based on the investigations of Ower[2] and the unpublished researches of Merriam and Spaulding at Worcester Polytechnic Institute. The coefficients of Ebaugh and Whitfield[3] are suggested for use with inlet orifices, while those of Stach[4] are suggested for discharge orifices used with flange pressure taps on the approach side. The alternative procedure of using an impact tube with the discharge orifice is discussed, but coefficients are not as yet available.

IN MAKING tests of fans with inlet or discharge ducts, the volume of air to be measured will vary from a maximum to zero, the variation being obtained by changing restrictions on either the inlet or the discharge side of the fan. The restriction may either be separate from the volume-measuring device or may be an essential part of it.

The volume-measuring devices and restrictions which come under consideration are (1) the pitot tube, with independent restrictions; (2) a single nozzle in the duct (duct nozzle) with independent restrictions, or a series of nozzles used individually, acting as restrictions; (3) a series of inlet or discharge nozzles at the end of the duct, acting as restrictions; (4) an orifice in the duct (duct orifice) with independent restrictions, or a series of orifices acting as restrictions; and (5) a series of inlet or discharge orifices, acting also as restrictions.

No one of these devices is satisfactory for the complete range of operation of a fan. The pitot tube will not give accurate indications at low fan capacities; nozzles and orifices will not permit the investigation of a fan with wide-open discharge. When a large single nozzle or orifice is used (with supplementary restricting devices), it will not give accurate indications at low capacities; while if the single nozzle or orifice is small, it will not permit fan operation near the wide-open condition.

As between nozzles and orifices, assuming that the coefficients of both are equally definite for stated conditions and that they have been determined with equal accuracy, the choice must fall on the orifice. In fan testing, the ducts may be as large as 10 ft diameter. Well-rounded nozzles of large size are costly and heavy. Other nozzle forms, fabricated from sheet metal, have been proposed, but they cannot be made inexpensively of any desired exact form and dimensions, and consequently their coefficients cannot be ascertained with accuracy. Moreover, they are heavier and more costly than orifices. The one advantage of a well-rounded nozzle is that its coefficient can be determined with sufficient accuracy by means of a traverse with a small impact tube. Such a nozzle is more nearly a primary standard for the measurement of large quantities of air than any of the other devices proposed. As such it may be used for the calibration of other measuring devices such as the orifice. When the coefficient of an orifice has been determined by the use of a nozzle or other means, it becomes just as accurate as the nozzle and is much cheaper and more convenient.

A duct orifice is practicable only for a single orifice because of the difficulty involved, and the time consumed, in changing orifices in a large-sized duct. A single orifice presents the disadvantages stated previously of having either low accuracy at low capacities or of preventing fan operation near the wide-open condition. Moreover, this method requires a considerable total length of duct. The only advantage of duct orifices over discharge orifices is that the coefficients for duct orifices have been well established by a number of investigators.

There remains the use of a series of orifices either at the entrance to the inlet duct (inlet orifices) or at the end of the discharge duct (discharge orifices). This is the simplest and most convenient method of measuring air and is comparatively inexpensive. Its only disadvantage is that it is not applicable to measurements at or near the wide-open condition.

It would appear from this survey that two of the methods enumerated for measuring the flow of air in a fan duct have definite advantages over all the other methods. The pitot-tube method can be made quite satisfactory at higher fan discharges, while the square-edged inlet or discharge orifice is equally satisfactory at lower fan discharges. A combination of the two methods should permit accurate volume measurements throughout the whole range of fan operation. The author proposes, therefore, that in testing fans which are to be used with inlet or discharge ducts, the air measurements be made by a pitot-tube traverse at capacities approximately down to the capacity at maximum efficiency and from there down, by square-edged orifices. Pitot-tube traverses should also be made while the two largest orifices are

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until January 10, 1936, for publication at a later date.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

in use so as to determine the accordance of the two methods of measurement.

Before the proposed method can be used satisfactorily, it is necessary (1) to standardize the pitot tube and methods of using it, and to know its errors, and (2) to standardize the square-edged orifice and methods of using it, and to ascertain its coefficients under various conditions of use.

Standardization of the Pitot Tube

The desirable characteristics of a standardized pitot tube are (1) known coefficients, eliminating the necessity for calibration; (2) ease of duplication with ordinary machine-shop processes; (3) insensitivity to minor changes in form and dimensions; (4) static holes as near the tip as possible; (5) rigidity; and (6) small size.

The features to be considered while designing such a standardized pitot tube are (1) diameters, thicknesses, and materials of the outer and inner tubes; (2) the shape of the impact tube; (3) the size of the impact opening; (4) the distance of the static holes from the tip; (5) the distance of the static holes from the stem; and (6) the size, number, and arrangement of the static holes.

The researches of Ower and Johansen,[2] and the unpublished researches of Merriam and Spaulding at Worcester Polytechnic Institute give the necessary data for selecting a design. The two entirely independent investigations, covering to a large degree the same field, give results remarkably accordant and justify complete confidence in their reliability.

The selection of diameters and thicknesses of the inner and outer tubes is arbitary. Adequate stiffness can be obtained for traversing ducts 3 or 4 ft across by making the outer tube of 0.04-in. thick brass (No. 18 gage), $^5/_{16}$ in. outside diameter, and the inner tube preferably of 0.0285-in. thick copper (no. 21 gage), $^1/_8$ in. outside diameter. Other sizes may be used without affecting accuracy as long as geometrical similarity is maintained.

The shape of the impact tube should preferably be hemispherical. A conical tip of proper design will give equally satisfactory results, but it is more liable to damage, increases the total length of the tube, and locates the static openings at a greater distance from the impact opening.

The diameter of the impact opening is immaterial when the tube is directed accurately into the air stream, but has considerable influence on the impact readings under conditions of yaw. This is illustrated, for a hemispherical head, by the following tabulation taken from the work of Merriam and Spaulding at Worcester Polytechnic Institute:

Ratio of impact opening to tube diameter	0.5	0.4	0.3	0.2
Error in impact reading, per cent of velocity head, with 16-deg yaw	3.3	4.5	6.0	8.5

The velocity-head reading under conditions of yaw will vary with both the impact reading and the static reading. If the errors of both impact and static readings in yaw were of the same sign and magnitude, the errors would cancel and the velocity-head reading would be correct. This desirable condition cannot be realized by any known design of pitot tube. With an impact opening 0.2 times the diameter and with the static-hole design recommended later in this paper, the velocity-head readings vary less with yaw than when the impact openings are larger.

If it is desired to find only the velocity or volume of the air flowing, an impact opening of 0.2 times the tube diameter should be selected. But in fan testing it is also necessary to find the work done on the air and this is proportional to the product of (1) the volume of air delivered, and (2) the impact pressure. An impact opening 0.2 times the tube diameter gives satisfactory values of the difference between impact and static pressures up to 12-deg yaw but gives larger errors in the values of the impact pressure, and of the work done on the air, than result from the use of an impact opening 0.4 times the tube diameter. This latter dimension appears to be the best to select for fan testing. With an effective straightener to eliminate yaw, all sizes of impact opening would give the same indications. The depth of this opening has no influence on the impact reading.

The variation of velocity head with yaw, and the error in the calculated work done on the air, with zero static pressure, for an impact opening 0.4 times the tube diameter (with stem-effect error included) is found to be:

Yaw angle, deg	8.0	12.0	16.0	20.0
Error in velocity head, per cent	—0.8	—1.7	—0.5	1.7
Error in work done, per cent	0.1	0.5	4.3	8.2

The error in calculated work done on the air diminishes as the static pressure is increased, being halved when the static pressure is equal to the velocity head.

The distance from the static holes to the tip of the tube, is made up of the length of the tip proper (conical or hemispherical portion) and a length of straight tubing between the tip proper and the static holes. The latter alone is found to have an influence on the static readings. This influence is considerable. The effect of the tip is to make the static reading less than the true static reading by an amount which depends on the length of straight tubing between the static holes and the tip, and on the velocity head. The error diminishes rapidly as the length of straight tubing increases, and becomes practically constant when this length is eight tube diameters. At this location the static-pressure reading is low by about 0.2 per cent of the velocity head according to Ower;[2] it is still smaller according to Merriam and Spaulding. This distance of eight tube diameters is indicated as desirable for the location of the static holes.

The distance from the static holes to the stem has an important influence on the static reading. According to Ower,[2] the presence of the stem increases the upstream static pressure as in the following tabulation:

Distance of stem aft of static holes, in tube diameters	5	10	15
Excess pressure due to stem, in per cent of velocity head	1.75	0.8	0.5

The investigations of Merriam and Spaulding show a slightly greater pressure excess. As this error cannot be eliminated without removing the stem to an impracticably great distance, and as the error changes very slowly after a length of 16 diameters, it seems desirable to select this length of 16 diameters for the distance between the static holes and the stem axis.

With the stem extending across the duct (which may be desirable for very large ducts) the static error has twice the value just given in the tabulation and, therefore, for a 16-diameter length, may be as much as 1 per cent of the velocity head.

The number of static holes and their distribution around the tube is determined principally by the consideration that the degree and direction of yaw, for the air current being measured, will ordinarily be unknown. Consequently the static holes should be uniformly distributed around the tube and should be numerous. The logical development of this concept leads to a gap instead of a number of holes, as in the the Prandtl tube. The objection to the gap is that it reduces the rigidity of the tube and in practice may lead to slight flexure at the gap. This would have the same effect as a burr and, while difficult to see, would materially affect the static reading. Eight holes with even spacing are suggested as a satisfactory compromise. If these holes are 0.04 in. diameter, they will take away less than one-third of the tube material.

The size of the static holes influences the static-pressure error

under yaw. Small holes (0.02 in. diameter) have the advantage of giving comparatively small errors in yaw but are likely to clog and yield static readings which under yaw conditions are very sensitive to changes in diameter. With holes 0.04 in. diameter, the following results were obtained by Merriam and Spaulding:

Yaw angle, deg	8.0	12.0	16.0	20.0
Static error, per cent of velocity head	1.5	3.5	5.5	8.0
Static error, including stem effect, per cent	1.0	3.0	5.0	7.5

It is proposed for the purpose of achieving comparative insensitiveness to slight imperfections, that the static holes be made 0.04 in. in diameter. One other feature is recommended. The inner tube should be maintained coaxial with the outer tube in the vicinity of the static holes. A spacing ring soldered to the

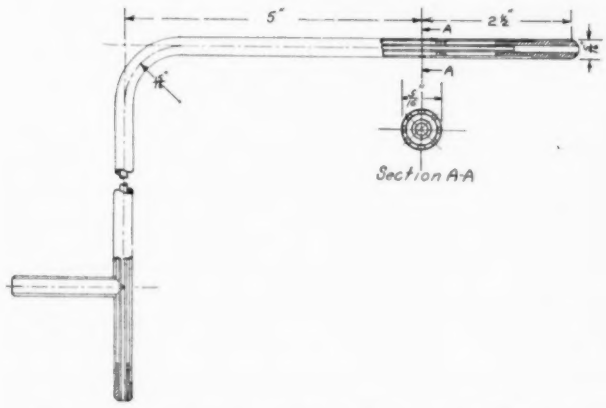

FIG. 1 PROPOSED STANDARD PITOT TUBE FOR FAN TESTING

copper tube will achieve this object. A pitot tube embodying the proposed features is shown in Fig. 1.

SQUARE-EDGED ORIFICES

The proposal to use square-edged orifices as a measuring device in fan testing is based upon the assumption that these orifices will always be comparatively large. If they are small, the condition of the edge of the orifice may influence appreciably the coefficient of discharge. Orifices above 8 in. diameter (approximately) will give predictable coefficients of discharge when they are machined with ordinary care and all burrs are removed. For smaller orifices, greater care is necessary; when the diameter is as small as 1 in., the orifice coefficient will be found to vary considerably with the condition of the edge of the orifice in which case the nozzle is preferable.

In addition to the minimization of the effect of edge sharpness when the orifice is large, there is the further fact that the coefficient varies but little with orifice size when the size is considerable. The elimination of these two disturbing factors leaves the orifice coefficient a function of two factors only: (1) the Reynolds number, and (2) the ratio of orifice area to duct cross-sectional area. These factors are considered later.

INLET ORIFICES

Square-edged inlet orifices have been investigated recently by Ebaugh and Whitfield[3] for a 22³/₄-in. duct with a 20 to 100 per cent orifice-area ratio. Some earlier work by Watson and Schofield[5] deals only with small orifices from ½ to 2 in. diameter and for very small orifice-area ratios and is not applicable to fan conditions. Both these investigations show discharge coefficients very close to 0.6. The volume of air flowing is based entirely upon the pressure drop at the orifice and this necessitates a choice as to the location of the pressure tap in the duct. The Ebaugh and Whitfield coefficients[3] are based on the location of the pressure tap in the plane of the vena contracta.

The recent investigations of Stach,[4] using the I.S.A. form of square-edged orifice with flange taps and carried out on a 10-in. duct with orifice-area ratios of 0.25, 0.36, 0.49, and 0.64 give a constant value of the coefficient of discharge of 0.60 for Reynolds' numbers in excess of 55,000. The accuracy of the coefficient is given by the following percentage tolerances:

Orifice-area ratio	0.25	0.36	0.49	0.64
Tolerance, per cent	+ 1.3	± 1.0	± 0.5	± 0.5

It would appear, using flange taps, that the coefficient of discharge is not quite constant and that the assumption of constancy leads to larger errors than are permissible at low orifice-area ratios. As a practical matter, it is desirable to have a definite location for the downstream pressure tap. Ebaugh and Whitfield[3] find that a location 40 per cent of the pipe diameter downstream will permit the use of a constant coefficient of 0.601 throughout a considerable range of orifice-area ratios with an error of less than 0.5 per cent for ordinary pressure drops.

The large amount of research on pipe orifices cannot be considered applicable to the conditions of an inlet or a discharge orifice. The bibliography of Ebaugh and Whitfield[3] does not include any investigations which actually apply to an inlet orifice of a size suitable for the testing of fans. While their work needs verification by others and extension to larger ducts, greater pressure drops, and smaller orifice-area ratios, it may be accepted for the present.

DISCHARGE ORIFICES

Square-edged discharge orifices have been investigated by Durley[6] up to 4½ in. diameter for very small orifice-area ratios. by Muller[7] up to 2½ in. diameter with large orifice-area ratios, and by Stach[4] for orifices from 5 to 8 in. diameter in a 10-in. duct.

The work of Durley[6] and Müller[7] does not cover the range of orifice sizes important in fan testing. The work of Stach[4] with I.S.A. orifices having flange pressure taps before the orifice, was for the same set of conditions as those stated previously, in the discussion of inlet orifices. The coefficients which Stach found are slightly lower than those for pipe orifices and vary with the orifice-area ratio m. The values are:

m	0.05	0.10	0.15	0.20	0.25	0.30	0.35
coefficient	0.598	0.602	0.608	0.615	0.624	0.636	0.651
m	0.40	0.45	0.50	0.55	0.60	0.65	0.70
coefficient	0.666	0.682	0.701	0.724	0.751	0.784	0.820

These values are found to hold for Reynolds' numbers R in excess of the following values:

m	0.25	0.36	0.49	0.64
R	45 000	55,000	75,000	183,000

The accuracy of these coefficients is given as ± 0.8 per cent. They apply to the simple flow equation $V^2 = 2gh$; and include the correction for velocity of approach.

The investigations of Stach[4] were made with a high degree of precision and his results apparently may be used with confidence.

The Reynolds numbers for inlet and discharge orifices in fan tests will ordinarily be in excess of the limit set by Stach.[4] The

absolute viscosity μ of air varies from 1.175×10^{-5} at 32 F, to 1.51×10^{-5} at 212 F, in lb-ft-sec units, the variation being proportional to the temperature change. The Reynolds number is $DV\rho/\mu$, where D is the orifice diameter, ft; V is the velocity of air in the orifice fps; and ρ is the density of the air in lb per cu ft. At 70 F with standard air density of 0.075 lb per cu ft, $\rho/\mu = 6.05 \times 10^3$. Assuming the lowest practical pressure drop through the orifice as 0.1 in. of water, which corresponds to an air velocity of approximately 21 fps, and assuming an orifice diameter of 0.5 ft, the Reynolds number $R = 0.5 \times 21 \times 6.05 \times 10^3 = 6.35 \times 10^4$. The conditions here assumed are those which would give the minimum value of R that is likely to occur in fan testing. It will be seen that Reynolds' numbers for actual fan-test condition generally will be in excess of Stach's minimum for constant-discharge coefficients for square-edged orifices. Any doubtful case should be calculated.

The weight or volume of air flowing through a discharge orifice may be determined either from observations of the drop of static pressure through the orifice or from impact-tube readings. In recorded investigations, only the pressure-drop method appears to have been used. It would seem, however, that the impact-tube method is as applicable here as it is for nozzles and that it has the same advantages.[8]

A traverse along the center line of the orifice shows that for orifices 8 in. diameter or larger, the impact reading is constant from the plane of the orifice to several inches out from that plane, and that it falls off slowly at increasing distances. Therefore, it is proposed that the impact tube be placed at a distance of 1 in. out from the plane of the orifice.

The weight of air discharging from a square-edged orifice is given by the equation[9]

$$w = 0.1145\, c\, D^2 \sqrt{(GBi/T_1)}$$

where w is the weight of air flowing, lb per sec; c is the coefficient of discharge; D is the orifice diameter, in.; B is the mean discharge pressure, in. of mercury; i is the impact pressure, in. of water; T_1 is the temperature of the air approaching the orifice, deg F abs; and G is the specific gravity of the air referred to normal dry air at the same pressure and temperature. The quantity B is preferably the mean of the static pressures on the two sides of the orifice, since this gives a somewhat greater constancy of coefficient of discharge than the use of the discharge (barometric) pressure. For small pressure drops it is immaterial which of these pressures is used; with a pressure drop of 1 in. of water the difference in weight of air flowing is only 0.125 per cent, and for a pressure drop, of 4-in. of water it will be 0.5 per cent. No coefficients are available at present for the determination of the volume of air flowing through a square-edged discharge orifice by means of an impact tube.

A desirable form and method of assembly of the square-edged orifices is shown in Fig. 2. The orifices are made from $^1/_4$-in.

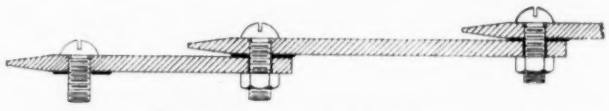

FIG. 2 SUGGESTED FORM AND METHOD OF ASSEMBLING SQUARE-EDGED ORIFICES

steel plate and are provided with studs to facilitate assembly. The studs are round-headed machine screws, $^3/_8$ in. diameter, threaded the whole length, and with the thread cut away in the immediate vicinity of the head. These screws are threaded into holes spaced 6 in. apart in the orifice ring; the holes are slightly countersunk on the entering side. If screwed up tight, the screws will act as studs. The studs are $1^1/_2$ in. from the orifice and are found to have no perceptible influence on the flow. A ring of hard packing such as vellumoid is shellacked on the back of each ring and the exposed face of the packing is graphited. A series of these orifices can be built from any desired maximum size, by steps of at least 4 in., down to any desired minimum size.

As shown in Fig. 2, the orifice plate is tapered on both sides for a distance of $^3/_4$ in. from the orifice, with a slope of 1 in. in 8 in., leaving a thickness of $^1/_{16}$ in. at the orifice. The purpose of this taper (which differs from the usual practice of having the approach side of the orifice flat and only the discharge side tapered) is to have an arrangement which will work equally well both for inlet orifices and discharge orifices. The justification is experimental. The author has investigated large orifices which were identical except that one was tapered, as in Fig. 2, and the other made in the usual manner with a flat approach side. The coefficients for orifices of this type are slightly higher than for the standard type.

The Definition of the Quantity-Head Characteristic of Fans

By M. C. STUART[1] and W. E. SOMERS,[2] BETHLEHEM, PA.

The purpose of a fan characteristic is to delineate usetul information regarding the performance of a fan in its installation. Specifically, the quantity-head characteristic shows the quantity of air delivered against a certain resistance in the intended installation. The authors discuss the set up of four basic arrangements of fan types and installations, and describe three currently used fan-head definitions. The definitions of fan head are evaluated, the fan head being defined as the discharge static head minus the inlet total head. A primary arrangement of each type of fan is described and a single primary quantity-head characteristic for each type of fan is defined. If a fan is installed in any arrangement other than its primary one, the primary characteristic cannot be assumed to apply, but a separate test must be conducted to determine its characteristic in its intended arrangement. Results of complete tests of a fan installed in its four possible arrangements are given to illustrate the principles which are set forth.

THE purpose of a fan characteristic is to delineate useful information regarding the performance of a fan in its installation. Specifically, the quantity-head characteristic shows the quantity of air which will be delivered against a certain resistance in the intended installation.

In general, it may be stated that for a given fan there does not exist a single easily defined relationship between the quantity of air discharged and the head produced by the fan. The two circumstances accounting for this situation are (1) the lack of agreement upon a definition of the term "head" as applied to fan performance, and (2) the performance of a given fan is influenced markedly by the different arrangements required in various applications.

He was selected for fellowship on graduation and has continued in that position for the past two years. At present he is employed as a cadet engineer with the Babcock and Wilcox Company, Barberton, Ohio.

Contributed by the Power Test Code Committee No. 10 on Centrifugal and Turbo-Compressors and Blowers for presentation at the Annual Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, New York, N. Y., December 2 to 6, 1935.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until January 10, 1936, for publication at a later date.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

DESCRIPTION OF BASIC FAN ARRANGEMENTS

An investigation of the different ways in which the arrangement of a fan in its application may affect the quantity-head characteristic reveals that four basic installation arrangements cover all cases. Before describing these basic arrangements the fan must be defined.

Prof. L. S. Marks in a series of papers[3] has shown that inlet boxes and other attachments at the inlets and outlets of fans have considerable effect on the performance of the fan in certain cases. Therefore, it is necessary in defining the fan to include not only the housing, but to have a definite understanding as to what attachments, such as inlet boxes, diffusers, mounting rings, flanges, dampers, etc., shall be considered as part of the fan. Having an understanding of what constitutes the fan, the four basic installation arrangements which are required to cover the various applications may now be developed. These basic installations are shown in Fig. 1 as arrangements *A*, *B*, *C*, and *D*.

Arrangement A—Bare Fan. In this arrangement there are no ducts attached to the fan; the intake is from one large space or room and the discharge is into another large space. This arrangement is that usually thought of in applications of propeller fans, although it is equally applicable to any housed fan. It may alternately be referred to as a wall installation.

Arrangement B—Blower. This arrangement consists of a fan installation with intake direct from a large space or room but discharging into a duct. This is the usual blower arrangement and is applicable whether the blower is of the centrifugal or the propeller type.

Arrangement C—Booster. This arrangement provides an intake through a length of duct and a discharge from the fan into a discharge duct. This arrangement is applicable to propeller as well as centrifugal-type fans thus installed.

Arrangement D—Exhauster. In this arrangement the intake is through an inlet duct but the air is discharged directly into a large space. It is applicable to all types of fans thus installed.

HEAD DEFINITIONS

Velocity Head h_v. The definitions of heads may be more readily understood if it is recognized that all heads represent essentially energy per pound of fluid. The velocity head at any point in the system, if expressed in feet of the fluid flowing, is the kinetic energy per pound of fluid at that point. This head expressed in inches of water is proportional to the kinetic energy by a factor involving the ratio of the density of water to that of the fluid flowing. In this investigation the velocity heads at the specified points in the inlet and discharge ducts were calculated from the quantity flowing, as measured by a nozzle installed

TABLE 1 QUANTITY-HEAD CHARACTERISTICS FOR THE INSTALLATION ARRANGEMENTS IN FIG. 1

Installation arrangement	Fan total head, H_T		Fan static head — 1st def., H_S		Fan static head — 2nd def., H'_S
A—Bare fan	H_{TA}	=	H_{SA}	=	H'_{SA}
B—Blower	H_{TB}		H_{SB}	=	H'_{SB}
C—Booster	H_{TC}		H_{SC}		H'_{SC}
D—Exhauster	H_{TD}	=	H_{SD}		H'_{SD}

NOTE: Characteristics H_{TA}, H_{SA}, and H'_{SA} can be represented by a single curve. Characteristics H_{SB} and H'_{SB} can be portrayed by a single curve. Characteristics H_{TD} and H_{SD} can be portrayed by a single curve. A separate curve is required for each of the following characteristics: H_{TB}, H_{TC}, H_{SC}, H'_{SC}, and H'_{SD}.

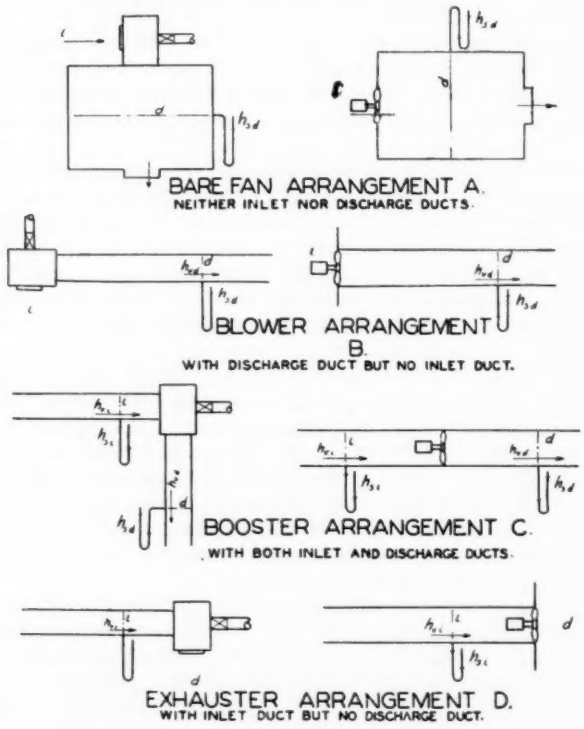

FIG. 1 BASIC ARRANGEMENTS OF FAN INSTALLATIONS

elsewhere in the system, and a knowledge of the duct area at the points in question.

Static Head h_s. Static head, if expressed in feet of the fluid flowing, is the work required per pound to cause the fluid to move against the pressure measured, in fan work, above atmosphere. This static head is equal to the product of the pressure above atmosphere and the specific volume of the air. It has been variously named pressure energy, flow work, displacement energy, and pressure head. This head, if expressed in inches of water, is proportional to the pressure energy by a factor involving the ratio of the density of water to that of the fluid flowing. In this work the static head was determined by observation of the static-pressure gages attached at the specified points.

Total Head h_t. The total head at a point in the system is the sum of the pressure energy and the kinetic energy, both measured at the point in question. If this head is expressed in inches of water, it will be proportional to this sum of energies.

In fan performance we are concerned with certain changes in energy that the fan produces for a given discharge. These increases in energy are the differences between the corresponding heads at the discharge and the inlet. These differences in head will be called the "fan heads," represented by the general symbol H, as distinguished from h, which is the symbol for the head at a certain point.

Of the several possible fan heads which may be obtained from various differences between the inlet and discharge heads, only three have been considered of value in fan work. These three are defined in the following paragraphs.

Fan Total Head. Fan total head is the total head at some specified plane on the discharge side of the fan minus the total head at some specified plane on the inlet side. It can be expressed as

$$H_T = h_{td} - h_{ti}$$

where H_T is the fan total head, h_{td} is the discharge total head, and h_{ti} is the inlet total head.

Fan Static Head—First Definition. The first definition of fan static head stipulates that this head is equal to the discharge static head minus the inlet total head, or

$$H_S = h_{sd} - h_{ti}$$

where H_S is the fan static head as given in this first definition, h_{sd} is the discharge static head, and h_{ti} is the inlet total head.

Fan Static Head—Second Definition. The second definition of fan static head stipulates that this head is equal to the discharge static head minus the inlet static head, or

$$H'_S = h_{sd} - h_{si}$$

where H'_S is the fan static head as given in this second definition, h_{sd} is the discharge static head, and h_{si} is the inlet static head.

With three definitions for fan head and four necessary arrangements to cover various applications, it appears that there are twelve possible quantity-head characteristic curves to completely cover the performance of a fan which has mounting flanges for inlet and discharge ducts, thus permitting it to be installed in any one of the four basic arrangements. However, twelve tests and as many corresponding curves are not required to determine and portray these characteristics.

THE FAN TESTS

In order to determine how the characteristics vary for the different arrangements, a fan was set up and tests conducted for all four basic arrangements, and the twelve characteristics computed. These characteristics are analyzed, both to evaluate their practical utility, and to determine the minimum number and character of the tests required to establish those characteristics which are considered to be of value. This leads to a definition of the quantity-head characteristic.

The tests were run on a single-inlet Clarage exhauster having forward-tilting blades. The inlet and discharge openings were both 9 in. in diameter. The fan was driven through a flexible coupling by a squirrel-cage induction motor of 1800 rpm synchronous speed.

The inlet and discharge ducts used were 9 in. in diameter and made of sheet metal, the joints being riveted and soldered to make them airtight. The inlet duct was 6 ft, or 8 diameters, long and the discharge duct was 10 ft, or about 13.5 diameters long. Brass bosses, drilled and tapped for $^1/_8$-in. pipe, were soldered on each duct for the static-pressure taps at points three-quarters of the duct length from the duct inlet. All burrs were removed from the edges of the static tap holes in the ducts.

All flow measurements were made with a 260-mm 1912 V.D.I. nozzle, using a coefficient of 0.97, placed at the outlet of a large test chamber 28 ft long and 33 in. in diameter. When the discharge duct was connected to the fan, the air was discharged from the duct into this test chamber, the control of the flow being made by means of a series of throttle plates inserted at the connection between the duct and the chamber as shown in arrangement *B* of Fig. 2. When no discharge duct was used the fan discharged directly into this test chamber as shown in ar-

rangement *A* of Fig. 2. Flow control was then effected by means of a multihole throttle plate inserted 10 ft downstream in this chamber. This plate also acted as a screen to straighten the flow for the nozzle approach.

In order to produce the four basic installation arrangements with the equipment described, it was set up as follows in the four test arrangements shown in Fig. 2.

Test Arrangement A—Bare Fan. The fan intake was directly from the room, and the discharge was directly into the test chamber.

Control of flow was effected by means of the multihole throttle plate 10 ft downstream in the test chamber.

Test Arrangement B—Blower. Intake was directly from the room, and the discharge was made through a discharge duct from which the air passed into the test chamber. The multihole throttle was removed, the chamber acting only as a device for smoothing the approach to the nozzle. Flow was controlled by means of the series of throttle plates at the point where the duct joins the test chamber.

Test Arrangement C—Booster. The intake was from the room through an inlet duct, and the discharge was through a discharge duct from which the air passed into the test chamber. Flow was again controlled by the series of throttle plates at the end of the discharge duct.

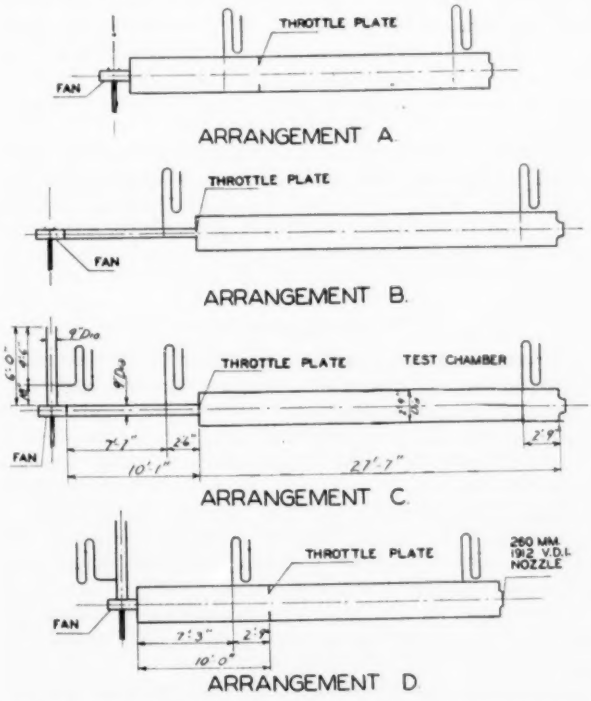

FIG. 2 FAN TEST INSTALLATIONS OF BASIC FAN ARRANGEMENTS

Test Arrangement D—Exhauster. The intake was again from the room through an inlet duct and the discharge was directly into the test chamber. The multihole throttle plate was used for flow control.

The inlet static head was measured, when required, by means of an inclined draft gage, read to 0.005 in. of water. The discharge static head was measured by a vertical U-tube water manometer. The velocity heads at the points at which the static heads were measured were calculated from the flow measured by the nozzle and the areas of the ducts at these points. When the fan discharged directly into the test chamber, the discharge pressure was read at a point 33 in. upstream from the throttle plate, or 2.7 chamber diameters after the discharge into the chamber. The nozzle differential was measured by means of an inclined-tube draft gage read to 0.001 in. of water. All draft gages were calibrated by means of a hook-gage manometer. Corrections were made to standard density, 0.07488 lb per cu ft, and to the fan speed of 1800 rpm. No measurements were made of power, since the scope of the investigation was limited to the study of the quantity-head characteristics.

Tests were conducted, giving six points, evenly distributed, on each characteristic curve for each of the four basic arrangements.

ANALYSIS OF DATA

Fig. 3 shows the 12 quantity-head characteristics obtained from this fan by applying the three definitions of fan head to the four

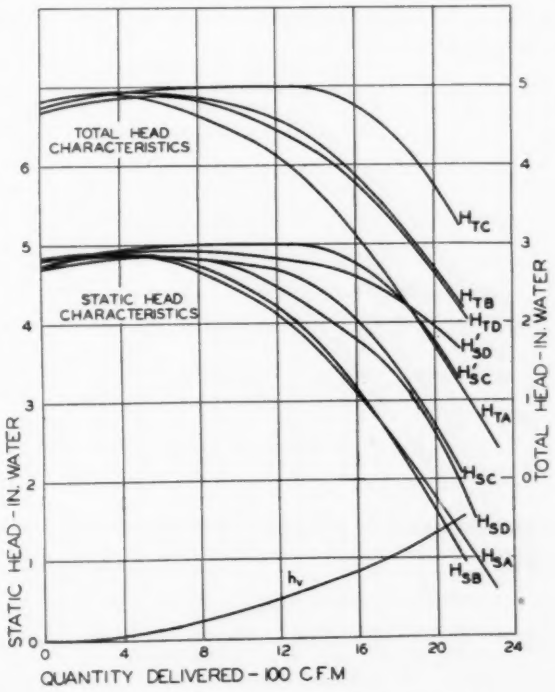

FIG. 3 QUANTITY-HEAD CHARACTERISTICS OF AN EXHAUSTER FAN

basic arrangements. The upper four curves are the total-head characteristics, while the lower group of curves are the static-head characteristics. These curves show the striking differences which exist between the characteristics for the different arrangements and for the various definitions of fan head. These differences show vividly the necessity for a very careful analysis of the definition of the quantity-head characteristic of fans. This is especially appreciated when it is recognized that these diverse curves represent results which may be obtained for a single fan by use only of definitions and arrangements which occur commonly in practice.

Before presenting a detailed analysis of the characteristics for each basic arrangement, a general principle will be stated relative to the places at which heads are measured or expressed. In any arrangement or definition, heads existing at the inlet must be measured at some specified plane on the inlet side, and heads at the discharge must be measured at some specified plane on the discharge side. On the discharge side of a blower for example, a procedure of adding heads measured at two different places on the discharge side is utterly untenable. The discharge total

head must be obtained by adding velocity and static heads, *both measured at the same plane.* This principle has been violated unfortunately, on occasion, in practice.

In arrangements where ducts are applied at the fan inlet or discharge, the heads are to be measured in the duct at a plane so located that the flow conditions have some measure of stability and uniformity. Where no duct is applied, the plane for head measurement may not be directly at the entrance to or exit from the rotor, because the uncertain flow conditions render impossible either the measurement or computation of heads at these places. The heads must be measured in these cases, at planes sufficiently removed from the fan inlet or discharge such that the kinetic energy at these planes is sensibly zero. In these circumstances the total head equals the static head.

Having established the places at which heads must be measured, indicated at i and d in Fig. 1, we may now proceed with the analysis of the characteristics as obtained for each basic arrangement.

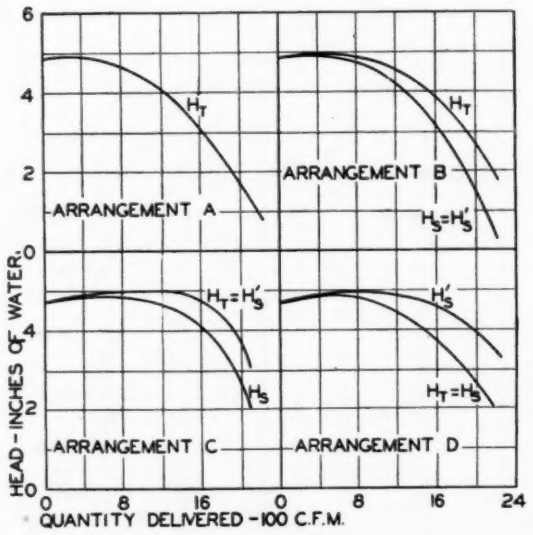

FIG. 4 QUANTITY-HEAD CHARACTERISTICS OF AN EXHAUSTER FAN SHOWN BY BASIC FAN ARRANGEMENTS

Arrangement A. It is recalled that arrangement A is for the bare fan, of either propeller or housed type, with no inlet or discharge ducts attached. The inlet total head, measured at i, Fig. 1, is equal to the inlet static head since the velocity head is sensibly zero at the plane of head measurement. The discharge total head, measured at d, is likewise equal to the discharge static head. Therefore, the single characteristic curve, shown in Fig. 4, represents the quantity-head characteristics of arrangement A for all three definitions of fan head.

Arrangement B. In arrangement B, which has a discharge duct but no inlet duct, the inlet heads are determined in open space at a plane i, Fig. 1, and the discharge heads are measured in the discharge duct at a plane d. The inlet static head will be equal to the total head. The discharge total head will be greater than the discharge static head by the amount of the discharge velocity head, all measured at plane d. This difference will cause the total-head characteristic to be higher than the static-head characteristic by the discharge velocity head, as shown in Fig. 4. However, the two definitions of fan static head give the same characteristic curve.

Arrangement C. As shown in Fig. 1, both inlet and discharge ducts are used in arrangement C. Therefore, the inlet heads are to be determined in the inlet duct at a plane i, and the discharge heads are to be determined in the discharge duct at a plane d. The inlet total head is greater than the inlet static head by the amount of the inlet velocity head. The discharge total head is greater than the discharge static head by the discharge velocity head. These circumstances cause the static-head (first definition) characteristic to be lower than the total-head characteristic by the discharge velocity head, as shown in Fig. 4. The second definition of fan static head is equivalent to adding the inlet velocity head to the fan head obtained by the first definition. This would, in general, make necessary three distinct characteristic curves applying to this arrangement. For this particular fan, however, the inlet velocity is the same as the discharge velocity, since the two ducts are of the same area. This makes the characteristic curve obtained by the second definition of fan static head coincide with the characteristic obtained by use of the fan total head.

Arrangement D. In arrangement D, it is recalled that there is an inlet duct but no discharge duct. The inlet heads are determined in the inlet duct at a plane i, while the discharge heads are measured at plane d, in open space at a distance sufficiently removed from the fan outlet that the velocity head is sensibly zero. The inlet total head and inlet static head, measured at plane i, differ by the inlet velocity head. The discharge total head is identical with the discharge static head, both measured at plane d, since the discharge velocity head is zero. Thus, the total-head characteristic and the static-head characteristic given by the first definition of fan static head will coincide, while the static-head characteristic given by the second definition of fan static head will be greater than these two by the inlet velocity head.

The various quantity-head characteristics for the four basic installation arrangements present the differences and equalities summarized in Table 1. It is seen from this table that a total of eight curves is required for the three head definitions and for the performance of fans arranged in the four basic installations shown in Fig. 1.

CHARACTERISTICS OF VARIOUS FAN TYPES

The foregoing analysis applies to fans provided with mounting flanges for inlet and discharge ducts, and thus adaptable to four possible installation arrangements. All fans do not have flanges to receive inlet and discharge ducts, however, and are thereby subject to certain limitations. The possible installation arrangements, the required test arrangements and the resulting characteristic curves for various fan types may now be established.

All fans may be classified under the four following types:

1 Fans with no mounting flanges for inlet or discharge ducts. Wall-type propeller or disk fans are frequently of this type.

2 Fans with no inlet-duct mounting flanges, but with discharge-duct mounting flanges. This is the common blower-type fan.

3 Fans with mounting flanges for both the inlet and discharge ducts.

4 Fans with inlet-duct mounting flanges, but no discharge-duct mounting flanges.

A wall-type propeller fan which is provided with no connections for ducts must be classified under type-1. It must be tested under arrangement A, and since this arrangement provides the only possible method for mounting such a fan, the single characteristic curve fully defines its performance.

A usual-type blower, having flanges for mounting only a discharge duct, is an example of type-2. The performance of this type fan for all its possible installation arrangements can be defined fully by three characteristic curves determined under test arrangements A and B.

Table 2 presents for each type of fan (a) all possible installa-

TABLE 2 NUMBER OF ARRANGEMENTS, CHARACTERISTICS, AND REQUIRED CURVES FOR VARIOUS FAN TYPES

	Fan type	Possible installation arrangements	Necessary test arrangements	Number of characteristics	Number of curves Per instal.	Number of curves Per type
1	No ducts	*A*	*A*	3	1	1
2	With discharge-duct flange only	*A*	*A*	3	1	3
		B	*B*	3	2	
3	With flanges for discharge and inlet ducts	*A*	*A*	3	1	8
		B	*B*	3	2	
		C	*C*	3	3	
		D	*D*	3	2	
4	With inlet-duct flange only	*A*	*A*	3	1	3
		D	*D*	3	2	

tion arrangements, (*b*) the corresponding necessary test arrangements, (*c*) the number of characteristics possible for each installation arrangement, (*d*) the number of curves required to portray the characteristics for each installation arrangement, and (*e*) the total number of curves required to portray all the characteristics possible for a given type of fan. The most significant deduction to be made from Table 2 is that from one to eight curves are required to portray the possible characteristics for the various fan types. It must be remembered that these characteristics are in strict accordance with the three currently used definitions of fan head as applied to the installation arrangements for which each type is adaptable.

Development of Fan-Head Definition

The purpose of a fan characteristic is to delineate useful and direct information regarding how the fan will perform in its installation. Specifically, the quantity-head characteristic shows the quantity of air which will be delivered against a certain resistance in the intended installation. It now becomes necessary to evaluate the three fan-head definitions to discover which of these truly contribute useful information toward this objective.

The fan-head definitions are each made up of various combinations of static and total heads at inlet and discharge. Let us first dispose of the heads on the inlet side. It will be shown that the only head on the inlet side which contributes a useful function in defining the fan characteristic is the total head.

Referring to the arrangement with no inlet duct, Fig. 5, let the inlet total head be measured at some point P at a distance from the fan inlet, the velocity being negligible at that point. Then let the static and velocity heads be measured at a point Q very close to the fan inlet, no inlet duct being used. At point P all of the energy is in the form of static-head or pressure energy. There are practically no losses in energy in the air in flowing from P to Q. The gain in kinetic energy at Q is at the expense of the pressure energy at Q. Expressed as a simple relation

$$h_{tP} = h_{sP} = h_{vQ} + h_{sQ}$$

Now let an ideal inlet duct (no inlet or wall-friction losses) be attached to the fan inlet. Let P be located outside the duct, again at a point of negligible velocity, and let Q be located inside the duct. Under these circumstances we again find that the total head remains constant from P to Q regardless of the kinetic-energy increase at Q. Thus, the fan, either without any inlet duct or with an ideal inlet duct, does not add any energy to the air before the air actually enters the fan rotor. This is counter to some current conceptions. For example, a fan draws air from the atmosphere. Then at point P, the total head and static head are both zero. At point Q the sum of the static and velocity heads are also zero. Any kinetic energy which the air possesses at fan inlet was not produced by the fan, but at the expense of a corresponding decrease in pressure energy in the air stream. The fact is, that any energies existing at the fan inlet are supplied *to* the fan and not *by* the fan.

The ideal inlet duct is now replaced by an actual inlet duct. Because of the inlet and wall-friction losses the total head at Q will now be less than at P. The energy which goes to the fan at the fan inlet is still exactly and only the total energy in the air at the inlet, regardless of losses or other conditions which exist up to the fan inlet. The conclusion is that in any definition of fan head, we must debit to the fan the energy supplied to the fan by the air at the fan inlet. This energy supply is the inlet total head and is equivalent to h_{sQ} for fans without inlet ducts, and to $(h_{sQ} + h_{vQ})$ for fans with inlet ducts.

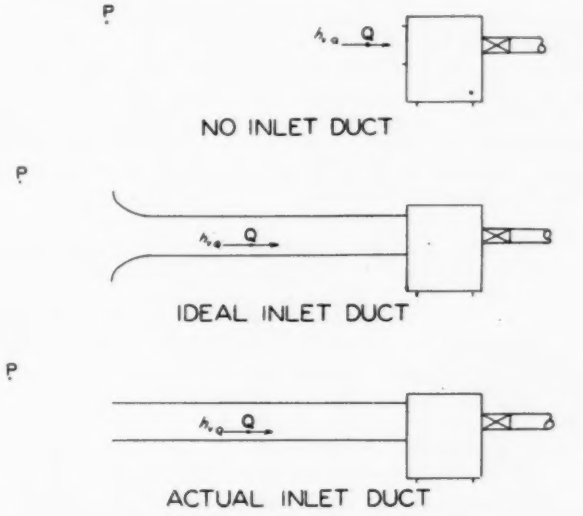

FIG. 5 HEADS AT INLET TO FAN

This eliminates the second definition of fan static head used throughout this paper, which erroneously credits the fan with the inlet velocity head.

Let us now consider the heads at the discharge side of the fan. In general, the resistance of the external system into which the fan discharges air is overcome by the energy of the discharge pressure. The only way by which the discharge kinetic energy of the air may have utility in overcoming resistance is by the introduction of a diffuser which converts kinetic energy into pressure energy. If the diffuser is applied at the fan discharge it should be considered as part of the fan and the discharge static head which is measured in this case would include the recovered kinetic energy at the fan outlet. If, on the other hand, the diffuser is installed at some point in the external system, it becomes a part of that system and any conversion of energy made by use of the diffuser cannot be properly credited to the fan. The authors, therefore, propose that in defining the fan head the discharge velocity head be entirely disregarded and the discharge static head only be used.

Consider two fans X and Y, having equal discharge total energy for equal quantity discharged, but fan X having a much larger portion of kinetic energy. These fans are not of equal utility for purposes of overcoming resistance. The purposes of factors such as good housing design and large outlet area are to convert kinetic energy to pressure energy. In most cases, if not in all cases, the fan should not be credited with unconverted kinetic energy.

We are now in a position to develop a definition of fan head. The fan head which gives the most useful information regarding fan performance in its installation is one which measures the

energy increase from the energy level of the air at the fan inlet to that energy level at the fan discharge which is directly usable, that is, without further conversions, in an external system. We have shown that at the fan inlet, the fan must be debited with both the pressure and kinetic energy existing there, while at the discharge of the fan, only the pressure energy may be properly credited to the fan.

The foregoing requirements for a fan-head definition are met precisely by the first definition of fan static head used throughout this paper. Specifically, *the fan head to be used in the quantity-head characteristic is defined as the discharge static head minus the inlet total head.* In arrangements which have discharge ducts, the discharge static head is measured in the duct at a specified plane so located that the flow conditions have some measure of uniformity. In arrangements without discharge ducts, the discharge static head is measured in the space into which the fan discharges. In arrangements which have inlet ducts, the inlet static and velocity heads are measured in the inlet duct at a specified plane so located that the flow conditions have some measure of uniformity. In arrangements without inlet ducts the inlet total head is the static head measured in the space from which air is supplied to the fan.

TABLE 3 NUMBER OF ARRANGEMENTS, CHARACTERISTICS AND CURVES FOR VARIOUS FAN TYPES, BASED ON STANDARD DEFINITION OF FAN HEAD

Fan type	Possible installation arrangements	Necessary test arrangements	Number of characteristics	Number of curves Per instal.	Number of curves Per type
1 No ducts.....	*A*	*A*	1	1	1
2 With discharge-duct flange only.....	*A*	*A*	1	1	2
	B	*B*	1	1	
3 With flanges for discharge and inlet ducts.....	*A*	*A*	1	1	4
	B	*B*	1	1	
	C	*C*	1	1	
	D	*D*	1	1	
4 With inlet-duct flange only.....	*A*	*A*	1	1	2
	D	*D*	1	1	

Using this definition of fan head, the complete schedule of fan types is given in Table 3, with all possible installation arrangements and corresponding necessary test arrangements, and the number of characteristics and curves required to completely portray the performance of each fan type.

From Table 3, it may be seen that for type-1, only one characteristic is possible, while for type-3, four characteristics and four curves are necessary to cover the four possible installation arrangements. The fan classified as type-3 is reported upon in this paper, the four characteristic curves being the four lower static-head characteristics shown in Fig. 3. Incidentally, the discharge velocity head, which is not included in the fan head, may be conveniently and usefully portrayed by plotting h_v vs Q, as shown in Fig. 3. This curve is identical for all possible arrangements which have discharge ducts, depending as it does only on the quantity discharged and the area of the discharge duct.

Quantity Measurement

A word need be said as to the measurement of the quantity term in the quantity-head characteristic. First, it should be recognized that by no means must the quantity be measured at the point at which a head is measured. The quantity may be measured at any convenient place in the system. Further, depending upon the test arrangement indicated for the particular cases, various acceptable methods of quantity measurement become more convenient and economical. The pitot tube, nozzle, and orifice are among the acceptable methods of measurement of air quantities in fan testing. Conditions of accuracy of these methods are under continual study by experimenters, and are eventually set forth in codes. In arrangements without inlet or discharge ducts, the use of nozzles or orifices in the walls of a large test chamber becomes an accurate, convenient, and economical method. In arrangements using small inlet or discharge ducts, nozzles or orifices at the entrance to inlet ducts or at the exit from discharge ducts are satisfactory. In very large ducts, nozzles, and orifices become more expensive, and the pitot tube is perhaps more satisfactory. In moderate-size ducts, the choice from among the acceptable methods of air measurement may be based upon considerations of convenience and availability of materials.

Definition of Quantity-Head Characteristic

The definition of fan head to be used in determining the quantity-head characteristic of a fan has been established. The quantity term is not subject to definition, but must be measured by some acceptable method. The quantity-head characteristic may now be defined as the relation between the quantity discharged and the defined fan head for a specified installation arrangement. Fan head is defined as the discharge static head minus the inlet total head.

It has been pointed out that for certain type fans there are possible more than one characteristic as defined by the established fan-head and quantity measurements, depending on the number of possible installation arrangements to which the fan may be adapted. Each particular fan type, however, is designed primarily for use in a particular installation arrangement which may be termed its *primary arrangement.* That characteristic which is obtained by use of the test arrangement corresponding to the primary installation arrangement of each type fan may be termed the *primary characteristic* for each type. For general use, then, this primary characteristic only need be determined, but with the understanding that this characteristic will not necessarily apply when the fan is installed in any arrangement other than its primary one. Thus, for fan type-1, with no mounting flanges for inlet or discharge ducts, and thus having only one possible arrangement, the only possible characteristic is the primary one. For the fan classified as type-2, the ordinary blower with only a discharge-duct mounting flange, and thus having two possible arrangements, the primary arrangement is considered to be that with a discharge duct attached. The primary characteristic will be that obtained using test arrangement *B*, the blower arrangement with the discharge duct attached. The primary arrangement of a fan classified as type-3 having mounting flanges for the inlet and discharge ducts, is that in which both inlet and discharge ducts are used. The primary characteristic is, therefore, that obtained by use of test arrangement *C*, which has both ducts attached. The primary arrangement for type-4 is that in which the inlet duct is attached. The primary characteristic is that obtained by test arrangement *D*. Thus, for any type of fan there may be established a primary arrangement and a single corresponding primary characteristic.

For the fan reported on in this paper, using the several fan-head definitions in common use and the four possible arrangements, 12 characteristics were originally determined and shown. By use of the established definition of fan head, the possible characteristics reduce to four. Of these four characteristics that one is considered the primary characteristic which shows the performance of the fan when installed in its primary arrangement which, for this fan, is the one with both inlet and discharge ducts in place. This characteristic is shown by the curve marked $H_{s,c}$ in Fig. 3. If the fan is to be installed in any other of the four possible arrangements it may not be taken for granted that this primary characteristic applies, but a separate test must be conducted to determine the characteristic for the intended arrangement.

Drying Problems of the Ceramic Industry

By JOHN L. CARRUTHERS,[1] COLUMBUS, OHIO

The purpose of this paper is to outline and discuss the various problems encountered in designing and operating ceramic-drying systems, and to indicate the several methods that may be used in attacking the more difficult problems that arise.

The process of drying clay wares may be a relatively simple one or it may be quite complex. This is due to (1) wide variations in production requirements in different industries, (2) extreme differences in the physical characteristics of clay bodies used, and (3) various sizes and shapes of different products. In many cases, the methods and equipment used may appear to be very slow and inefficient when considered in the light of modern drying practice. Their use is generally justified, however, when all factors are taken into consideration. However, this does not imply that all present systems are best suited for their particular task.

The problems discussed in the paper center around the development, maintenance, and determination of safe, rapid, and economical drying rates and the reduction or prevention of ware losses in order to increase drying and manufacturing efficiencies.

IN MANUFACTURING some wares, drying is immediately followed by a firing process, which in its early stages could function as a drying process, since there is a supply of heat and a suitable means for removing water vapor. Vitreous floor tile and small porcelain wares are commonly dried in the kiln, because the pieces are small and fragile and must not be subjected to unnecessary handling. However, a drying process is ordinarily required for the following reasons: (1) To give ware sufficient strength to be handled in loading kilns. (2) Kiln drying increases the time of the firing cycle thus requiring additional equipment. (3) There is danger of the ware being marred by kiln scum which forms if sulphur gases come in contact with water in the surface layers of the clay ware. (4) The ware must be dried before the glaze can be applied. (5) The temperature and humidity of the kiln gases cannot be readily controlled within the desired limits for satisfactory drying conditions.

Requirements of the Drying Process

The most important requirement is safe drying which means that the ware from the drier will be free of any defects that may be caused by improper drying conditions. Any ware spoiled during drying is practically worthless except in the few cases where cracked ware can be patched or repaired. Expenditures on spoiled ware are lost and the salvaged clay is of little value.

Clay wares should ordinarily be dried rapidly and uniformly and to the hygroscopic or regain water content (2 to 4 per cent). However, in some cases complete drying is not desired, because the ware may be too brittle for handling when bone dry, or it is too expensive to remove the last small percentage of water from the ware while in the drier. Also, several partial drying processes are used in the industry, e.g., drying of filtered clay for dry pressing and conditioning of clay blanks for turning, repressing, or "sticking."

Ware Forming Methods

A consideration of the methods used to form ceramic wares is necessary in the solution of drying problems, since some of the physical characteristics of the plastic and dry pieces will be affected by the method used. Following are brief descriptions of forming methods with lists of products indicating some of the conditions encountered:

1 *Dry Pressing.* A slightly moistened or damp clay body in dust form (water content 6 to 15 per cent) is placed in a steel mold and then compacted by the application of pressure to the die. The pressure may vary from several hundred to several tons per square inch. Products: Floor and wall tile, low-tension electrical porcelain, special refractories, and fire-clay bricks and shapes.

2 *Stiff-Mud Extrusion.* A semiplastic clay body (water content 15 to 25 per cent) is forced through an orifice or die which controls the dimensions of the cross-section of the piece. The extruded column is cut into required lengths by steel wires. Products: Common, face, glazed, paving, and fireclay brick; hollow building tile; telephone conduit; sewer pipe; drain tile; roofing tile; spark-plug cores; machine-made terra cotta; and blanks for electrical porcelain bushings.

3 *Soft-Mud Forming.* A soft plastic clay body (water content 20 to 30 per cent) is either modeled by hand or is pressed by hand or by mechanically operated mandrels into plaster, wood, or steel molds. Wares made in plaster molds are partially dried in the mold so that they may be easily removed and also to develop sufficient strength for handling and finishing. Products classified by name of process are: (*a*) Hand modeling—terra-cotta statuary, saggers, glass pots, and pottery. (*b*) Throwing on potter's wheel—art pottery and specialties. (*c*) Jiggering (plaster molds)—dinnerware, stoneware, chemical porcelain, and art ware. (*d*) Hot pressing (plaster molds)—electrical porcelain. (*e*) Machine pressing (plaster and steel molds)—roofing tile, flower pots, saggers, and crucibles. (*f*) Hand pressing (plaster molds)—terra cotta, faience tile, and chemical stoneware. (*g*) Hand and machine pressing (wood molds)—common and fireclay brick, and refractory shapes.

4 *Casting.* A clay-water mixture of the consistency of cream (water content 20 to 40 per cent) is poured into plaster molds. The clay is deposited on the side walls of the molds as the water is absorbed by the plaster. The use of electrolytes in the mixture makes it possible to use relatively small amounts of water. The ware must dry to a rigid condition by absorption while in the mold to permit removal. Products: Hollow shapes in dinnerware, art pottery, saggers, and sanitary ware.

5 *Additional Forming Methods.* Other methods may be required

[1] Associate Professor of Ceramic Engineering, Ohio State University. Fellow of the American Ceramic Society. Professor Carruthers was graduated from Ohio State University in 1921 and received the degree of Ceramic Engineer in 1934. He served in the Air Service during the War. He has held the following positions since 1921: Ceramic engineer with the Denver (Colo.) Terra Cotta Co. until Dec., 1922; construction, design, and service engineer for the Harrop Ceramic Service Company, Columbus, Ohio, from December, 1922, until September, 1925. This work was in connection with tunnel kiln installations in various sections of the U. S. From 1925 to 1930 he was assistant professor of ceramic engineering at Ohio State University and has held his present position since 1930. He is the author of several papers on kiln design, clay drying, and other phases of ceramic engineering.

Contributed by the Process Division and presented at the Semi-Annual Meeting of The American Society of Mechanical Engineers, held in Cincinnati, Ohio, June 19 to 21, 1935.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until December 10, 1935, for publication at a later date.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

to complete the piece only partially formed by one of the preceding operations. These methods either change the structure of the clay body or develop other conditions which may influence the drying operations. The methods are: (*a*) Repressing—applied to stiff- and soft-mud products, such as paving and fireclay brick. Preliminary drying is necessary with soft-mud products. (*b*) Finishing or tooling of surfaces—applied principally to wares formed in molds. (*c*) Turning on a lathe—spark-plug porcelains and electrical insulator bushings. (*d*) Mitering or "Sticking"—two or more pieces formed separately are combined by pressing the adjoining surfaces together, using a very soft plastic clay or clay slip as the bonding agent. This method is used for cup handles, sewer-pipe fittings, closet bowls, and terra-cotta corner pieces.

Drying Problems

The various problems of ceramic drying comprise: (1) Elimination of ware losses in drying; (2) developing faster safe rates of drying for clay bodies and shapes; and (3) developing methods for determining, experimentally, the safe drying time.

Elimination of Ware Losses. The seriousness of this problem depends upon local conditions. Ware losses may be due to cracking, checking of surfaces, warping, strains, slumping, efflorescence or "drier scum," blistering, or other troubles. The causes of these troubles may be in the drying system or may be attributed to raw materials or processing. There may be a lack of control in the system preventing the maintenance of uniform drying conditions, or there may be changes in the properties of the raw materials. Also, processing conditions are encountered that markedly influence the drying behavior of the ware. Unless such changes can be anticipated, it is impossible to know that drying conditions should be altered until after a considerable amount of ware has been spoiled.

Cracking, checking, warping, and strains in the ware are all due to drying at excessive rates, which set up too extreme variations in shrinkage throughout the piece and prevent an adjustment of the stresses. The actual fault developed will depend upon the degree of localized shrinkage, the shape and position of the piece, and the strength of the clay body. The factors influencing the rate of drying and the development of these troubles are humidity of the air; velocity of air; direction of air flow; temperature of the air and ware; size and shape of the piece; diffusion and shrinkage characteristics of the clay body; water content; and strength of the clay body.

Slumping is due to the absorption of water condensed from humid air on the surface of the piece. Also, plastic clay wares may slump if they are heated in a humid atmosphere that permits little, if any, drying. The increase in temperature lowers the viscosity of the water, and the clay-water mixture cannot support its own weight. Blisters are caused by air entrapped in surface layers of the piece. If the clay is softened by condensation and the air expanded by heating, then a blister will be formed. Efflorescence or "drier scum" is due to either soluble salts in the clay, brought to the surface during drying, or formed by the reaction between sulphur gases in the drier chamber, water and minerals in the clay. Other items that may cause a loss of ware are vibrations of conveying equipment, poor handling of the ware, or lack of provisions for shrinkage when setting the piece.

There are three general methods which may be used to solve the problem of ware losses. The choice of method will depend upon the results of an analysis of the prevailing conditions and the weight of the various factors. The mode of attack may be along any of the following lines:

(*a*) The use of a drier that may be closely controlled over a fairly wide range of drying conditions and changes in atmospheric conditions. This may require remodeling or replacing existing driers.

(*b*) The use of a control system which will eliminate changes in the drying system or the drying behavior of the clay ware. Ware of uniform characteristics should be delivered to the drier. However, possible variations in clays and processing conditions beyond the control of the drier or its operator often prevent satisfactory drying.

(*c*) Change the physical properties of the clay body, where possible, so that the ware can be safely dried under conditions that can be economically maintained in the existing equipment. This method is discussed in more detail in the next section.

2 *Development of Faster Safe Drying Rates.* A reduction in the excessive safe drying time required in many clay plants would have several obvious advantages. The solution of this problem is by improving drier designs and techniques or the application of ceramic technology. Research work in ceramics during the past ten years has made available new information on the nature of clays and methods of varying them, especially in respect to their drying behavior. Consequently any of these methods, or others, may be the most desirable one to use, providing the drier equipment is satisfactory.

Rapid drying is not always desirable from an economic standpoint, especially with wares such as dinnerware, stoneware, or art pottery. In some plants, a supply of partially fabricated ware is maintained at several stages of the manufacturing process in order to meet fluctuations in production orders. Consequently, storage rooms in which the ware is dried slowly are more economical than regular driers since this procedure eliminates an extra handling. Also, there are some types of ware, such as glass pots, which seem to have better service qualities if they are dried slowly.

Changes in drier design or operation quite often make it possible to dry ware safely at rates that would be disastrous with the existing system. Cut-and-try methods may be required to obtain the desired results due to conditions often difficult to explain. Several features of design or methods of operation, that might be investigated in the remodeling of old driers or the design of new ones, are as follows:

(*a*) Direction and velocity of air flow. This feature is quite vital with many products. Whenever possible, all surfaces should have uniform treatment.

(*b*) Location of heating units. Rapid safe drying has been obtained in some driers by placing the steam-radiator elements in the drying chamber. This arrangement eliminated the necessity for a large recirculating-air volume to deliver the required units to the ware.

(*c*) Heating the ware before placing it in the drier or heating it (with little drying) in a controlled humid atmosphere at the start of drying, will ordinarily make possible the use of increased drying rates.

(*d*) Provide a uniform air circulation throughout the ware setting, especially in continuous driers. If all ware does not receive the proper initial treatment due to poor circulation, then the rapid drying conditions later on will damage that ware not properly treated. In some cases the ware setting in the drier may require adjustment.

(*e*) Adjust air volumes and temperatures to prevent condensation of water vapor on the ware.

(*f*) Both continuous and intermittent drying systems have definite applications in the industry. A change from one type to another is sometimes indicated.

There are several methods, based upon application of ceramic technology that may be used to increase the safe drying rate of a clay or make it possible to dry certain clays satisfactorily for commercial use. These methods alter various physical properties that govern or influence the rate at which the clay may be safely dried. The properties are shrinkage, pore structure, and

strength which are dependent upon the grain size, the amount and state of colloids of the clay, the water content, and the nature of the minerals in the clay. Briefly, the methods are: (*a*) The addition of a non-plastic material or a less-plastic clay to decrease shrinkage in drying. (*b*) Preheating the clay at temperatures between 400 and 500 F to alter the character of the colloids and thus decrease shrinkage in drying. (*c*) Coarser grinding of materials to decrease shrinkage. (*d*) Weathering of raw clay, additional tempering, aging the plastic body, addition of an organic bond, or the addition of a more plastic clay may be used to increase the strength of the clay. (*e*) A small amount of sodium chloride (NaCl) added to a clay has been effective in several cases. (*f*) The addition of an electrolyte to flocculate the colloidal material. This increases the strength of the body and apparently increases the rate of water diffusion. (*g*) A chemical treatment to cause an exchange of bases in the colloidal material.

In some cases, drier troubles are due to the development of planes of weakness or strains in the pieces by faulty forming processes. The presence of auger, die, or hand laminations, pressure planes, etc., will require the use of slow drying rates to prevent heavy ware losses.

Determination of Safe Drying Rates. At the present time, there is no correlation between the drying behavior of trial pieces under controlled laboratory conditions and that of actual pieces of ware in commercial driers. A solution of this problem is needed for advancing the art of drying clay wares. The determination of required drying rates in commercial driers is a very expensive proposition.

Considerable work has been done both in this country and abroad to obtain more information in regard to the nature of clays and the forces or agencies that govern or influence phenomena such as shrinkage, diffusion, vapor pressures. Other studies have been made to determine what relationships there might be between humidity, temperature, pressure, water content, shrinkage, or clay characteristics and drying behavior. While much valuable information has been obtained, the methods now available for determining the safe drying time of a clay when formed into a definite shape are of a cut-and-try nature. The problem is exceedingly complex since there are many variable factors that must be considered.

Summary

The problems discussed center around the development, maintenance, and determination of safe, rapid and economical drying rates and the reduction or prevention of ware losses in order to increase drier and manufacturing efficiencies.

The principal factors involved in the solution of the problems are: (1) Requirements for drying systems; (2) manufacturing methods employed; (3) the physical characteristics of clays and product shapes; (4) ordinary phenomena of drying such as temperature, humidity, air flow (direction and velocity), heat transfer and vaporization; and (5) economic considerations.

The methods that may be used in solving the existing problems include the following:

(1) Provide correct drying conditions for the ware by remodeling or replacing existing driers so as to eliminate ware losses or increase safe drying rates. Also, provide suitable control methods and apparatus.

(2) Improve the drying behavior of the clay bodies by altering their physical properties so as to prevent ware losses and to increase the safe drying rate. This general method can only be used when the quality of the finished product is not adversely affected. The methods that may be employed are (*a*) the use of non-plastic or less-plastic materials, (*b*) chemical treatment, (*c*) the addition of stronger clays or organic bonds, (*d*) the use of additional processes such as preheating, weathering and aging, and (*e*) varying the methods used in grinding and tempering the clay.

There are plants that are continually encountering many of the difficulties described, while others seldom have drier troubles. However, the industry as a whole encounters these problems continually and only by recognizing that there are problems can improvements be made.

It is believed that the art of drying ceramic wares in the major portion of the industry is on a fairly high level when consideration is given to the complexity and wide variations in the composition and properties of clays, the variety of products made, the different processes used in manufacturing, and the science of drying.

Discussion

A New Basis for the Rating of Roller-Chain Drives[1]

NORMAN ARNOLD.[2] Refinements in methods of design are handicapped in their adoption unless the mathematical work introduced by the change can be made simple. At the suggestion of Professor Bartlett, an effort has been made to devise a simple graphical method for performing the computations on the basis set forth in his paper.

The method here developed employs an alignment chart with a sliding scale, a device that is not as common among engineering computing diagrams as its convenience and simplicity warrant. Attention is called to the three mathematical conditions which must be satisfied. They are obtained from Equations [22] and [27] and Table 1 of the original paper:

$$x = \frac{1000 \text{ hp}}{N_1 N_2} \gtrless 23\ PB \quad \ldots\ldots\ldots\ldots\ldots\ldots [22]$$

$$y = \frac{1000 \text{ hp}}{N_1 n_1} \gtrless 12.7\ PBd \quad \ldots\ldots\ldots\ldots\ldots\ldots [27]$$

$$z = n_1 \gtrless \text{rpm} \quad \ldots\ldots\ldots\ldots\ldots\ldots \text{Table 1}$$

The right-hand members of these inequalities involve pitch, bushing length, wt per ft, etc., all of which are constants for any particular standard chain. The author supplied tabulated values of the right-hand members for the various standard chains; and these values were used in preparing the chart.

It will be noted that 1000 hp/N_1 is contained in both Equations [22] and [27], therefore, in preparing the alignment chart, this division can be performed first, and the result used in solving both Equations [22] and [27]. On the accompanying chart, Fig. 1, this division is carried out by drawing a straight line through the points on the scales for N_1 and hp to the Q-axis, (dashed line A in the figure). The inequality 22 is satisfied by any chain whose number appears on the X-scale above the index line from the point on the Q-axis to the value of N_2 (line B in the figure). In general, the conditions limiting the rpm are satisfied by chains whose numbers are nearer the bottom of the chart than the given rpm, n_1; and inequality 27 is satisfied by chains whose numbers are on the Y-scale above the index line from the

[1] Published as paper MSP-57-1, by G. M. Bartlett, in the April, 1935, issue of the A.S.M.E. Transactions.

[2] Instructor, Engineering Drawing, Purdue University, West Lafayette, Ind.

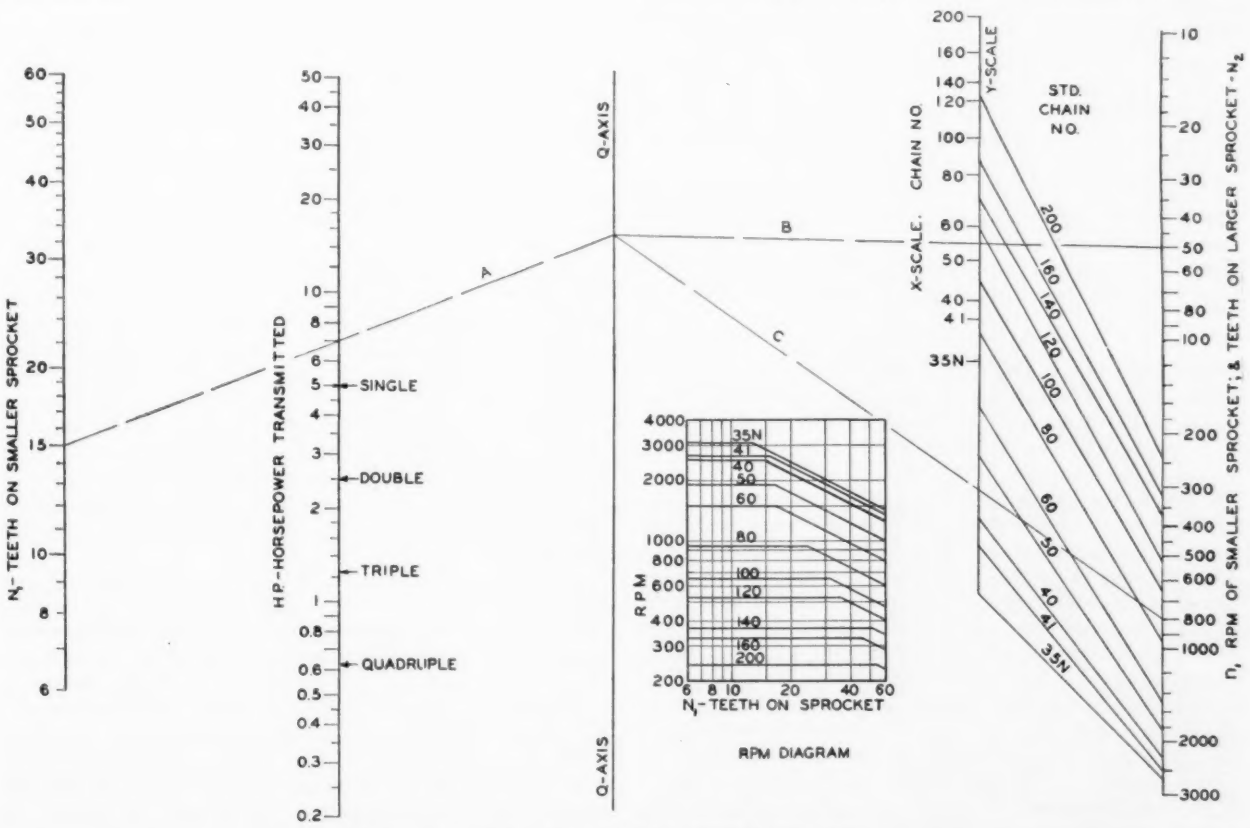

FIG. 1 ALIGNMENT CHART FOR SELECTING ROLLER CHAINS

Operation: (1) Draw index A through N_1 and hp to the Q-axis, (2) draw index B from the Q-axis to N_2, (3) draw index C from the Q-axis to n_1. A chain is satisfactory if index C cuts the inclined line with that number, and if index B passes below the number on the X-scale, and if the allowable rpm for the number of teeth, N_1, as obtained from the rpm diagram, is not exceeded.

point on the Q-axis to n_1. Therefore, both are satisfied by chains in the inclined lines cut by the index line from the Q-axis to n_1.

As an example, let it be required to select a chain to transmit 7 hp over sprockets having 15 and 50 teeth, where the smaller wheel turns 800 rpm. (1) Draw the index line, A, from 15 on N_1 through 7 on the horsepower scale to the Q-axis. (2) Through this point on the Q-axis draw an index line, C, to $n_1 = 800$, and note that chains Nos. 50 60, and 80 (cut by this line), satisfy two of the three conditional equations. (3) The index line, B, from the Q-axis to $N_2 = 50$, cuts the X-scale below chains Nos. 60, 80, 100, etc., only two of which satisfy the first two conditions. Hence, either chain No. 60 or chain No. 80 is satisfactory for this example.

This chart as shown is for single chains only. If it is found that a single chain will not satisfy the conditions, the chart may be easily modified to select multiple chains on the same basis. If the horsepower scale is made movable along its axis, then to select double chains, the arrow at 5 on the horsepower scale is matched with the arrow marked "double," and the chart is used in the same manner as just described. The procedure for triple and quadruple chains is obvious. Incidentally, shifting the horsepower scale in this way has the effect of dividing by 2 for double chain, by 3 for triple chain, and by 4 for quadruple chain. Therefore, one can use the chart as it is, if the horsepower is divided by 2, 3, or 4 as the case may be, when selecting multiple chains.

The conditions limiting the rpm are not completely fulfilled by the alignment chart, therefore, after tentatively selecting a chain by means of the chart one should refer to the rpm diagram shown here, or Table 1 in the author's paper, to make sure that the allowable speed is not exceeded. It will be observed that the No. 60 chain found in the example is satisfactory for 1500 rpm unless the number of teeth is greater than 17; above 17 teeth a gradual reduction in speed must be made. No. 80 chain is satisfactory for 940 rpm if the number of teeth is less than 24, and above 24 teeth a gradual reduction must be made as shown by the inclined portion of the curve marked 80.

The time required to select a chain by means of the chart is seldom greater than a minute if N_1, N_2, n_1, and hp are known. Obviously, the chart may be used inversely to find the maximum horsepower which may be transmitted or the limiting numbers of teeth that satisfy the two equations and the set of rpm curves.

Author's Closure

The closure can be used to no better advantage than to summarize briefly the conclusions of the mathematical research advanced in the paper and to add appropriate remarks relative to the possibilities and limitations of the theory, the formulas, and the tables developed.

Maximum Revolutions per Minute and Chain Velocities. Table 1 of the paper should have been provided with heavy lines drawn so as to divide it into three areas: An upper left-hand area showing figures calculated from formulas [6] and [7]; an upper right-hand area calculated from formulas [8] and [9]; and a lower left-hand area calculated from formulas [4] and [5]. Each of these formulas contains a constant the value of which can be determined properly only from practical tests. Arbitrary values have been used in this table only to show the general plan. They are subject to change so as to conform to facts as they may be discovered from a study of actual performance in practice.

Formulas [8] and [9] affecting the upper right-hand area of the table are built upon a theory the only excuse for the existence of which is that it seems to satisfy, to an approximate extent, the general belief that centrifugal force in some way limits the allowable chain velocity. Not only are the constants in formulas [8] and [9] subject to change, but also the structure of the formulas may be changed in case a more plausible theory is discovered.

Merely changing the constants in formulas [4] to [9], inclusive, would not alter the theory on which they are based. If, for example, it is found that the figures for a 17-tooth sprocket carrying a No. 40 chain should be 10 per cent higher than those given in Table 1, the constants in formulas [8] and [9] can be increased 10 per cent and this would increase most of the figures in the upper right-hand area and cause a shift in the location of the line dividing that area from the lower left-hand area.

Conditions for a Uniform Chain Elongation. This mathematical research on the rapidity of chain wear has been conducted on the assumption that it would be desirable to know just how the life of a roller chain is affected, in theory at least, by changes in pitch, width, pin diameter, chain length, and the number of sprocket teeth. Disregarding centrifugal pull, the effect of which is almost negligible, it is concluded from formulas [20] and [21] that if uniform conditions of lubrication and service are assumed, the rate of chain elongation due to wear is proportional to

$$H(N_1 + N_2)/BPN_1N_2L_p$$

If now it is assumed that all chain drives are to be designed so that, under uniform conditions of lubrication and service, the chains will reach a 3 per cent elongation at the end of a specified number of hours of service, as 10,000 hours for example, the horsepower to be transmitted would have to be calculated from the formula

$$H = KBPN_1N_2L_p/(N_1 + N_2) \ldots\ldots\ldots [22a]$$

where K is a constant to be determined by experiment. The constant K has been taken tentatively equal to 0.023 for the sake of illustrating the use of the formula and of tables computed from the formula. This formula and the ones given later in this closure are numbered as supplements to those given in the paper to facilitate reference to the paper.

In order to simplify the horsepower tables computed from formula [22a], it has been further assumed that the chain length L_p contains in every case as many links as there are teeth in the two sprockets. That is, the tabulated horsepowers in Table 3 in the paper are for chains containing exactly $(N_1 + N_2)$ links. This must not be overlooked since, when $L_p = N_1 + N_2$, the center distance is very much shorter than would be used in the average drive, and Table 3 is only designed to give horsepower ratings for drives having short center distances. In a drive using 16 and 25 teeth, $N_1N_2 = 400$ and the chain length is assumed as $16 + 25 = 41$. The center distance would then be about 10 pitches, and at 1200 fpm the rated horsepower is 7.3. If the chain length is doubled the center distance would be about 31 in., which is much closer to the average distance in actual practice. This makes the rated horsepower 14.6 instead of 7.3 as found in the Table 3.

If Tables 3 and 4 had been based upon an assumed minimum chain length of $2(N_1 + N_2)$ pitches, the constants in formulas [26], [28], and [30], inclusive, would be doubled, the horsepower ratings in the upper right-hand area would all be increased, and the heavy stepped line would be moved to a higher position.

Table for the Selection of a Suitable Chain. Table 5, given with this closure, illustrates an attempt to provide some means by which a proper chain can be quickly selected for a drive when the horsepower, the number of teeth N_1 and N_2, the revolutions per minute, and the approximate center distance (in pitches) are known. Disregarding the slight effect of centrifugal action, but taking account of the chain length, we have from formula [28]

$$H = 0.023PBN_1N_2\ L/(N_1 + N_2) \ldots\ldots\ldots [28a]$$

Substituting $2C + [(N_1 + N_2)/2]$ for L in formula [28*a*], this substitution being sufficiently accurate, we obtain

$$H = 0.023PBN_1N_2[2C/(N_1 + N_2) + 1/2] \quad \ldots\ldots [28b]$$

$$H = 0.0127PBdN_1n_1 \quad \ldots\ldots [29b]$$

The horsepower rating can now be said to be the lesser of the two values computed from formulas [28*b*] and [29*b*]. The effect of a change in center distance is shown in the following example.

Let $P = 1$ in., $N_1 = 15$, $N_2 = 21$, $C = 21$, and the speed = 547 rpm. Then the rated horsepower is 10.5.

If the center distance is changed to 42 pitches, the rated horsepower is one and two-thirds times as great, or 17.5 hp.

Now from formulas [28*b*] and [29*b*]

$$23PB = \frac{1000H}{N_1N_2[2C/(N_1 + N_2) + 1/2]} \quad \ldots\ldots [28c]$$

$$12.7PBd = 1000H/N_1n_1 \quad \ldots\ldots [29c]$$

The first member of formulas [28*c*] and [29*c*] has a fixed value for each standard *chain*, and the second member has a particular value for each chain *drive*.

In this closure the author gives a table, numbered Table 5 as a continuation of the table numbers given in the paper. In Table 5, column X shows values of $23PB$ for the several standard chains listed in Table 1 of the paper. The column headed Y shows values of $12.7PBd$ for the same chains, and the column headed Z gives the max rpm for a 17-tooth sprocket as listed in Table 1 of the paper.

If we compute

$$x = \frac{1000H}{N_1N_2[2C/(N_1 + N_2) + 1/2]}$$

and

$$y = 1000H/N_1n_1$$

for a proposed drive, and z is taken as the revolutions per minute of the smaller sprocket, it is then only necessary to refer to the table for a set of values of X, Y, and Z, each of which is greater than x, y, and z. The standard chain number is then found in column 4 of Table 5. In most cases there will be several possible selections, and the one highest in the list will usually be the most economical. A quick reference to the table of maximum revolutions per minute will give an adequate check on the selection.

As an example, let it be required to select a chain to transmit 15 hp over sprockets having 15 and 25 teeth, the smaller wheel turning at 900 rpm, and the center distance to be about 30 pitches. Then

$$x = \frac{1000 \times 15}{15 \times 25\{[(2 \times 30)/(15 + 25)] + 0.5\}} = 20$$

$$y = 1000 \times 15/15 \times 900 = 1.111, \quad \text{and } z = n_1 = 900$$

In Table 5, sixth row from top, the values of X, Y, and Z are 20.20, 3.470, and 940, respectively, all of which are greater than the required values. The standard chain number is 80 and is a 1-in. pitch chain. It will be noticed that double-, triple-, and quadruple-width chains are listed as well as the single-width chain. If a selection cannot be made from the list of single chains, reference is made to the double-width chains, then to triple-width or the quadruple-width chains. In this case chain number *D*60 could be used but it would not be as economical as the single-width chain No. 80.

TABLE 5 VALUES FOR THE SELECTION OF ROLLER CHAINS

Single-width chains					Triple-width chains				
X	Y	Z	Std. chain no.	Pitch and width	X	Y	Z	Std. chain no.	Pitch and width

Referring to J. N. Arnold's discussion, the difference in the results obtained from his chart and those obtained by the method just described is due to the fact that the author is here taking account of the effect of a change in center distances, whereas Mr. Arnold's chart was designed to give results corresponding to formulas [28] and [29] and to Table 3. Doubtless Mr. Arnold's chart could easily be modified to take care of varying center distances if desired.

Effect of an Excessive Number of Teeth. One more comment seems to be important. An inspection of Table 4 of the paper shows that in the case of drives having over 60 teeth in the larger sprocket the horsepower ratings seem to run higher than they should. The reason for this is that the present research has dealt only with the rate of chain elongation and has not taken into account the fact that, whereas chains operating over sprockets with less than 60 teeth can often stretch 3 per cent before being discarded, this is not true where the sprockets have considerably more than 60 teeth.

In the case of 90 teeth the chain will climb very nearly to the top of the teeth when the elongation is only 2 per cent; and this means that the allowable life of the chain on a 90-tooth sprocket is only two-thirds as great as one running on a 60-tooth sprocket. To take account of this a note may be attached to Table 5 stating that, where N_2 is more than 60, the values of x are to be multiplied by $N_2/60$ before being applied to the table.

The Leakage of Steam Through Labyrinth Seals[1]

R. L. Scorah.[2] The subject of flow through labyrinth seals has received rather limited study, even though it has been known for sometime that the older formulas do not always give reliable results. Mr. Egli's paper will no doubt form a welcome addition to the literature of this field.

It should be pointed out, however, that the static tests referred to in this paper do not simulate the real conditions of operation. In practice, the leakage steam flows in a different sort of channel, one part of which is stationary while another part, the shaft, rotates at high speed. It has not been demonstrated that the leakage is independent of the speed of rotation. Furthermore,

[1] Published as paper FSP-57-5, by Adolf Egli, in the April, 1935, issue of the A.S.M.E. Transactions.

[2] Mechanical Engineering Department, Stanford University, California.

the argument presented here is confined to the gas phase of the flowing fluid, that is, superheated steam. In some cases, the steam entering the seal will be wet or only slightly superheated. Under these conditions, the effect of supersaturation and water drops further complicate the problem. In view of the wide variety of designs used in practice and the absence of precise information regarding supersaturation and the behavior of entrained water drops, it would seem expedient at this time to investigate experimentally the leakage through various labyrinth constructions using a rotating-shaft element. Such experiments would not only provide reliable leakage data for the particular constructions tested but would also serve as a helpful check on the rational theoretical treatment of the problem.

H. G. Yates.[3] The writer is interested in knowing if Mr. Egli has studied the effect of inclining the baffle strips at an angle of 45 deg. Glands of this type in conjunction with a spring mounting have been found satisfactory. It is uncertain, however, how far their good sealing properties are due to the inclination and how far to the accurate maintenance of fine clearances by means of the spring mounting. Any gain in sealing properties would probably be proportionately smaller with very fine clearances (of the order of 0.01 in. or less) as the small radius, which necessarily exists on even a "sharp" baffle strip, would assume proportionately greater importance, and the constriction would cease to be a sharp-edged orifice and would tend toward one with well-rounded edges. It is presumably this effect which gives rise to the curves of Fig. 18 of the paper. An important advantage of the inclined baffle strip is that in the event of local heating due to a momentary rub, the strips tend to cockle up away from the shaft rather than to expand toward it.

Another gland which has been employed frequently is of the "straight-through" type but with the baffle strips adjacent to a number of thin closely pitched ribs turned on the shaft or gland sleeve, of different pitch from the strips themselves, so that there is no fear of a straight blow-through if the rotor should be moved in an axial direction. Besides having the property of rapid cooling in the event of a rub, it is believed that the "valleys" between the ribs or pips serve to break up the steam flow and give almost as good a seal as a gland of the well-staggered type. The writer would welcome Mr. Egli's opinion on this.

B. Hodkinson.[4] Mr. Egli refers more than once in his paper to the high velocity through the last throttling and points out that the Fanno line may at this stage be departed from.

A way of allowing for this in the calculation suggests itself. The pressure before the last throttling may be taken as twice the final pressure, and the calculation carried only to this point. In other words, the last throttling could be done away with, and the final pressure doubled. This would raise the calculated figure slightly, except in odd cases, and in the light of some tests at Trafford Park, Manchester, on a grooved valve spindle, would make the answer more reasonable, because we found a greater mass flow than appeared, according to calculation, to be possible.

The odd cases where the calculated discharge would not be increased occur when p_2/p_1 is higher than about 0.2, and then the last throttling probably does not carry sound velocity. Most practical labyrinths operate with p_2/p_1 a good deal less than 0.2. Thus, it would be well to use the above suggested way only when p_2/p_1 equals, say, 0.1 or less.

Author's Closure

The author fully realizes the fact, mentioned by Prof. R. L. Scorah, that the actual flow conditions are not correctly simulated in the static tests referred to in the paper. Some of Friedrich's[5] tests, which were made with a rotating shaft, show the effect of peripheral speed to be rather small. At 200 ft per sec the decrease of leakage due to the speed of the shaft has been found to be 3.4 per cent. For moderate peripheral speeds, therefore, the static tests will not be much in error.

There is a further point with a view to simulating the actual flow conditions, which has been neglected in the static tests. It is the exact shape of the edges of the sealing strips after they have been rubbing in the running turbine. The strip generally becomes burred over and the sealing edge is no longer sharp, as assumed in the static tests, but is in cross-section shaped rather like a mushroom. The characteristic function ψ of such a mushroom-shaped throttling undoubtedly is somewhat different from the function ψ of a sharp-edged orifice shown in Fig. 2 of the paper. It would be principally possible to determine this function by testing a single "mushroom-shaped" strip. Curves φ versus pn/po similar to those of Fig. 7 of the paper could then be constructed with the methods there presented. For most practical purposes, however, the φ curves of Fig. 7 will be sufficiently accurate.

The author has had no experience with the sealing properties of the particular types of baffles described by H. G. Yates, and does not believe that by inclining the labyrinth strips the amount of leakage for a given clearance should descrease measurably. If such glands have proved successful in the turbine, it apparently is due to the maintenance of a fine clearance. The "straight-through" type seal with strips adjacent to a mumber of closely pitched ribs is probably somewhat tighter than the "straight-through" type gland referred to in the paper. It is his opinion, however, that this type of packing will not reach the good sealing properties of a well-staggered labyrinth. The leakage jet issuing from one clearance very easily "bridges" over the narrow "valleys" between the ribs by simply maintaining a series of stationary vortices in each valley.

The method of considering the great pressure drop across the last throttling, as suggested by H. B. Hodkinson may give fairly correct results, although the assumption of the pressure before the last throttling to be twice the final pressure is quite arbitrary. There is, however, no need of treating separately the last throttling when following the methods outlined in the paper. The curves of Fig. 7 and 7*a* automatically take into account the flow characteristics of each throttling in the labyrinth including the last one.

The physical nature of the leakage flow along a grooved valve stem, to which Mr. Hodkinson refers, is quite different from that in a labyrinth packing. Here the loss of kinetic energy due to friction in the narrow space between stem and bushing must be taken into consideration whereas in a labyrinth the friction in the short passage through the throttling gap plays a minor rôle only.

Cause and Prevention of Turbine-Blade Deposits[1]

By FREDERICK G. STRAUB,[2] URBANA, ILL.

A survey was made of power plants encountering turbine-blade deposits and it was found that this trouble results from contamination of the steam by the boiler water. A study in the laboratory showed that sodium hydroxide is the material which causes the sticking to the blades. It was also shown that when the sodium hydroxide is neutralized and changed to a salt such as sodium carbonate, it will not adhere. The presence of sufficient amounts of inert salts, such as sodium sulphate, with the sodium hydroxide also will stop the deposit from forming.

The action of sodium sulphate in preventing the blade deposits was studied in a large central power plant, and the deposit was materially reduced. A small testing unit for detecting the presence of adhering salts in the steam was developed and used in the power-plant tests.

STEAM-electrical generating stations have encountered difficulty in the form of fouling of turbine blades. This difficulty has become of major importance in many large stations whereas it has only meant annoyance in other stations.

There are several types of deposits which form on the turbine blading and cause this fouling. One is that which is apparently caused by a deposition of solids carried in the steam from the boiler water and another is that caused by a chemical reaction between chemicals in the steam and the material in the turbine blade. The first type is most common and is readily distinguished because it is largely water-soluble and is washed off with comparative ease, whereas the other type adheres tenaciously to the blades.

The difficulty caused by the deposition of solids carried in the steam appears to be the one causing the major difficulty. The efforts of this research have been expended entirely toward the study of this type of deposit and no study has been made of the other type.

He holds the degrees of Master of Science and Metallurgical Engineer from Pennsylvania State College. He has been conducting special research for the Utilities Research Commission, Inc., on boiler-feedwater treatment for the last eleven years at the University of Illinois. This has included work on determining the causes and methods of prevention of embrittlement in steam boilers and a study of the methods of preventing scale in high-pressure boilers.

Contributed by the Power Division for presentation at the Annual Meeting of The American Society of Mechanical Engineers to be held in New York, N. Y., December 2 to 6, 1935.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until January 10, 1936, for publication in a later issue of Transactions.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Industrial Experience

A survey was made of power plants encountering this trouble as well as those not having difficulty with blade deposits.

The summary of conclusions reached after assembling the available data in regard to turbine-blade deposits is as follows:

(1) The deposits formed independent of steam pressure or temperature.

(2) The deposits were not proportional to the total concentration of solids in the boiler water.

(3) The total solids in the steam were very low in many plants where deposits occurred.

(4) The deposits all contained sodium present as hydroxide, carbonate, or silicate.

(5) The deposits were practically all water-soluble.

LABORATORY EXPERIMENTS

Possible Cause of Deposits

The deposits which were formed in the plants under consideration all originated in the boiler water. A small amount of the boiler water may be easily carried into the steam. Actually, this amount does not have to be more than one-tenth of one per cent of moisture in the steam to cause appreciable trouble at the turbine. Thus if a boiler water should contain about 300 ppm total solids, which is a rather low concentration, and one-tenth of one per cent of the steam were present as boiler water, the steam would contain 0.3 ppm of total solids. This appears a negligible amount; however, with a turbine using one million pounds of steam per hour, 8 lb of solids would pass through the turbine in 24 hr. If only 10 per cent of this were to adhere to the turbine blades, the efficiency and capacity loss would increase at an alarming rate. Thus if there is present in the boiler water any material which would cause adherence to the turbine blades, the better quality steam might cause appreciable difficulty.

In order to determine whether there is present in the average boiler water material which would cause adherence or sticking to the turbine blade a study was made of the behavior of the various salts encountered in boiler waters as they pass from solution in wet steam to superheated steam. If only pure water were present in the boiler and a small amount of the boiler water were mechanically carried into the steam and to the superheater, the droplets of water would vaporize in the superheater and no free moisture would be present in the superheated steam. However, if sodium chloride, sodium carbonate, or sodium sulphate were present in the boiler water the droplet of water entering the superheater with the steam would contain a dilute solution of the salt or salts. As the steam became superheated the water would vaporize and leave a dry salt or powder of the salt or salts with the superheated steam. Consequently, they would pass through the steam pipes and turbine as a fine powder or dust and cause no appreciable difficulty. This is based on the assumption that there is only a small percentage of moisture in the steam. However, if sodium hydroxide were present this would not happen. This results from the fact that the behavior of sodium-hydroxide solutions is entirely different from that of the other salts discussed.

When a solution of sodium chloride, carbonate, or sulphate is boiled, the solution is concentrated as the steam is released and the solution concentrates until a saturated solution is obtained. Any further release of steam results in the precipitation of the salt. Eventually, if the boiling is continued, all the water is evaporated and dry salt or salts are left behind. If a solution of sodium hydroxide is boiled, the solution concentrates with a continual increase in temperature until a concentration is reached where the concentrated solution is in equilibrium with the vapor pressure of the surrounding atmosphere and further heating will cause a release of steam to the surrounding atmosphere with an increase in concentration of the caustic solution and an increase

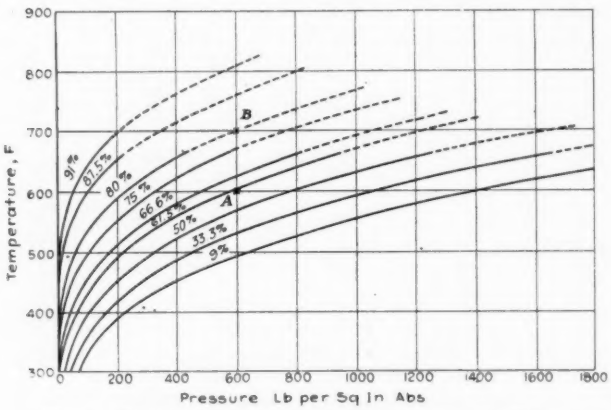

FIG. 1 CONCENTRATION OF NaOH IN RELATION TO STEAM PRESSURE AND TEMPERATURE

in the temperature of the solution. This is shown graphically in Fig. 1 and may be illustrated as follows:

If a drop of water containing sodium hydroxide in solution leaves a boiler at a pressure of 600 lb per sq in. abs and enters the superheater with the steam, the water will vaporize, thus concentrating the solution. When the temperature of the steam reaches 600 F the concentration of the caustic will represent about a 60 per cent solution, shown as *A* in Fig. 1. If the temperature and pressure remained constant, the droplet of caustic would remain 60 per cent sodium hydroxide and 40 per cent moisture, even in contact with superheated steam. As the temperature increases, the pressure remaining constant, the caustic concentration will increase. At a pressure of 600 lb and a temperature of 700 F, the concentration would be as shown at point *B*, an 80 per cent solution.

The concentration of caustic in equilibrium with superheated steam at various pressures and temperatures is shown in Fig. 1. This shows that the concentrations of sodium hydroxide reached in the average higher pressure plant is between 80 and 90 per cent. A solution of sodium hydroxide containing between 10 and 20 per cent moisture at these temperatures will be in a pasty or semi-fluid state and in going through the turbine will adhere to the blades. The other salts, present as a fine dust, will adhere with the sodium hydroxide, but not necessarily in the relative proportions in which they exist in the boiler water. When the temperature of the steam in the turbine is lowered until saturated steam exists these salts will be dissolved and thus wash off of the blades. The experience which turbine operators have had with washing of turbines confirms this.

In order to substantiate this theory tests were run in the laboratory. The procedure followed in these tests was to produce steam in a small boiler, contaminate the steam with a solution of a desired salt or combination of salts, superheat the contaminated steam, pass the steam through an orifice so that it impinged on a stationary blade, and then condense the steam at a predetermined pressure.

Fig. 2 shows the apparatus used for the tests. Condensed steam from the steam-heating system was passed through a small deaerating heater and then pumped to an electrically heated boiler to generate steam. The steam was then passed under pressure into the contaminator. The contaminator contained a dilute solution of the contaminating salt or salts and was so built that the steam entered the bottom, bubbled up through the solution, and was taken off at the top. The contaminator was heated by means of a hot plate to compensate for radiation loss and to maintain a constant level of solution. The steam leaving the contaminator was passed through an electrically heated superheater, then through an orifice so as to impinge on the removable blade, and then through a copper-coil condenser to the condensate storage. The steam pressure and the superheated-steam temperature were maintained constant by means of potentiometer temperature regulators. The temperature of the blade on the side opposite the point of steam impingement was recorded on a recording potentiometer temperature recorder. When a vacuum was maintained in the condenser this was done by evacuating the condensate storage to the desired pressure. The pressure in the container holding the blade was determined by means of a pressure gage.

If the temperature and pressure existing in the generating

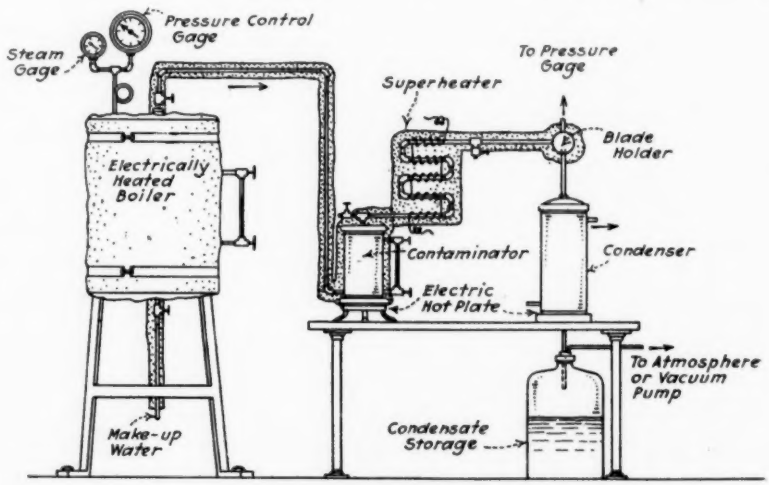

FIG. 2 ASSEMBLY OF APPARATUS

stations was in range of 600 lb and 700 F, a concentration of about 80 per cent sodium hydroxide would result. In order to simplify the construction of the test apparatus the tests were run at 45 lb per sq in. abs and 400 to 700 F, with a pressure of 0.8 lb in the blade chamber. Reference to the curve in Fig. 1 will show that under these conditions the sodium hydroxide should reach a concentration of between 85 and 90 per cent. This concentration is in the range of that reached in turbines. The orifice was $^1/_{16}$ in. in diameter and the blade was set at an angle of 30 deg to the line of steam flow leaving the orifice.

The first tests were run for 22 hr with 2 grams sodium hydroxide added to the contaminator and the temperature of the superheated steam varied between 400 and 700 F. Deposits formed on the blades. The theoretical composition of the sodium hy-

droxide in the steam at the time of contact with the blade during these tests varied from about 85 per cent at 400 F to about 98 per cent at 700 F. Tests run with distilled water alone in the contaminator gave clean blades. When sodium chloride was added to the contaminator and tests run at 500 F, no deposit formed on the blade in the area of high velocity. Similar tests with sodium sulphate gave like results. Trisodium phosphate and sodium silicate both formed deposits on the blade.

The sodium-hydroxide, silicate, and phosphate deposits were formed because hydroxide was present in all these salts. If this is true, any chemical added to the contaminated steam which would neutralize the hydroxide should prevent the hydroxide from forming. In order to prove this hypothesis the apparatus was modified so that carbon dioxide could be slowly added to the steam beyond the contaminator and ahead of the superheater. The carbon dioxide, if present in excess, should react with the hydroxide to form sodium carbonate. This salt should exist as a dry powder in the steam and no deposit should form. When carbon dioxide was added after contamination with sodium hydroxide, sodium silicate, and sodium phosphate, no deposits formed. This showed conclusively that the sodium hydroxide was the binding or adhering agent, and if it were changed to carbonate prior to reaching the blade, no deposit would form.

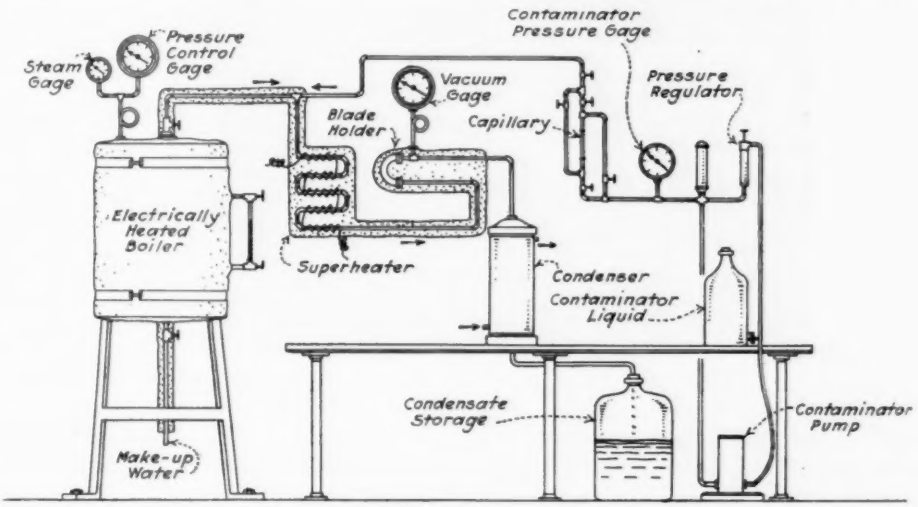

FIG. 3 ASSEMBLY OF APPARATUS, REDESIGNED

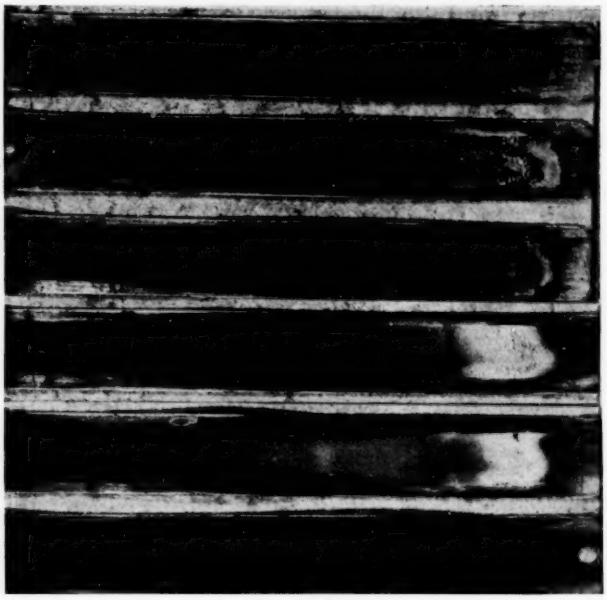
In order to study the possibility of the utilization of carbon-dioxide treatment the apparatus was modified so that the carbon dioxide could be added to the superheated steam instead of the wet steam. When tests were run using this method of treatment the deposits continued to form even when large excesses of carbon dioxide were present.

This change in the action of the carbon dioxide is easily explained. When the gas is added to the wet steam the sodium hydroxide in the droplets of water is in a dilute solution. In this state the carbon dioxide also is soluble in the water depending upon its partial pressure in the steam. As the two chemicals are in dilute solutions, they are strongly ionized and will react readily so that the sodium carbonate is formed before the steam is superheated. However, when the steam is superheated before adding the carbon dioxide the excess water present is converted to steam and the sodium hydroxide is present in the form of a highly concentrated solution, more than 80 per cent NaOH. In such a solution the hydroxide is only slightly ionized, the carbon dioxide is present in the steam as a dry gas, consequently there is practically no reaction between the gas and the sodium hydroxide. This appeared to make the carbon-dioxide method of treatment rather complicated.

CONCENTRATION OF CAUSTIC NECESSARY FOR DEPOSIT

After this substantiation of the hypothesis that sodium hydroxide is the basic adhering material in the turbine-blade deposits it seemed desirable to obtain further data on the limiting concentration of sodium hydroxide in the steam which would cause blade deposition and on other methods of prevention of this troublesome deposit.

In the apparatus already described the carry over or contamination of the steam was excessive in the early period of the test. This was shown by the fact that with a constant water level in the contaminator the concentration of the contaminating salts steadily decreased. At the same time it was almost impossible to know the amount of contamination in the steam at any particular time.



In order to overcome these objections the apparatus was redesigned as shown in Fig. 3. The blades were made from watch springs ($^3/_8$ in. by 0.020 in.) and were removed at the end of each test. The steam nozzle was made by slotting the end of the tube and this brought a sheet of steam in contact with a curved blade in a manner similar to that in which the steam strikes the blade of a turbine.

The contamination was brought about by pumping the solution containing the desired concentration of chemicals into a small reservoir where it was held at a definite pressure by means of a ball-seat pressure regulator. The excess liquid leaving the regulator was returned to the pump suction. The reservoir was connected through a small capillary orifice to the steam line ahead of the superheater. The steam pressure was maintained constant by means of a steam pressure regulator connected through relays to electrical heat controls on the boiler.

With a constant pressure drop across the orifice the amount of contaminating liquid entering the steam through the orifice was constant and depended upon the pressure drop across the orifice which was under definite control. About 0.55 ± 0.02 lb per lb per hour of contaminating liquid was fed into the steam. The total amount of steam—steam from boiler plus steam from contaminator liquid vaporized in the superheater—passing through the nozzle was about 10 lb per hr.

The water fed to the boiler was condensed steam from the steam-heating system which had passed through an electrically heated boiling deaerating heater prior to being pumped to the boiler. The boiler pressure was maintained at 40 lb gage. Several pressures in the chamber holding the blade were used.

Tests were then run using the new apparatus and holding the vacuum in the blade chamber at 20 in. of mercury. With the sodium hydroxide in the steam (calculated) at 48, 18, 5, 2, and 1.5 ppm deposits formed in 20-hr tests. Tests in which distilled water was added to the steam gave no deposit. When the steam was passed through the nozzle there was a marked change in velocity. The calculated velocity in the steam line ahead of the nozzle was 21.5 fps. The velocity through the nozzle was 1175

TEST NO.	CHEMICALS ADDED TO STEAM, PPM $NaOH$	Na_2SO_4	SiO_2

152	4.4	17.5	2.5

FIG. 4 PHOTOGRAPHS OF BLADES AFTER TESTS

fps, and the velocity past the blade was 950 fps. Thus the velocity at point of contact with the blade was approximately 1000 fps.

The maintenance of a vacuum in the blade holder complicated the operation of the test. Consequently, tests were run in which atmospheric pressure was maintained in the blade holder. With such a change in conditions the velocity of the steam in the holder dropped from a nozzle velocity of 1175 fps to 320 fps. Undoubtedly the velocity at the point of impact with the blade was still in the range of 1000 fps. Tests run under these conditions with 4, 5, 4.0, 3.2, and 2 ppm of sodium hydroxide added to the steam gave deposits in the 20-hr tests. This showed that a deposit would form with the sodium-hydroxide content of 2 ppm in 20 hr. The remainder of the tests were run at this pressure unless otherwise noted.

Sodium sulphate alone was added so as to have 10 ppm in the steam and no deposit formed. A mixture of sodium hydroxide and sulphate was then added so that the NaOH was 4.2 and the Na_2SO_4 8.6 ppm in the steam and small deposits formed, but not as much as that formed by the sodium hydroxide in the absence of the sodium sulphate. The sodium hydroxide was then increased to 5.8 and the sulphate to 25 ppm and no deposit formed. This test was followed by one with a sodium-hydroxide concentration of 2.9 ppm and no sulphate. A definite deposit formed. This appeared to indicate that the sulphate was preventing the hydroxide from adhering to the blade.

Tests were then run with the sodium-hydroxide concentration held constant at 3 ppm and the temperature at 350, 400, and 615 F. A deposit formed in all these tests, indicating that changing the temperature did not have much effect upon the tendency of the sodium hydroxide to adhere to the blade.

The theoretical composition of the sodium hydroxide in the steam leaving the nozzle and in the blade holder are given in Table 1 for these temperatures. This shows that the caustic soda is adhering over a range of approximately 50 to 93 per cent and possibly a greater range, and illustrates the fact that temperature does not materially affect the tendency to deposit if the steam is superheated.

The procedure followed in running these tests involved attaching the blade holder after the steam was superheated and removing it while the steam was still superheated. Modification of this procedure so as to attach the blade holder before the steam was superheated but while the caustic solution was being pumped into the steam gave a condensate having a distinct caustic alkalinity which corresponded with the theoretical contamination. However, when the steam was superheated the condensate was practically free from sodium hydroxide. This showed clearly that the sodium hydroxide was being removed prior to the condensing of the steam. The deposit on the blade showed that the last bit of sodium hydroxide was being removed there.

It was doubtful that all the sodium hydroxide was being removed at the blade since a large amount was undoubtedly being removed in the superheater and piping ahead of the nozzle. At the end of each run the wet steam was run through the superheater and pipe after the blade holder had been removed. This contained appreciable amounts of caustic soda and proved that it was depositing in the superheater.

In order to determine the actual amount of sodium hydroxide in the steam at the nozzle and to see how completely it was being removed at the blade the apparatus was redesigned so that the conductance and pH value of samples of the contaminated steam and condensed steam before and after the blade holder could be determined. The boiler, superheater, blade holder, and condenser were the same as those previously used. A steam sampler was installed just ahead of the nozzle. The $^3/_8$-in. steam pipe was expanded into a $1^1/_4$-in. pipe in which two $^1/_8$ in. tubes had been inserted. These were drilled with small holes. The $^1/_8$-in. tubes passed through condensers to a valve on the cool side of the condenser. In this manner a small amount of the contaminated superheated steam was removed continuously from the steam,

TABLE 1 THEORETICAL CONCENTRATION OF SODIUM HYDROXIDE IN STEAM BEFORE AND AFTER NOZZLE

Steam press. gage, lb per sq in.	Steam temp, F	Pressure in blade holder	—NaOH in steam— Before nozzle, per cent	In blade holder, per cent
40	350	atm	45	63
40	400	atm	62	75
40	500	atm	79	87
40	600	atm	90	93

condensed under pressure, cooled, removed, and passed, without exposure to the air, to a conductivity cell and a glass electrode. Thus the conductance and the pH value of the condensed contaminated steam were determined. The condensed steam leaving the condenser after the steam had passed over the blade was also passed through a conductivity cell and a glass electrode. A comparison could thus be made of the values obtained from the condensed steam.

Distilled water was used for make-up. It was passed through the electrically heated boiling deaerating heater to remove dissolved gases such as oxygen and nitrogen and was pumped to the boiler. With this type of boiler feedwater the condensed steam from the boiler had a conductance of 0.05×10^{-6} mho or less.

When feedwater of this better quality was used the test procedure was modified so that the larger blade was weighed before and after the tests. The time of the tests was reduced from 20 to $5^1/_2$ hr. Tests for carbon dioxide were also run on the condensed steam after the blade in some cases.

Tests were run under these new conditions. Fig. 4 shows photographs taken of the blades after the tests. The blades have been flattened out. These results are interesting because they show that when sodium hydroxide is added to the steam in amounts as low as 0.55 ppm appreciable deposits, 2.7 mg in $5^1/_2$ hr, formed. This concentration in the steam is a maximum value.

The results in Table 2 also show that sodium sulphate and disodium phosphate did not cause deposits to form, whereas trisodium phosphate and sodium chloride caused small deposits to form.

TABLE 2 RESULTS OF TESTS USING STEAM CONTAMINATED WITH SULPHATE, CHLORIDE, AND PHOSPHATE

Prevention of Deposit

Table 3 shows the results of tests run with varying amounts of sodium sulphate when the sodium-hydroxide content was constant. When the ratio of the sodium sulphate to the sodium hydroxide was 4.4 and greater the deposit did not form. This checked with the previous results and indicated that the presence of a sufficient amount of sodium sulphate with the sodium hydroxide prevents the formation of a deposit on the blade.

The addition of sodium chloride to the sodium sulphate so that the ratio of sodium sulphate to sodium hydroxide was 3.3 and sodium chloride to sodium hydroxide was 2.5, or the ratio of the total of the sodium sulphate and chloride to the sodium hydroxide was 5.8, did not entirely prevent the deposit; however, the deposit was less than it would have been with the sulphate alone present with the hydroxide, indicating that sodium chloride when present with the sulphate aids in the prevention of the deposit.

The presence of silicate along with the hydroxide tended to decrease formation of the deposit. When the sodium sulphate was present in an amount four times the sodium hydroxide, only a small deposit formed. This indicated that the sulphate was also effective in the presence of the silicate.

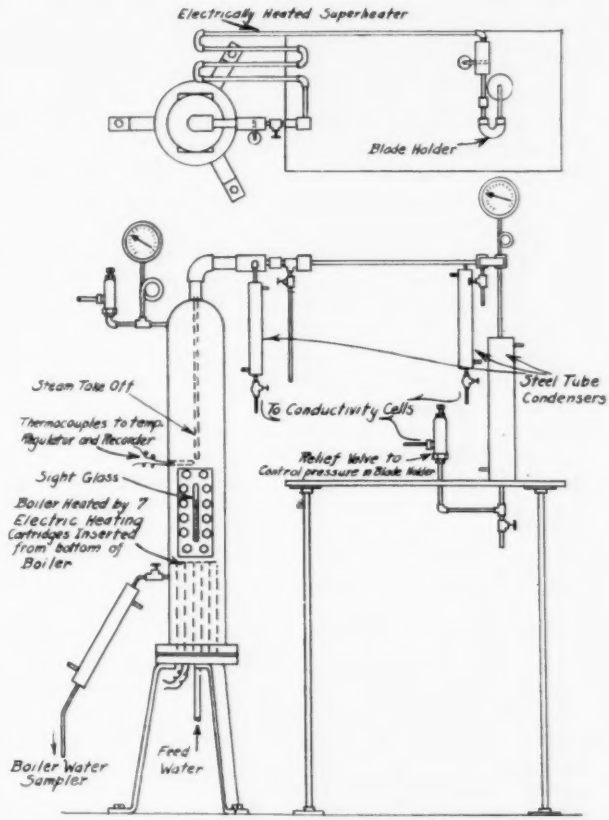

FIG. 5 APPARATUS USED FOR HIGHER-PRESSURE TESTS AND CONTAMINATION OF STEAM FROM BOILER WATER

Effect of Contaminating the Steam With Boiler Water

In the tests previously run the contamination was accomplished by adding the desired chemicals to the steam. This showed that if these chemicals were present in the steam the deposits could be formed or prevented. However, it seemed advisable to determine the actual ratios of the inhibiting chemicals necessary in

the boiler water to prevent deposits. In such tests the contamination of the steam would result entirely from carry over from the boiler and the results would be more readily applied to actual operation.

The apparatus used for these tests is shown in Fig. 5. The superheater and the equipment beyond the boiler involved the same type of equipment as used before, except high-pressure fittings were used and stainless-steel pipe (18–8) was used for the superheater and subsequent piping. The boiler involved the use of seven 1.1-kw electric heating cartridges. These were inserted from the bottom into tubes welded into the bottom of the boiler. The water level and the behavior of the solution during boiling was observed by means of sight glasses placed on opposite sides of the boiler. The heat imput was controlled by means of potentiometer temperature regulators so as to maintain constant temperature and pressure in the boiler. The boiler feedwater was the same as previously described. The chemical contamination of the boiler water was accomplished by pumping the desired amount of chemical into the boiler at the beginning of the tests. Samples of the boiler water were taken for analysis at the beginning and end of each test. Condensed steam samples were taken ahead of the superheater, ahead of the nozzle and beyond the blade holder and the conductance and pH values were determined. These tests were run for $5^1/_2$ hr at a steam pressure of 600 lb per sq in. and a total steam temperature of 700 F. The orifice was changed to a round hole, No. 75 drill, instead of a slot. The pressure in the blade holder was changed from atmospheric to 500 lb per sq in. gage, thus giving a pressure drop of 100 lb across the nozzle. The amount of steam passing through the nozzle per hour was the same as in the previous lower-pressure tests.

When these tests were started the blades were found to be coated with a film of what appeared to be magnetic oxide. This coating formed all over the blade and appeared to be the result of a reaction between the superheated steam and the steel in the blade. When the pressure was dropped to 300 lb and the temperature to 500 F, this action stopped. Stainless-steel blades, 18 chromium, 8 nickel, were substituted for the steel blades. When the steam was of high quality and apparently contained no sodium hydroxide, the blade remained clean and was not attacked by the steam. When the boiler water contained sodium hydroxide the blades were attacked and became so brittle that they broke upon being removed. Substitution of monel-metal blades appeared to overcome these difficulties and a series of tests was run with this type of blade. The results of these tests are given in Table 4.

PLANT EXPERIMENTS

The results reported from many power plants indicate that the detection of the difficulty encountered with blade deposits is mainly in the form of loss of capacity. The efficiency loss becomes appreciable before capacity loss is detected. When capacity loss is noticed the deposits have formed, and they must be removed to obtain normal operation. Thus if the water treatment is to be studied or modified to prevent the deposits from forming, it is advisable to have a rapid method of studying the effect on the formation or prevention of deposits. Early in the research, attempts were made to devise a small testing unit which could be used to test samples of the steam in an operating plant and tell in a relatively short period of testing whether the steam would cause blade deposits or not. If such a unit could be devised, a definite study could be made on the effect of modification of water treatment on the deposits formed without waiting for the effect to be noticeable at the turbine.

A small test unit was made which would allow a small amount of the steam from the heater just ahead the turbine to flow through a nozzle, strike a section of regular turbine blades, and then exhaust through a regulating valve. With data relative to the temperature, pressure, and size of nozzle available, the velocity of the steam passing the blade and the quantity per unit of time could be calculated. The blade could be removed at any time desired and the amount of deposit formed determined by weighing.

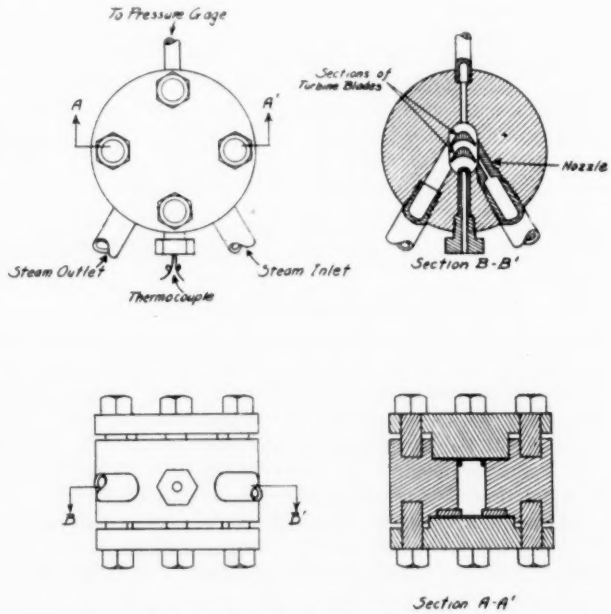

FIG. 6 TEST UNIT USED IN PLANT TESTS

Fig. 6 is a drawing of the test unit developed and used in the plant tests. The steam passed through a nozzle and over sections of regular turbine blades. Leaving the blades, the steam passed out of the unit and was piped through a valve to a desired point for disposal. By regulation of the exhaust valve the pressure in the chamber holding the blade could be held at any desired value. The temperature was determined by means of a thermocouple inserted in a well. The blade was cleaned, dried, weighed, and inserted into the holder. The cover was then bolted on and the steam pressure adjusted to the desired value. At th

[1] Approximate.

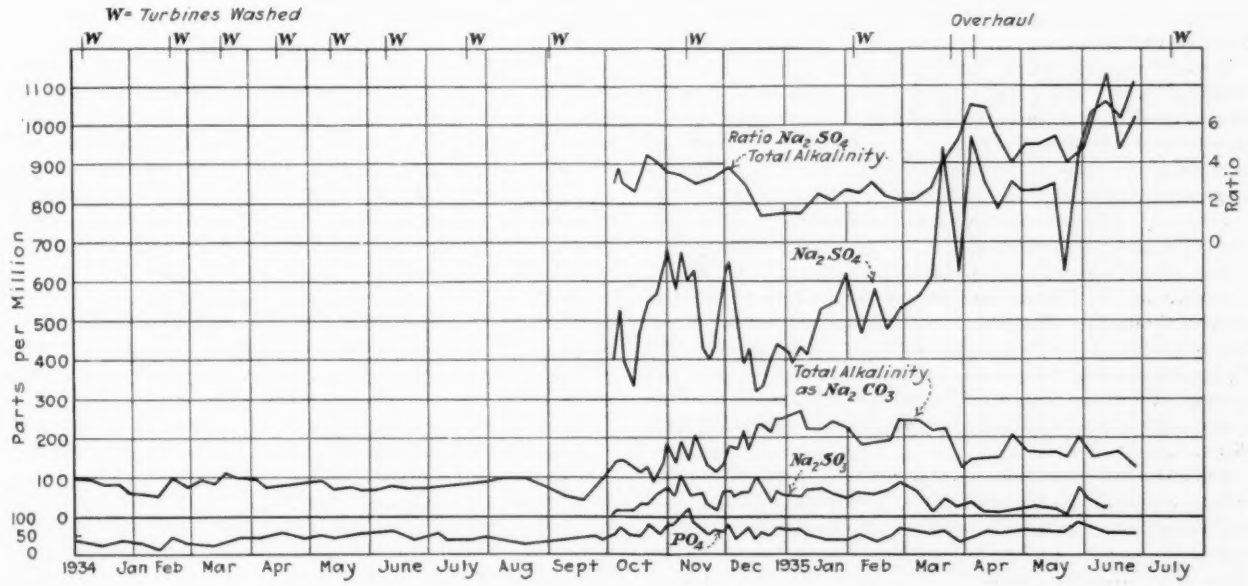

FIG. 7 AVERAGE ANALYSES OF ALL BOILERS IN SERVICE

end of the test the steam was shut off, the blade removed while still hot, cooled in a desiccator, and weighed. The amount of steam passing through the unit was calculated and the amount of deposit per unit of steam was determined. The deposit formed was reported in milligrams per million pounds of steam passing through the unit.

The unit was tested in a central plant operating at a pressure of 600 lb per sq in. and a temperature of 725 F. The steam pressure at the nozzle was between 350 and 520 lb per sq in. and the temperature between 635 and 725 F. The pressure drop through the unit was adjusted so as to obtain the desired rate of flow. This was held at 870 lb per hr in the majority of tests and was accomplished with a pressure drop of 100 lb. With this pressure drop the velocity of the steam passing the blades was about 460 fps. Table 5 gives the results of the tests run with the test unit.

The unit was installed on a line connected to the steam header just ahead of the turbine. The first test was run for 53 hr and gave a total deposit of 11.3 mg or at the rate of 251 mg per million pounds of steam. The next test was run under the same conditions for 234 hr and the amount of deposit was 45.5 mg and the rate of deposit was 221 mg per million pounds of steam. This indicated that the rate was almost constant and a test of 52 hr was sufficient to detect the amount of deposit forming.

In the next test the rate of flow was lowered from 870 to 430 lb per hr, which changed the velocity from 460 to 140 fps. The deposit increased forming at a rate of 310 mg per million pounds of steam. This third test showed that the deposit would form over a wide range of steam flow through the unit. During these tests the regular water treatment was in use and the plant was experiencing difficulty with blade deposits. The turbine was washed every four weeks.

Fig. 7 shows the average boiler-water conditions during these tests and the time of turbine washings. The boiler-water treatment was modified early in October, 1934, to increase the sulphate concentrations so that they would be similar to those found advisable in the laboratory tests. In order to obtain the desired sulphate, sodium sulphite was added. The sulphite would react with the small amount of oxygen present and reduce corrosion. The sulphate formed would aid in the prevention of blade deposits.

The sodium-sulphate content before the addition of the sul-

phite was between 15 and 30 ppm and is not shown. At the time of change in water treatment the sodium-hydroxide content was also increased with a corresponding change in pH value. All of these changes increased the total dissolved solids in the boiler water from a maximum of 260 ppm to about 1200 ppm. The ratio of the sodium sulphate to total alkalinity increased to a range between 3.5 and 4.6 for the period between October 1 and November 11.

The turbine was washed on July 22 and not washed until Sept. 2, a duration of six weeks instead of four weeks as usual. The loss due to blade deposits, calculated from increase in stage pressure over that of clean turbine, was greater at the end of these six weeks than for a regular four-week period, as was to be expected. The water treatment was changed about October 1, a period of four weeks after the turbine had been washed. At this time the tests of the turbine showed about the regular amount of loss due to deposits. The turbine was not washed. The deposit did not appear to increase as rapidly as before the changes in water treatment and the turbine was allowed to run until November 11 before washing. The deposit did not appear to be causing any more difficulty at the end of the ten weeks than at the end of the first four weeks.

Tests run on the small testing unit during the period after change in water treatment showed a deposit rate of between 20 and 66 mg per million pounds of steam as compared to 250 mg per million pounds of steam prior to the change, a reduction of about 90 per cent in the deposit. The amounts of deposits weighed were about 0.5 mg which was about the limit of accuracy of weighing. These results appeared to indicate that the deposit was being materially reduced.

The turbine was not washed again until February 3, a duration of twelve weeks. During this period the sodium sulphate to total-alkalinity ratio dropped from 3.5 to 1.6 and was 2.5 at the time of washing. The turbine was taken out of service on March 24, for overhauling and inspection, and was washed to aid in cooling. When the turbine was opened it was found free from deposits, indicating that if any deposits were forming they were all removed by washing.

While the turbine was out of service the method of adding the sodium sulphite was changed from intermittent dosage to a continuous feed. It was hoped that this would give a better control of chemical feed and thus show a more consistent sulphate concentration. However, the sulphite was added at a point where appreciable oxygen was present, ahead of the heaters, and this brought about an increase in the sulphate formed. The sulphate content increased to a much higher value than was previously maintained.

When the turbine went back into service blade-deposit formation appeared to be slow. The turbine was not washed again until July 14, a duration of 14 weeks. Thus the time of washing was changed from four-week periods prior to the change in water treatment to an average of 12 weeks; and this change resulted during the period when the control of the water treatment was in the experimental stage.

DISCUSSION OF RESULTS

The results of these studies indicate that the turbine-blade fouling is caused by chemicals carried into the steam from the boiler water. The amount of this contamination does not have to be large and steam which would normally be referred to as being of excellent quality might cause a great amount of deposit. The chemical causing the major portion of the difficulty appears to be sodium hydroxide. This is present in practically all boiler waters and when carried with steam that is superheated forms a concentrated sticky solution. This sticky material forms the basic binder and adheres to the turbine blades. Other salts present in the form of a dry powder would normally be swept past the blades. However, when caustic soda is present these salts adhere with the pasty caustic. This may cause a deposit in which the relative proportions of the constituents bear no relationship to the ratios in which they occur in the boiler water.

The amount of deposit is not proportional to the carry over from the boiler, but depends upon the relationship which exists between the various salts in the boiler water. Thus high hydroxide in respect to the total solids may cause an excessive deposition even with a low concentration of sodium hydroxide in the boiler water. However, a boiler water with a sodium-hydroxide content low with respect to the total solids present but high in concentration might not cause a deposit. This is because salts other than sodium hydroxide apparently aid in the prevention of the deposits.

The salts which form a dry powder in the superheated steam apparently adhere to the surface of the droplet of concentrated pasty sodium hydroxide, and if present in sufficient amount entirely coat the particle and allow it to pass through the turbine without sticking to the blades. Such a method of prevention naturally requires large amounts of the dry powder in proportion to the sticky material. The plant tests and laboratory experiments indicate that if sodium sulphate is to be used to prevent turbine fouling it must be present in amounts greater than four or five times the actual sodium hydroxide present. Power-plant operators hesitate to increase the total solids in the boiler water because they fear carry over. However, if this is properly controlled and the carry over does not become excessive, the deposits will be prevented.

The application of the inorganic-salt treatment to one large central power plant while still in the experimental stage showed that the period of turbine washings were reduced from four weeks to about twelve weeks, or from twelve times a year to four. It is quite possible that when the water treatment is better understood washing in this plant may be entirely eliminated. The cost of the treatment used has been low, less than $500 per year, and the savings have been materially high since corrosion has also been reduced.

The application of these data to power-plant operation should be made only after a careful study of the conditions existing at the particular plant and changes which are made should be under the control of a chemical engineer who thoroughly understands this field of water treatment.

CONCLUSIONS

A summary of conclusions drawn from the results of this work is as follows:

(1) The basic material causing turbine-blade fouling is sodium hydroxide.

(2) Inorganic salts, such as sulphate, chloride, and carbonates, if present in sufficient amounts, will prevent turbine-blade fouling.

Cavitation Testing of Model Hydraulic Turbines and Its Bearing on Design and Operation

By L. M. DAVIS,[1] HOLTWOOD, PA.

The author discusses cavitation tests made with model turbines at the Holtwood hydraulic laboratory of the Pennsylvania Water and Power Company and points out benefits which have been realized therefrom. In addition to presenting the results of these tests the author compares them with results obtained by other investigators in this field. The author presents his views regarding the further application of the equipment in the Holtwood laboratory for the purpose of investigating various elements in the design of turbines which may have some bearing on their cavitation characteristics. He points out the need of coordinating the results of cavitation investigations now being conducted in various laboratories so that the industry as a whole may be benefited thereby.

THE Holtwood hydraulic laboratory was put into operation early in the summer of 1930 and since that time has been in almost constant use. Although most of the work done in the laboratory has been in connection with the Safe Harbor development, turbine models of three large projects have been tested for manufacturers on a rental basis.

Since the initial Safe Harbor development is now complete, it seems desirable to review the accomplishments of the laboratory and to point out what benefits have been realized from the research which has been conducted.

The laboratory shown in Fig. 1 is laid out to accommodate normally a model 16 in. in diameter. The pressure chamber is 12 ft by 18 ft inside, so that scroll cases of the desired design may be constructed of wood or other material.

The wheel setting is vertical, and directly below the runner there is an observation chamber in which elbow draft tubes of the shape desired may be constructed. The discharge passes a diaphragm separating the observation chamber from a vacuum chamber, so called because it may be necessary to produce a vacuum in the space above the water in order to maintain the level sufficiently high to seal the draft tube. The set-up allows sufficient flexibility so that spreading tubes, or even straight conical tubes, may be tested, providing a collector is used to direct the discharge into the vacuum chamber. A more detailed description of the laboratory may be found in two previously published papers.[2,3]

In making complete tests of a model the procedure is first to determine the efficiency characteristics in the usual manner, except that with a movable-blade runner there is one more variable to be considered. Tests are made by adjusting the dynamometer to cover the range of speeds desired, observations being taken of the speed, the quantity of water used, the power output, and the head. The water quantity is measured by a 36-in. and 15-in. venturi meter, the output of the wheel by an electrical dynamometer capable of absorbing 300 hp, the speed by a synchronous timer driven by an a-c generator geared directly to the dynamometer shaft, the headwater elevation by a mercury manometer connected to piezometers in the pressure chamber, and the tailwater elevation by a float gage connected to pressure orifices in the vacuum chamber.

For each blade angle, curves are drawn as shown in Fig. 2 for appropriate gate openings, selecting these gate openings so that the most efficient combination of blade and gate will be bracketed. By adjusting the torque absorbed by the dynamometer, the speed may be varied over the desired range which is dictated by the need of including the extreme values of ϕ, which is the ratio between the peripheral speed of the runner and the theoretical spouting velocity of the water, which corresponds to the synchronous speed of the prototype and the maximum and minimum heads at which it may be operated. These tests are run at a very low, or even negative, draft head in order to create as great a pressure around the blading as possible, and thus preclude any likelihood of the results' being affected by separation between the water and the blades, which is cavitation.

After a series of such tests, one for each blade angle, the complete efficiency characteristics of the unit can be plotted. In this way the efficiency curves for the values of ϕ for the various heads in the prototype may be determined. More important, as far as subsequent cavitation tests are concerned, is the selection of the gate openings which will bracket the best combinations of blade and gate for each value of ϕ.

Tests must then be repeated for each value of blade and ϕ with individual series of tests for at least three gate openings; but while the foregoing are held constant, the headwater and tailwater levels are varied to change the ratio between draft head and total head. Any failure to maintain absolutely the right speed to correspond with the head actually used may be corrected on the basis of information obtained from the previous test in the same way that field tests are corrected to guaranteed head by means of the characteristics determined from model tests.

As the draft head becomes greater there will be a tendency for the water to pull away from the underside of the blades with consequent alteration of the efficiency and output characteristics as determined in the first series of tests. Therefore, the object of this second series is to measure to what extent the draft head can be increased without causing this so-called cavitation. It is consequently necessary to adopt some criterion which may be

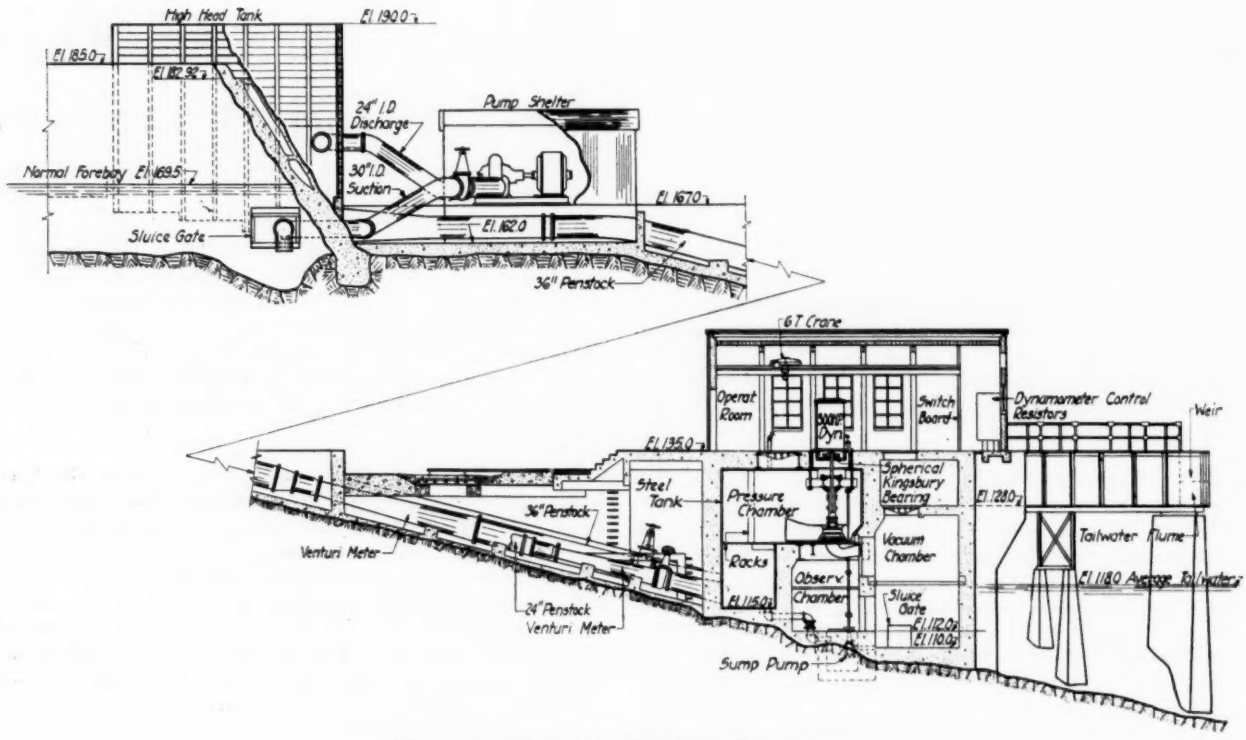

FIG. 1 THE HOLTWOOD HYDRAULIC LABORATORY

used for defining the conditions under which a given model will just begin to cavitate.

L. F. Moody and F. H. Rogers have offered[4] a cavitation coefficient K_c which is obtained from the equation

$$K_c = [h_a - h_m - h_s - (E_d C_2^2/2g)]/H$$

where h_a is the atmospheric-pressure head, ft; h_m is the absolute pressure at the point of minimum pressure, ft; h_s is the static draft head, ft; E_d is the draft-tube efficiency; C_2 is the absolute-discharge velocity from the runner, fps; g is the acceleration due to gravity, ft per sec per sec; and H is the total effective head on the turbine, ft.

Inasmuch as cavitation is assumed to take place only when the lowest pressure h_m becomes equal to the vapor pressure, this substitution may be made, and the value to be used is a function of water temperature alone. To obtain a numerical value of K_c it is necessary also to know the draft-tube efficiency and the absolute discharge velocity. It should be noted that since all the terms in the right-hand side of the equation are expressed in feet of water, K_c is dimensionless.

D. Thoma originated the cavitation coefficient σ through his work at Munich. The physical meaning of this coefficient can be visualized by imagining the following sequence of events. Suppose the model turbine to be operating without cavitation under a constant head and with constant discharge. Since the forebay and tailrace elevations are variable, the tailrace can be lowered while the total head is maintained constant. As the draft head is thus increased, the pressure on certain parts of the runner blade will decrease. When the minimum pressure at any point on the blades just reaches the vapor pressure H_v, cavitation is said to begin. Suppose the unit is shut down as soon as this condition is reached. After the turbine gates are closed, the absolute pressure on the blades is obviously the barometric height H_b minus the draft head H_s. In the operation of the unit, the pressure at some point on the blades was, therefore, lowered from

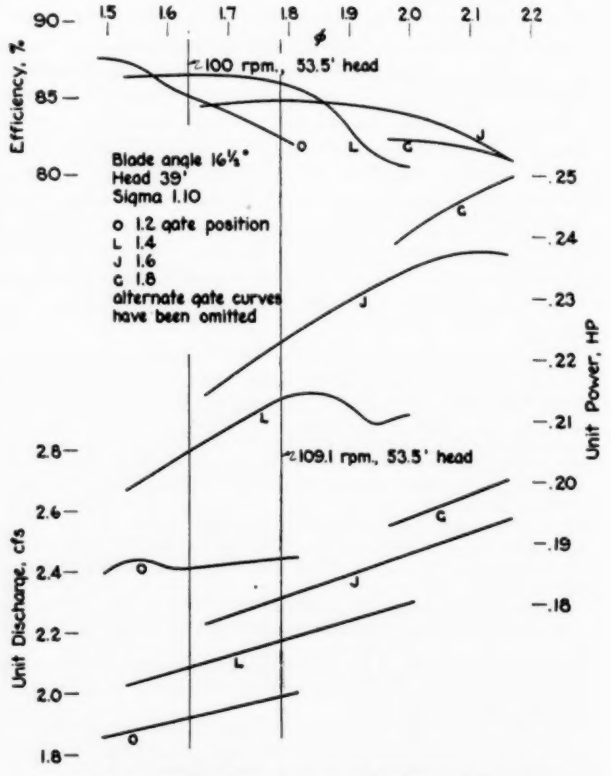

FIG. 2 TYPICAL RESULTS OF ϕ-EFFICIENCY TESTS

[4] "Inter-Relation of Operation and Design of Hydraulic Turbines," by L. F. Moody and F. H. Rogers, *Engineers and Engineering*, July, 1925, vol. 42, no. 7, pp. 169–187.

$H_b - H_s$ to the vapor pressure H_v. This decrease in pressure is a function of velocity and in fact is proportional to the square of the discharge of the unit. Since the square of the discharge is proportional to the head, it follows that the reduction in pressure, $H_b - H_s - H_v$, is itself proportional to the head. Therefore, it is possible to use in place of the pressure drop $H_b - H_s - H_v$, which applies only to the conditions of the test, the ratio $(H_b - H_s - H_v)/H$, which applies to all heads and which is identified as σ.

Comparison between the Moody and the Thoma formulas shows marked similarity. The h_a of the former is the same as H_b, or barometric pressure, in the latter. Likewise the static draft head h_s is the same as the suction head H_s. It has already been pointed out that h_m is equal to H_v. Consequently, the only difference lies in Professor Moody's term $E_d C_2^2/2g$ which is omitted by Dr. Thoma. The inclusion of this term simply means K_c applies to the runner alone since correction is therein made for the effectiveness of the draft tube, whereas σ applies to the wheel and setting as a whole.

The results of the cavitation or σ tests are shown in Fig. 3, where again efficiency, horsepower, and discharge are plotted, but this time as functions of σ. These curves represent the results of three gate openings corresponding to but a single combination of blade angle and ϕ, and similar tests must be conducted to cover all others in the range desired. Ordinarily, only the higher blade angles are of importance and from three to five values of ϕ are used generally to investigate fully the cavitation characteristics for the entire range of head used in the finished plant. From complete cavitation information at four or five values of ϕ

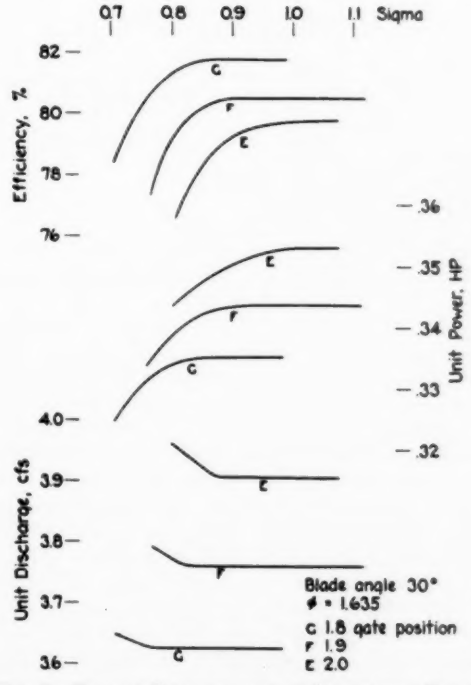

FIG. 3 TYPICAL RESULTS OF σ OR CAVITATION TESTS

it is possible to cross-plot and obtain data for any intermediate value.

It will be noted that on the right of Fig. 3 all of these curves become horizontal. The constant values correspond to those which have been observed in the preliminary ϕ-efficiency tests.

As σ becomes smaller with greater draft head, there occurs a change in the ordinates. The point at which this occurs is known as the break in the curve, or the beginning of cavitation. The exact determination of this point depends somewhat on judgment, and some variation will be found therein, but if several persons pick these points and results are plotted to form smooth curves, independent interpretations of the same data will agree satisfactorily.

One criterion of the break is the dropping off in efficiency. Another is the increase in discharge. These will not coincide precisely on account of the fact observed by Dr. Thoma that there is a slight tendency for efficiency to increase just as cavitation

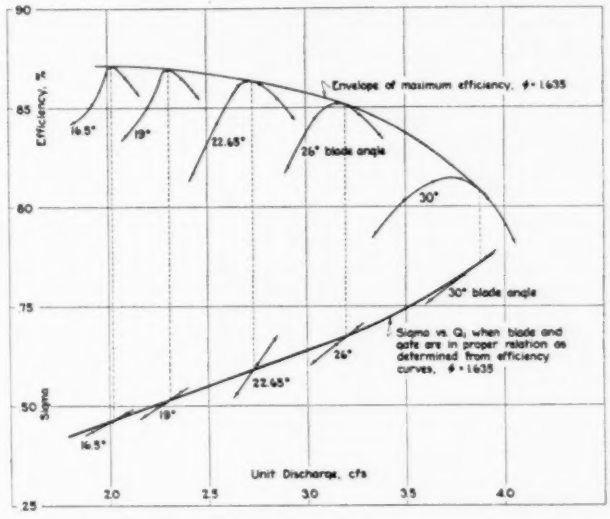

FIG. 4 RECAPITULATION OF σ-TEST RESULTS FOR $\phi = 1.635$

starts which, he explains, is probably due to the decrease in skin friction.

However, it has been observed that with some models the efficiency tends to decrease at a higher value of σ than the point where the unit discharge starts to increase. It is felt that this is due to faulty design resulting in local cavitation which takes place at one or more points on the blade at draft heads somewhat lower than the draft head which causes cavitation over a general area.

It has been the practice in the Holtwood hydraulic laboratory to use the break in the unit-discharge curve to determine critical σ. If there is any great discrepancy between the break in the efficiency curve and the break in the unit-discharge curve, the more conservative should be used, although it is felt that this is an indication of defective design, and possible alterations to correct this discrepancy should be investigated.

The question may be asked whether the break in the σ curve is affected by the head at which the test is conducted. Theoretically there should be no effect and tests made at one head should be applicable to others. This matter was investigated by Prof. Wilhelm Spannhake, of Karlsruhe, whose laboratory was adapted particularly for experiments covering a wide range of heads from about 33 ft down to 5 ft. It was found that especially at the very low heads there was a marked effect, but that for higher heads the break in σ reaches practically a constant value which is independent of further changes. Similar tests at much higher heads were performed at Holtwood without revealing any appreciable difference in σ at which the breaks occur. Therefore, it seems preferable, but not essential, that the cavitation test be made at a head closely approximating that of the prototype.

The next step is to recapitulate the results of the foregoing tests. This is done by plotting the value of σ corresponding to the break against unit discharge as shown in Fig. 4. In order to determine the value of σ at which cavitation begins when the unit is operated at the correct relation between gate and blade, the envelope of the individual efficiency curves is drawn, and

vertical lines are dropped from the points of tangency. The intersections of these verticals with the σ versus unit-discharge curves for the corresponding blade angles locate points on the final curve representing the relation between σ and discharge for a Kaplan unit when operating with the blade and gate in the proper relation to each other. This procedure is repeated for each value of ϕ, thus giving in the end the plot shown in Fig. 5. By cross-plotting, curves may be obtained for any intermediate values of ϕ.

The group of curves given in Fig. 5 gives the complete cavitation characteristics of the model for the range of ϕ indicated. From these curves the proper setting of a homologous runner for any installation with reference to tailwater for a given power output may be determined.

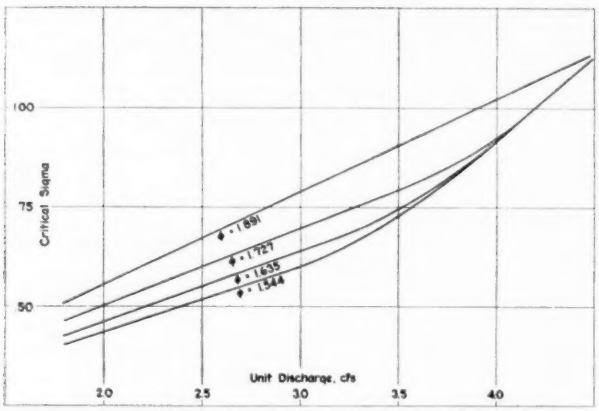

FIG. 5 σ VERSUS UNIT DISCHARGE FOR VARIOUS VALUES OF ϕ

One general characteristic of all tests so far has been the marked effect which the increasing of ϕ has had in aggravating the danger of cavitation. The practical application of knowledge gained through tests is illustrated by the adoption of a lower rotational speed for the most recent installation at Safe Harbor. This reduction proves to have resulted in a substantial increase in capacity in spite of the fact that judging only from the output-ϕ characteristics of the model, the capacity would have been adversely affected. Therefore, it is apparent that when cavitation becomes a limiting factor, the urge for higher speeds for the sake of greater capacity and lower generator cost must be tempered. Since it is obvious that, without cavitation, increasing speed gives greater physical capacity, while the effect of increasing speed on power output as limited by cavitation is just the opposite, it becomes exceedingly important to explore completely the characteristics of a model before making a decision regarding the speed of rotation.

The proper setting for the turbine with reference to tailwater elevation can be determined from Fig. 5 as soon as the runner diameter, speed, rated power, and total head are established. From the efficiency tests, the expected efficiency at the rated head and output may be determined and the discharge computed. The unit discharge may then be obtained, and from Fig. 5 the critical σ will be found. The values of all the terms in the formula for σ have now been obtained except the draft head H_D, which is readily obtained. Adding this value of the draft head to the tailwater elevation gives the runner elevation which will give the desired output without cavitation. Since cavitation would be expected to result if the maximum output as determined by test were slightly exceeded, it is customary, as a factor of safety, to lower arbitrarily the setting a small amount.

Not only is the determination of the critical σ, which is the value of σ at which cavitation begins, useful in fixing the proper height of setting, but conversely the laboratory results can be used to determine the allowable output under given conditions of forebay and tailwater level after the setting has been established.

At this point distinction should be made between critical σ as applied to the runner and plant σ which refers to the plant. Both are expressed by the same formula, but obviously plant σ must not be less than critical σ if avoidance of cavitation is to be expected. It is also clear that by assuming the critical value of σ equal to the plant σ for any given H_s and H_t, the maximum allowable unit discharge can be read directly from the scale of abscissas in Fig. 5.

Whereas it is probably correct, since cavitation is logically a function of water quantity, to derive the discharge for the prototype directly by stepping up from the model without allowance for improved efficiency, nevertheless hydraulic engineers are faced with a serious problem in determining the corresponding limiting power. In the investigations which have been made on the subject of the relation between maximum efficiency of the model and the prototype, no information has been made available as to whether the increased efficiency is obtained as a result of increased output from the same quantity of water, or decreased quantity for the same output. Perhaps there may be a combination of the two effects. It will be seen from Fig. 6, however, that as a practical matter it ordinarily makes very little difference whether better efficiency results from lowering the power-discharge curve or by shifting it to the right except for values near the extreme end of the curve. Thus, to find the prototype output corresponding to a discharge of Q', case 1, it makes no appreciable difference whether we use curve A derived by reduction in discharge, or curve B derived from increase in output. However, for a discharge of Q'', case 2, there may be some doubt as to whether cavitation will reduce the output from HP' to HP'' or whether HP'' would still be above the physical capacity HP''', and, therefore, not a limiting consideration.

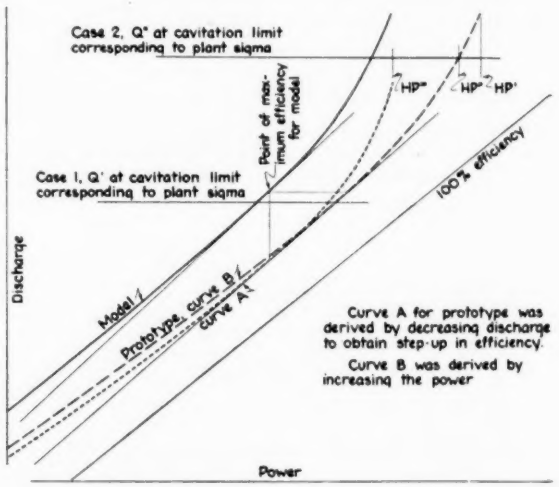

FIG. 6 EFFECT OF STEP-UP ON INTERPRETATION OF MODEL-TEST RESULTS

Therefore, it is sufficient in determining the output as limited by cavitation to assume increase in output in proportion to the expected rise in efficiency resulting from the computed reduction in hydraulic losses. On the other hand, there is great need for further investigation as to the exact nature of this shift by comparison of the discharge versus output curves for various units which have been tested in the field. It is no longer sufficient for our purpose to use a formula by which an increase in maximum efficiency alone can be estimated. There is obviously a need for

further investigation before it may be considered that the principles of stepping-up performance curves are well understood. Uncertainty in this respect is apparent from the fact that the application of the formulas of three separate authorities to the result of the test on one model which has come to our attention is reported to have given answers differing by as much as 4 per cent.

A convenient form for presenting the limiting power output for various head conditions is to draw constant limiting power-output lines using tailrace elevations as ordinates and forebay elevations as abscissas. To obtain this curve it is well first to develop a curve of limiting power output versus gross head, drawing lines of constant forebay elevation. Such a chart is useful in plant operation so that with varying conditions the risk involved in approaching the critical σ of the runner is always the same.

As cavitation data become available it is desirable to compare them so that progress in design may be noted and conclusions drawn as to the features which are or are not advantageous. Fig. 7 shows a plot of critical σ versus unit discharge at rated ϕ for several models which have been tested in the Holtwood laboratory, together with other tests which have come to the author's attention.

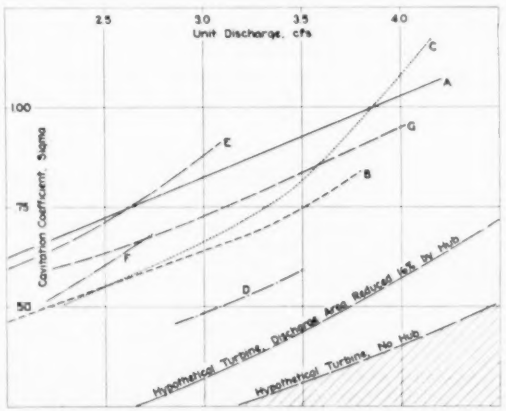

FIG. 7 COMPARISON OF CAVITATION TESTS ON SEVERAL MODELS ON THE BASIS OF UNIT DISCHARGE

While improvement can be expected with experience, this progress, like efficiency, cannot go on indefinitely. There must be some limit beyond which further improvement is impossible.

To illustrate this principle, there may be imagined a hypothetical turbine in which there would be no drop in pressure below the static pressure as the result of pressure difference on the two sides of the blade or irregularities of the pressure distribution along the blade; although this is clearly impossible, it is at least a limiting case. In spite of this, there would be a reduction in pressure simply by reason of the velocity through the throat. In other words the $(H_b - H_v - H_s)$, previously mentioned as the reduction of pressure caused by the operation of the turbine, now becomes only the velocity head of the water passing through the throat. Assuming that this throat may be perfect as an orifice, that the velocity is axial and equally distributed, and also that there is no reduction in area on account of the runner hub, it could then be shown that when H_t is equal to unity this drop in pressure would be equal to the velocity head $c^2/2g$.

Thus, since $Q_1 = ac$ and $a = \pi/4$

$$\sigma = (4Q_1)^2 / 2g\pi^2$$

The values of σ corresponding to various values of Q_1 are shown by the lowest curve in Fig. 7 which illustrates the ultimate limit of perfection. Should we assume, by way of example, a 16 per cent reduction in discharge area by reason of the runner hub, this limit obviously would be raised still further. Keeping this in mind, progress toward the ultimate goal may be judged. The economic importance of any move in this direction will be seen from a study of Fig. 7 where, at a value of 0.75 for plant σ, the gain in allowable power output for curve B over curve A is approximately 27 per cent. In a new installation for 35-ft rated head and a unit discharge of 2.6 cfs the turbine could be set 6 ft higher for curve B than for curve A.

F. H. Rogers and R. E. B. Sharp, in a paper[5] presented at the Cincinnati meeting of the A.S.M.E., June, 1935, discussed a relationship between plant σ and specific speed derived from a comparison of nine important propeller installations in America and Europe, as shown in their curve Fig. 7,[5] which is reproduced in Fig. 8 of this paper for comparison with the results of the models tested at Holtwood and other laboratories. In the discussion of the paper[5] by Rogers and Sharp, R. V. Terry, hydraulic engineer of the Newport News Shipbuilding & Dry Dock Company, suggested the relation $\sigma = N_s^2/25{,}600$ as a close approximation to the critical σ for normal design of turbines. For small installations where cavitation tests are not warranted, he suggests using a more conservative relation, $\sigma = N_s^2/22{,}500$, for determining the turbine setting with reference to tailwater elevations. It appears from test D, Fig. 8, that actually there are potentialities which may be realized as a result of further development and research and that a substantial improvement in design can be made over that which might be expected from the three relationships.

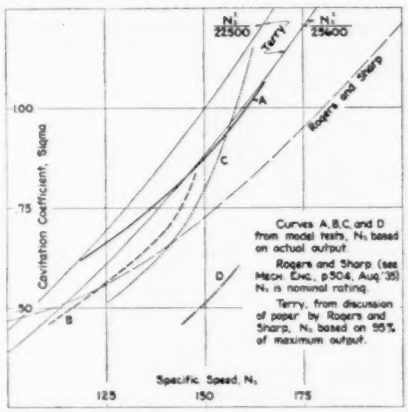

FIG. 8 COMPARISON OF CAVITATION TESTS ON THE BASIS OF SPECIFIC SPEED

BENEFITS DERIVED FROM TESTS

It would be well now to consider the use that has been made of the laboratory results and the benefits derived from the tests made in cooperation with the manufacturers in connection with the design and improvements on the Safe Harbor units.

As a preliminary step in cavitation testing, there is the derivation of complete ϕ-efficiency characteristics of the model. In important installations, strict accounting for the use of water is necessary for reasons of record, and for economy in the preparation of operating schedules. It is seldom possible, without unwarranted expense and loss of time in waiting for extraordinary circumstances, to conduct formal efficiency tests over a sufficient range of heads to gain complete knowledge of the operat-

[5] "45,000-Hp Propeller Turbine for Wheeler Dam," by F. H. Rogers and R. E. B. Sharp, *Mechanical Engineering*, August, 1935, vol. 57, no. 8, pp. 499–506.

ing characteristics of a unit. Consequently, model tests are relied upon in interpreting acceptance-test data to cover the desired variety of conditions to draw up those charts or tables which are necessary in daily operation and in planning the economic loading of units. So much has been written on this subject by other authors that the use of model tests for this purpose seems to be well understood.

An interesting application of model tests in conjunction with index tests in the field is described in a paper by E. T. Schuleen.[6] The reason for conducting the test described by Mr. Schuleen was that in the past there has been considerable uncertainty regarding the effect of runner size on the value of ϕ at which the peak efficiency occurs. Some hydraulic engineers contended that

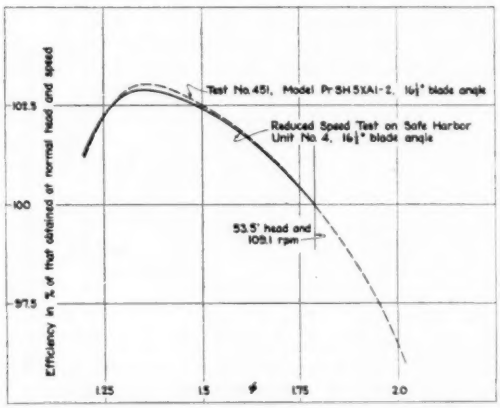

FIG. 9 THE ϕ-EFFICIENCY CHARACTERISTICS OF MODEL AND PROTOTYPE

the peak efficiency occurred at higher values of ϕ as the runner diameter was increased. This question became of vital importance in connection with establishing the speed of Safe Harbor unit No. 2 for 25-cycle railroad service since the model tests indicated an appreciable gain in efficiency at 100 rpm instead of 109.1 rpm, which is the speed of the 60-cycle units. It was consequently decided to test one of the Safe Harbor units at variable speed by means of an artificial load consisting of two other units operated as motors so that a direct comparison could be made between the model and prototype.

Fig. 9 shows a comparison between the envelope efficiencies obtained on this test and the envelope efficiencies obtained on a 16-in. model at the same blade angle of $16^1/_2$ deg. It is felt that this unique experiment proves that the peak efficiency of a given runner design occurs at the same value of ϕ regardless of runner diameter.

Operation of Kaplan units at Safe Harbor, the capacity of which is greater than other units installed so far in this country, has brought up many questions regarding the behavior of these units as affected by cavitation. In seeking an explanation for observed facts and in establishing principles and policies in operation, the laboratory has served as a guide in many cases. This is particularly true in understanding the need for correct setting of the cam for controlling the gates and blades. The importance of correct adjustment and the seriousness of departure from this relation have been brought out clearly by laboratory tests. It is evident from these that whereas error in adjustment on one side of the best blade position may be accompanied by rapid loss in efficiency, on the other side the drop in efficiency is more gradual, but the danger from cavitation is greatly increased.

[6] "Tests at Variable Speeds on a Safe Harbor Turbine," by E. T. Schuleen, published by Pennsylvania Water & Power Company, Holtwood, Pa., May, 1934.

Extensive tests have been made for determining what improvements in blade shape could be made in anticipation of installations of additional capacity. These tests were naturally confined to a narrow range of alterations, being restricted to some blades which were already cast with enough additional finish to allow fairly extensive revamping in machining, and on other blades which could only be chipped to the desired contour. The tests, however, have been sufficiently extensive in their scope to demonstrate the correctness of certain design principles.

Practically every hydraulic engineer who visits the Holtwood laboratory asks: "How do laboratory cavitation tests check actual cavitation conditions at Safe Harbor?" Fig. 10 shows this comparison. The solid line gives the results of the field efficiency tests in per cent of maximum efficiency. The dashed line shows the expected curve from laboratory tests which, as explained previously, are not affected by cavitation. It will be noted that the actual efficiency curve starts to depart from the expected curve at about 33,500 hp. From laboratory tests using the break in the unit-discharge versus σ curve as the criterion for the starting point of cavitation, a limiting output of 34,950 hp was obtained, thus showing a very reasonable agreement.

It should be borne in mind that the test from which Fig. 10 was drawn was conducted when the tailrace was particularly low in order to determine what effect there would be from the worst condition of cavitation. This does not represent ordinary operat-

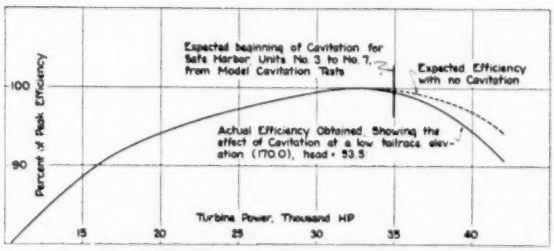

FIG. 10 BREAK IN EFFICIENCY OF PROTOTYPE COMPARED WITH THAT PREDICTED FROM MODEL TESTS

ing conditions and, therefore, the reduction in capacity is not indicative of failure to derive rated output continously from these units. With a normal forebay, the limitation apparently imposed by cavitation in Fig. 10 would be sufficiently raised so that the unit would deliver its full rated output.

It has been found from experience that it is possible to operate somewhat above the limit as determined by the laboratory without accruing enough damage from pitting to be considered out of proportion to the benefits derived from increased output. Inconvenience caused by vibration at these high ratings is successfully combated by the use of a moderate amount of air injected under the head cover.

During the three and one-half years that the Safe Harbor plant has been in operation a certain amount of pitting has occurred. It has been concluded after careful study of the pitting at the time of the numerous turbine inspections and also when the pitted areas were repaired by welding, that the major portion of this pitting resulted from local cavitation induced by irregularities in the blade surface. It is evident that water traveling at high velocities along the blade surfaces cannot follow sudden changes in curvature. When a hollow is present the water leaps over it, forming an unstable cavity. In making repairs great care was taken to grind the welded areas down to a smooth surface free from irregularities or reversals in curvature. Some of these welded portions have been in service two years and no pitting has occurred. This is partly due to the greater resistance to cavitation of the 18 per cent chrome and 8 per cent nickel stainless-steel welding rod which was used, but the improved surface, no

doubt, eliminated local cavitation on the areas which have been repaired and is largely responsible for the absence of pitting.

Further Application of the Holtwood Laboratory Tests

While the accomplishments in the past have proved the wisdom of establishing this laboratory for the purpose for which it was intended, consideration should be given to the future and to what possibilities lie ahead now that the laboratory equipment is available for further work. Up to the present time the experiments have been confined to the change of comparatively few variables, but there still remain for investigation many other elements in the design of a turbine which may have some bearing on its cavitation characteristics, such as the shape of guide vanes, arrangement of the scroll case, form of the head cover, design of the curb ring, influence of the hub diameter, and the runner clearance. Furthermore, there will eventually arise important problems in connection with redevelopment work necessary to secure the maximum amount of additional power from new wheels placed in existing equipment.

The desirability of undertaking further experimentation depends naturally upon what possibilities of improvement are to be expected. Such experimentation is important because it requires but a very slight betterment of either efficiency or cavitation characteristics of the large turbines being built today to justify considerable effort on the part of the designer. A few years ago it was the common impression that because of the high efficiencies attained by Francis turbines, the ultimate goal had been reached. However, with the introduction of the movable-blade propeller, a new field of possibilities was created because it became possible to widen the band of efficient loading. In a like manner cavitation has presented still another field of endeavor wherein the primary object is to make the σ-unit discharge curves, as shown in Fig. 7, approach nearer and nearer to the theoretical limit. It is clearly demonstrated by the admirable performance indicated by curve D, Fig. 7, that actually there are possibilities for a marked advance in this direction.

There is clearly needed some means of coordinating results of different laboratories so that progress may be measured. W. M. White, chief engineer of the Hydraulics Division of the Allis-Chalmers Manufacturing Company, has pointed out[7] his objection to the use of σ. He claims that there is too great a disparity between σ for a propeller turbine such as the Wheeler unit[5] and for a Francis turbine such as used at Boulder dam.[7] In place of σ he proposes the coefficient λ which is simply the expression for the Moody coefficient K_e with the term H omitted. As pointed out previously all of the terms in the formula for the Moody coefficient K_e are expressed in feet of water and therefore, by omitting the divisor H, the result is an expression which indicates simply the pressure available to hold the water to the low-pressure side of the blade. Although Dr. White secures in this way a figure which is more uniform in numerical value, the question may be raised whether or not extreme differences in σ do not express after all the essential difference between the very dissimilar conditions of operation.

Suggestions to relate σ to specific speed have been offered by Messrs. Rogers and Sharp[8] and also R. V. Terry, as mentioned previously. Their criteria have been shown already in comparison with actual tests in Fig. 8. By comparing Fig. 7 with Fig. 8 it is evident that there is a decided shifting of one curve with respect to another resulting from the element of rotational speed which enters into the determination of specific speed.

The ideal comparison would be on the basis of unit horsepower, but in this respect the engineer is still faced with the uncertainty in regard to the applicability of the set-up formula to values other than the point of peak efficiency. Until this problem is solved, the unit-discharge curve is probably the best basis of comparison and should be satisfactory at least for present needs.

A further suggestion comes from the fact that the σ curve is a parabola for the hypothetical turbine, with and without a hub as shown in Fig. 7. It seems logical then to attempt to plot σ against the square of the unit discharge as shown in Fig. 11. If this is done, the hypothetical curves obviously become straight lines.

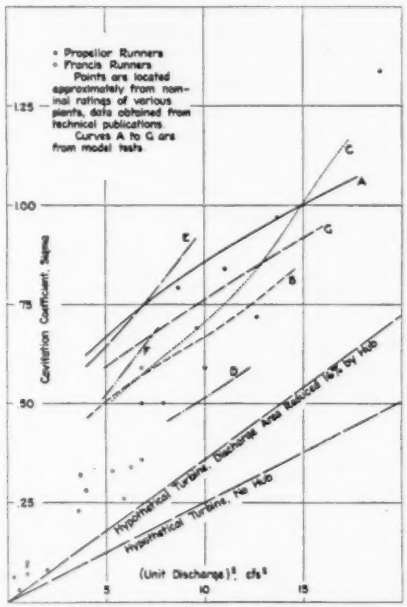

Fig. 11 Comparison of Cavitation Tests on the Basis of the Square of Unit Discharge With Addition of Plant σ's for a Number of Existing Installations

Many of the test curves are distinctly convex downward, particularly those which can be considered as the more reliable. Therefore, it would appear in general that if the curves were extended sufficiently in each case there would be an approach to a straight line passing through the origin followed by subsequent departure. Is it not possible that the point of tangency of a straight line through the origin with the curve in question indicates that value of unit discharge to which the blading is best adapted? Is it not possible also that as more data are collected and plotted in this way, considerable light may be thrown on the perplexing problem of correct shaping of the blades?

As further evidence of the hypothesis that σ is a function of the square of the discharge, there has been added to Fig. 11 points representing the approximate plant σ's and unit discharges for important installations of both Francis-type and propeller-type units. These points have been estimated as accurately as possible from data published in engineering literature, but without going back to original sources. Although this is but a rough comparison it is, nevertheless, striking that, over a wide range of conditions, the setting has been selected by experience (for as far as known no cavitation tests have been made), since for Francis runners there seems to be a distinct straight-line relationship between σ and the square of the unit discharge. Furthermore, if approach to the value of σ for the hypothetical turbine is the thing that is desired, the plant σ's for the propeller installations, most of which have been selected from laboratory tests, do not appear to be as advantageous from the point of excavation as those for the installations of Francis units. This raises the question whether or not in the past hydraulic engineers have been inclined to take risks

[7] "The Construction of the 115,000-Hp Boulder Dam Turbines," by W. M. White, *Mechanical Engineering*, September, 1935, vol. 57, no. 9, pp. 539–546.

that are too great in so far as the settings of the Francis wheels are concerned, or whether, on the other hand, there is some inherent reason why propellers would require more conservative values of σ. One element may be the loss of area taken up by the hub. On the other hand, to decrease the diameter of the hub involves, in the case of Kaplan turbines, mechanical problems and difficulties from clearance spaces, while for all propeller turbines the design of the blading near the hub is particularly difficult and can be mastered only by laboratory tests.

The apparent straight-line relation in Fig. 11 indicates that all that is necessary to reconcile the extremely low σ for the unit at Boulder dam with the high plant σ at the Wheeler dam is to divide each by the square of the unit discharge. No attempt is made here to estimate a normal value for this quotient, since the data for the points shown are but rough approximations. Furthermore, only the plants for which figures were most readily available are included, and no attempt has been made to differentiate between plants encountering serious pitting and those at which operation has been entirely satisfactory.

Inasmuch as the σ versus the unit-discharge curve does offer a reasonably satisfactory basis for comparison, it would seem desirable to have the results of the several laboratories in Europe and America coordinated in this manner. The accumulated data would serve a most useful purpose by informing each laboratory whether the results obtained in any one test were extraordinary in any respect, and thus aid in selecting hidden information that may be found from these tests. For example, curve *D* in Fig. 11 taken alone is simply a test result, but in comparison with the entire group of curves in Fig. 11 it is an achievement —an advance in hydraulic design.

Such a compilation might be undertaken by some central agency, such as the National Hydraulic Laboratory, although consideration should be given to whether or not laboratory errors might not render it worthless. Strange to say, the results are affected very little by laboratory errors because the measure of the break in the σ curve is a change of condition. Consequently, errors in power measurement may have any magnitude as long as they are consistent, while errors in discharge measurement would only shift the final curve slightly to the right or left. In this respect the situation differs essentially from the usual model efficiency tests since the results are not sensitive to ordinary errors.

Finally, it is the author's hope that efforts being made in the investigation of cavitation in various laboratories can be coordinated so that the industry as a whole may be benefited. The Holtwood laboratory offers its support to any movement of this kind.

PRO-57-4

Radiation From Nonluminous Flames

By H. C. HOTTEL,[1] CAMBRIDGE, MASS., and V. C. SMITH,[2] DETROIT, MICH.

Experimental results on the total radiation due to carbon dioxide, water vapor, and mixtures of the two that were recently reported were obtained in a chromel-wound furnace, the maximum operating temperature of which was 1850 F. The final plots were obtained by extrapolating to 3600 F the experimental data covering the range from room temperature to the furnace maximum.

A method is now described for determining these properties directly in the upper temperature range. It consists of measuring the emission of radiation, and the corresponding temperature, from overventilated flames of carbon monoxide, hydrogen, and mixtures of these in a Meker burner of varying length. The products in the flame are calculated from the mixture fed to the burner.

Results are presented for flames of carbon monoxide in mixtures of oxygen and nitrogen in which the burner grid length is varied from 2 to 16 in., the theoretical oxygen from 100 to 300 per cent, and the flame temperature from 2600 to 3800 F. The results establish the validity of the carbon-dioxide radiation chart in its high-temperature range. Less extensive measurements on illuminating-gas flames establish the validity of the water-vapor radiation chart at temperatures of 2500 to 2800 F when the thickness of gas layer is small.

THE problem of evaluating the expected radiant-heat transmission from a nonluminous flame has an obvious practical importance in the design of certain types of industrial furnaces, the evaluation of heat transmission in the internal-combustion engine, and studies in the mechanism of combustion of gases. The literature on the subject includes diverse opinions as to the nature of the phenomenon and does not contain data adequate for the substantiation of any proposed method of predicting the magnitude of the flame radiation. Accordingly the present work was undertaken to determine whether one of the proposed theories could be substantiated by experiment.

The radiation emitted from a nonluminous flame is due in part to radiation emitted consequent upon chemical changes of the molecules in the flame, called chemiluminescence; and in part to thermal radiation from the hot products of combustion, such as carbon dioxide and water vapor. The first kind of radiation depends upon the nature of the chemical reactions involved and is approximately proportional to the amount of fuel burned; the second depends on the temperature, size, and shape of the flame and its hot combustion products and on the concentration of radiating constituents in it, and is influenced by the amount of fuel burned only to the extent that the latter affects the temperature distribution in the flame.

The work of Garner and Johnson (1)[3] and of Johnson (2) has indicated that chemiluminescence, though of extreme importance in studying the mechanism of combustion reactions, accounts for a very small portion of the total radiation emitted from a flame. The calculation of total radiation from a nonluminous flame in an industrial furnace depends, consequently, on quantitative knowledge of the magnitude of thermal radiation from those hot products of combustion which are capable of radiating, namely, carbon dioxide and water vapor.

The earliest quantitative measurements of radiation from carbon dioxide and water vapor were made in 1894 by Paschen (3), who mapped the infrared emission and absorption spectra of hot carbon dioxide and water vapor and showed the interrelation between emission and absorption for those gases. Further work by him on the emission spectra of nonluminous flames led him to conclude that the radiation from them was purely thermal in origin and due solely to the carbon dioxide and water vapor in the flames. The work of H. Schmidt (4) in 1909 confirmed the validity of the assumption that radiation from the products of combustion in flames was thermal in character by proving that Kirchoff's law of the equivalence of absorptivity and emissivity (applicable only to thermal radiation), was applicable to radiations from an illuminating-gas flame. These fruitful suggestions of the physicists remained unused by engineers until Schack (5) in 1924 pointed out how data on the infrared absorption spectra of gases could be used to predict the magnitude of emission of radiation from them.

Moeller and Schmick (6) in the following year measured the radiation from small Bunsen flames, making the measurements in such a way as to permit comparison with the calculations of Schack. Although their experimental results were in agreement with the calculations within 5 to 25 per cent, the agreement was not conclusive since (*a*) the flame diameter was so small as to make edge effects large, (*b*) the effect of water vapor in the combustion products was hidden by the much greater effect of carbon dioxide, (*c*) the basis of comparison with theory (i.e., Schack's calculations based on infrared absorption data) was not established with adequate precision.

Recent experimental data have been presented by Hottel and Mangelsdorf (7), giving the total thermal radiation from hot carbon dioxide, water vapor, and mixtures of the two over a wide range of variation of concentrations, and at temperatures up to about 1900 F. By appropriate plotting, the data have been extrapolated to higher temperatures. Precise measurements of the right kind on nonluminous laboratory flames should serve as a basis for testing the numerical accuracy of the carbon-dioxide and water-vapor radiation charts at high temperatures; those charts could then be used for calculations of radiant-heat transmission from large industrial flames.

Measurements of total radiation of the type of Callendar (8), von Helmholtz (9), and Haslam, Lovell, and Hunneman (10) were made with the whole flame in view of the radiation receiving instrument. These are difficult to compare with the calculation of the expected radiation from hot carbon dioxide and water vapor, because knowledge of the variation of temperature and composition in the flames is not available, and because in some

[1] Associate Professor of Fuel Engineering, Department of Chemical Engineering, Massachusetts Institute of Technology. Professor Hottel received the degree of A.B. in chemistry from Indiana University in 1922, and that of M.Sc. in chemical engineering from the institution with which he is at present connected.

[2] Research Division, General Motors Corporation. Dr. Smith received the degree of B.S. in 1924, M.S. in 1926, and D.Sc. in 1930 from Massachusetts Institute of Technology. Until this year he was engaged as research associate with the Institute.

Contributed by the Process Industries Division and presented at the Annual Meeting of The American Society of Mechanical Engineers to be held in New York, N. Y., December 2 to 6, 1935.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until January 10, 1936, for publication at a later date.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

cases a considerable portion of the thermal radiation was absorbed by a column of cold gas containing combustion products and occupying the space between the flame and the radiometer. Fishenden and Saunders (11), making a rough calculation of what to expect for one set of conditions studied by Callendar, found agreement with predictions based on thermal radiation inconclusive.

EXPERIMENTAL PROCEDURE

To permit a comparison of experimental results with calculations involving the temperature, composition, and depth of flame it is necessary to burn the gas in a burner of such type as will produce a flame uniform in composition and temperature along a line of sight normal to the direction of flow of the gases; to restrict the geometrical limits of vision of the radiation-measuring instrument to a narrow pencil of rays along such a line of sight; and to measure the temperature, composition, and depth of flame along that same line of sight. These experimental requirements are met in the apparatus shown in complete assembly in Fig. 1. For a description of apparatus and experimental procedure sufficiently detailed to permit judgment of the validity of the results, the reader is referred to the Appendix of this paper. Briefly, equipment is provided for generating, drying, and metering carbon monoxide, for drying and metering illuminating gas, air, and oxygen, and for burning the desired mixture of gases in a Méker-type burner *G* (top right center of Fig. 1) consisting of an approach chamber diverging upward to a rectangular water-cooled nickel grid 15.75 in. by 0.813 in., the open length of which can be changed by slide *H*. To measure the temperature of the flame the method of spectral reversal of the sodium-D line is used (see Appendix). The temperature as measured is an average value along the horizontal line of sight of the spectroscope, set just to clear the tips of the small Bunsen cones of the burner grid. During the temperature measurement sodium must be supplied to the flame. This is accomplished in either of two ways, (*a*) by using compressed air in tank *Q* to produce mechanical atomization of a salt spray at *R* in the base of the burner, or (*b*) by vaporizing molten salt with an electric arc in vessel *S* and sweeping the vapor into burner *G* with a stream of nitrogen. The latter method adds no moisture to the flame. Immediately following the temperature measurement, the spectroscope system *M-W-N-W'-N-L* is rocked out of position on its hinged base, and replaced by a thermopile *K*, which consists of a single thermoelement at the focus of a gold mirror. The thermopile, containing no lenses or windows between it and the flame, is suitably diaphragmed to receive a narrow pencil of rays from the same part of the flame in which temperature was previously determined. The thermopile is calibrated by allowing it to "see" into a black-body furnace kept at a fixed and measured temperature.

RESULTS ON CARBON-MONOXIDE FLAMES

The major portion of the experimental work was conducted on carbon-monoxide flames. Radiation was measured for various burner grid lengths, fuel-gas rates, and air-gas ratios, with dry and with moist gases. In addition, oxygen was added in about half the experiments to produce higher flame temperatures or to increase the velocity of flame propagation. The range of variation of the factors studied is shown in Table 1.

TABLE 1 RANGE OF VARIATION OF FACTORS STUDIED, CARBON-MONOXIDE FLAMES

Length of burner grid, L, ft	0.164–1.312
Partial pressure carbon dioxide in combustion products, P_c, atm	0.241–0.369
LP_c, ft atm	0.047–0.476
Flame temperature, t, F	2568–3778
Radiation from flame, Btu per sq ft per hr	8540–20,070
Flame emissivity, p_F	0.022–0.076
Theoretical oxygen, primary, per cent	95–309
Rate of burning carbon monoxide, cu ft per hr	7.1–40.1
Ratio, oxygen to air	0–0.79

Table 2 presents the data with measured radiation converted to "flame emissivity" by dividing by the radiation from a black body at the measured flame temperature. The data are difficult to present graphically because of the number of variables. However, if the radiation from a carbon-monoxide flame is due almost wholly to radiation from hot carbon dioxide, it should depend only on the flame temperature T and on the product term P_cL, where P_c is the partial pressure in atmospheres of carbon dioxide in the combustion products and L is the flame depth or burner grid length in feet. Unfortunately the data were not taken in such a way that either T or P_cL was constant during variation of the other. However, a large number of runs were made with a small variation in the product term P_cL and a large variation in temperature. Fig. 2 shows the results for all runs in which P_cL lies between 0.16 and 0.23, with flame emissivity plotted against temperature. The data points are seen to lie definitely in a band the width of which, within the limits of experimental error of the work, is probably due to the variation in P_cL. Fig. 3 is a carbon-dioxide gas-radiation chart from Hottel and Mangelsdorf (7) based on their measurements of radiation from an electrically heated furnace full of hot carbon dioxide. Although the maximum gas temperature attainable in their experiments was about 1900 F, their extrapolation was guided somewhat by measurements of absorption from a black body at 2400 F. Values from Fig. 3 for P_cL of 0.16 and 0.23 have been converted to emissivity and superimposed on the present experimental data of Fig. 2 as solid lines. Considering the fact that these lines were obtained by an extrapolation for which the authors could not claim a probable error less than 10 per cent or perhaps 20 per cent at 3600 F, the agreement represented by Fig. 2 is excellent. It is taken by the authors as a proof that the gas-radiation chart, Fig. 3, is substantially correct in its high temperature range, along the line $P_cL = 0.2$.

The relation between P_cL and flame emissivity, for a constant temperature, is presented in Fig. 4, in which all the data of Table 2 corresponding to flame temperatures between 1800 and 2200 K have been corrected to a common temperature of 2000 K (3140 F) by assuming that Fig. 2 establishes the relation between emissivity and temperature. In Fig. 4 a solid line is superimposed from the carbon-dioxide radiation chart, Fig. 3, corresponding to 3140 F. Although the line is possibly slightly low at low values of P_cL, the agreement with the data is considered satisfactory and within the errors of individual data points. Factors contributing to the imperfection of the correlation are (*a*) experimental

a = All runs preceding 92 with wet salt spray.
b = Sodium in flame during radiation measurement.
M = In all runs so labeled the combustible mixture contained 0.7 to 1.8 per cent moisture.

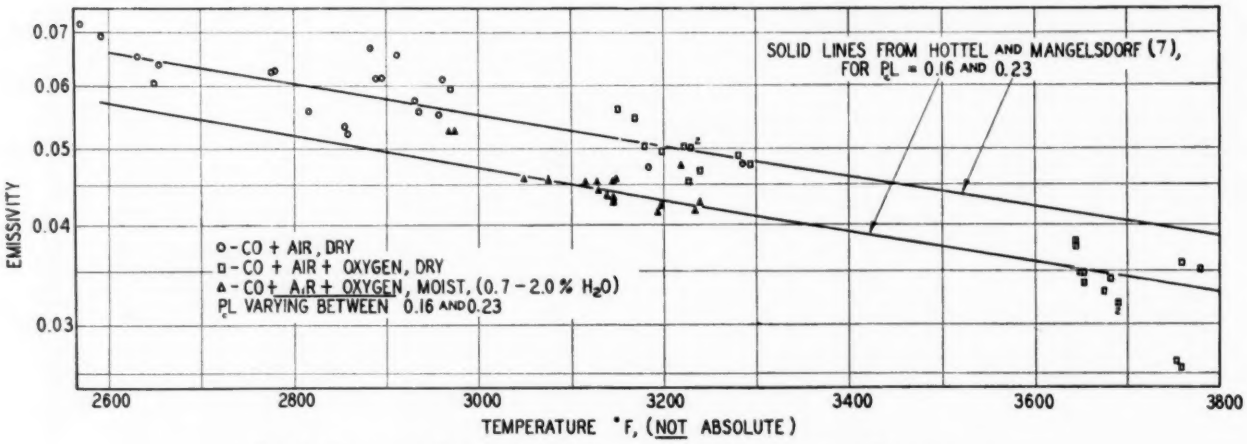

FIG. 2 RADIATION FROM CARBON-MONOXIDE FLAMES—EFFECT OF TEMPERATURE

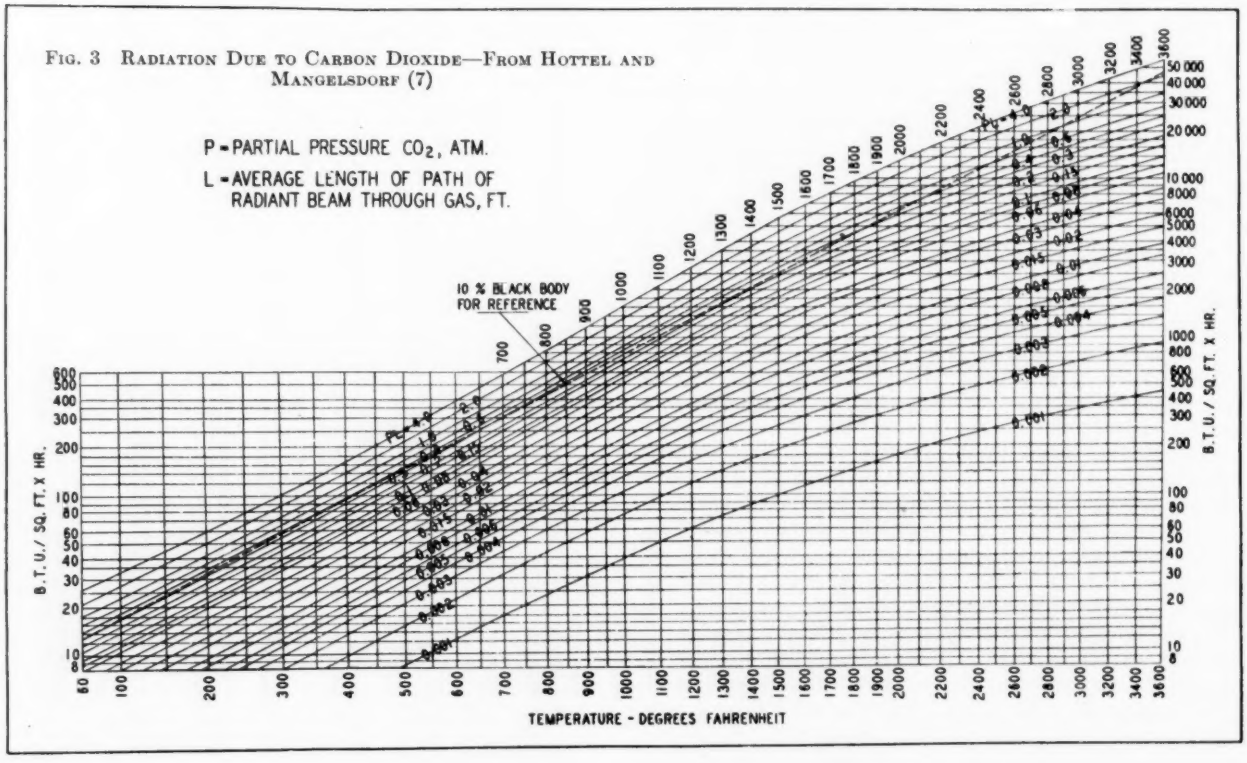

FIG. 3 RADIATION DUE TO CARBON DIOXIDE—FROM HOTTEL AND MANGELSDORF (7)

error, (*b*) difference between actual and assumed carbon-dioxide content of the combustion products due to dissociation (estimated error 3 per cent at highest temperatures), (*c*) infiltration of secondary air, producing a change in composition of combustion products, (*d*) edge effects due to absence of abrupt change from hot flame to cold air at the near flame face.

In some of the experiments (run numbers marked *M* in Table 2) the measurements of flame temperature and radiation were made with 0.7 to 1.8 per cent moisture in the flame. The effect of the moisture, as indicated in Fig. 2, was small. Because of the effect on flame speed of the salt spray used for temperature measurements in runs 1–91 and the consequent possibility that successive measurements (first of temperature with the flame moist and then of radiation with the flame dry) did not corre-

spond, the method of introducing salt was changed in all runs following No. 91. Addition of the salt in dry form had no appreciable effect on the correlation presented in Fig. 2.

RESULTS ON ILLUMINATING-GAS FLAMES

With the verification of the carbon-dioxide radiation charts at high temperatures established by combustion of carbon monoxide, the next logical step is a similar study on hydrogen flames. Experimental difficulties involved in the maintenance of proper flames of hydrogen have prevented such measurements thus far. However, some results have been obtained with illuminating gas-air flames (12). Although the experiments were somewhat less extensive than those on carbon-monoxide mixtures, the data are sufficiently reliable to warrant interpretation.

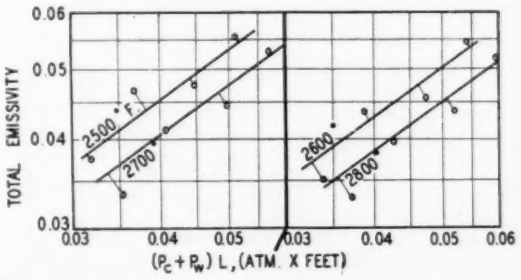

FIG. 7 RADIATION FROM ILLUMINATING-GAS FLAMES—COMPARISON OF EXPERIMENTAL RESULTS WITH CALCULATIONS BASED ON FIGS. 3 AND 8

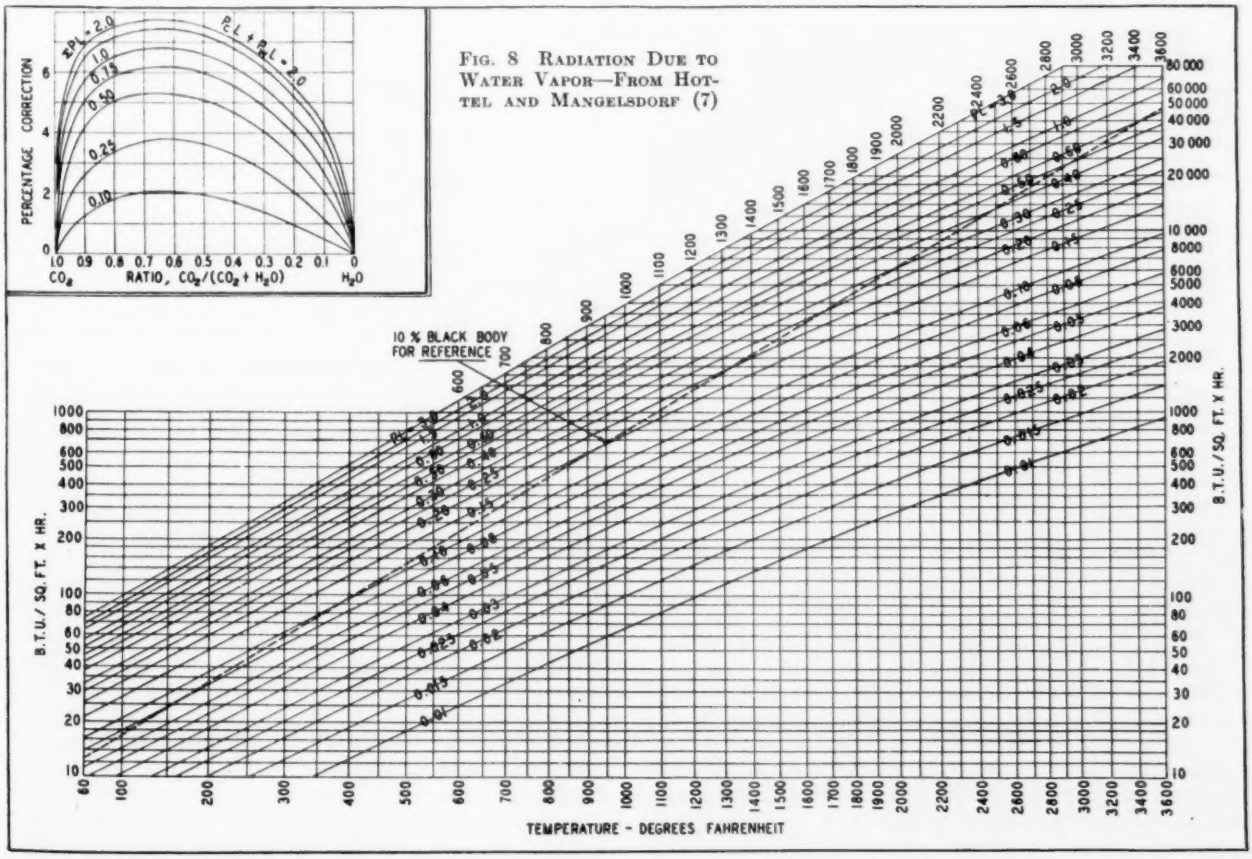

FIG. 8 RADIATION DUE TO WATER VAPOR—FROM HOTTEL AND MANGELSDORF (7)

Fig. 5 shows total radiation versus the air-gas ratio for four different lengths of burner grids and Fig. 6 flame temperature versus the air-gas ratio. The latter plot shows that, as expected, the measured flame temperature is independent of the length of the burner grid for the same air-gas ratio.

If as in the case with carbon monoxide, the radiation is dependent solely upon the combustion products, it may be expected that in the illuminating-gas flames the radiation will depend only upon the temperature and upon $(P_c + P_w)\,L$, where P_c and P_w are the partial pressures of carbon dioxide and water vapor, respectively, in the combustion products, and L is the length of the burner grid. Figs. 5 and 6 have accordingly been converted,

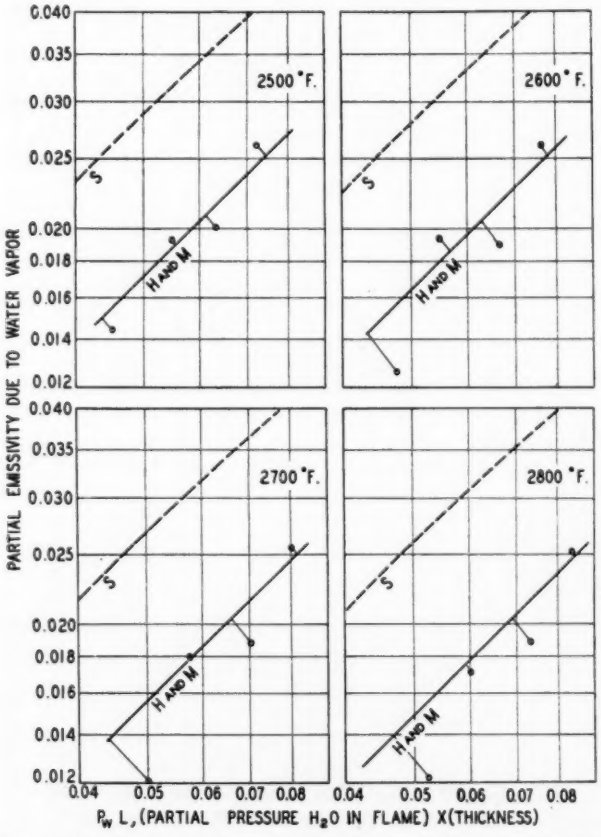

FIG. 9 RADIATION DUE TO WATER VAPOR IN ILLUMINATING-GAS FLAMES—COMPARISON WITH CALCULATIONS BASED ON FIG. 8, AND E. SCHMIDT (13)

by the use of the data of Table 3 on fuel-gas composition, to the form represented in Fig. 7; there total flame emissivity is plotted against $(P_c + P_w)L$ for each of four flame temperatures. By the use of Fig. 3 for carbon dioxide and the analogous Fig. 8 for water vapor (also from Hottel and Mangelsdorf, loc. cit.), the expected total radiation from the combustion products may be calculated. This has been done, the results appearing as solid lines in Fig. 7. It is seen that the gas-radiation charts for carbon dioxide and water vapor account satisfactorily for the measured radiation from an illuminating-gas flame.

TABLE 3 COMPOSITION OF ILLUMINATING GAS BURNED

CO_2	C_2H_4	H_2	CO	CH_4	O_2	N_2
2.2	4.2	48.0	9.4	22.0	1.2	13.0

At the time of publication of the water-vapor radiation chart, Fig. 8, it was pointed out (7) that the literature contained other data on water-vapor radiation by E. Schmidt (13), and that the new chart, though in agreement with Schmidt's results at high values of P_wL, called for considerably less radiation from water vapor at low values of P_wL. Since the first part of the present investigation has established the validity of the carbon-dioxide radiation chart at high temperatures, the data on illuminating gas may be used to obtain the radiation due to water vapor by subtracting from the experimentally measured total radiation that due to carbon dioxide. The residue, presumably due to water vapor, has been converted to an emissivity and plotted versus P_wL in Fig. 9, data points, for each of four temperatures. On that same plot appear solid lines representing water-vapor radiation, taken from Fig. 8 by Hottel and Mangelsdorf; and dotted lines representing water-vapor radiation, taken from the data of E. Schmidt. The agreement of the data points with the solid lines seems to indicate that Fig. 8 is not unduly conservative at low value of P_wL.

CONCLUSIONS

(1) The radiation from flames of carbon monoxide and illuminating gas is calculable from a knowledge of flame size, temperature, and composition.

(2) The accuracy of a chart giving radiation from carbon dioxide has been established over the temperature range 2600 to 3800 F, and the range of P_cL from 0.04 to 0.40 (atm × ft).

(3) The substantial accuracy of a chart giving radiation from water vapor has been established over the temperature range 2500 to 2800 F, at low values of P_wL where there had been some doubt as to whether the radiation chart was unduly conservative.

ACKNOWLEDGMENT

We wish to acknowledge our appreciation of the assistance of John E. Millard, who carried out the work on illuminating-gas flames as a part of a master's thesis at the Massachusetts Institute of Technology.

Appendix

Description of Apparatus and Procedure

CARBON-MONOXIDE GENERATOR

Methods of generating carbon monoxide of high purity in large quantities have been described by Hutton and Petavel (14), Burstall and Ellis (15), and Thompson (16). The principle involved depends upon the thermal decomposition of formic acid in the presence of a dehydrating agent, according to the reaction, $HCOOH = CO + H_2O$. The generator described herein is based on the method of Thompson with a few improvements to be mentioned later.

In Fig. 1, aspirator bottle *A* contains 85 per cent formic acid which is fed to the bottom of the rubber-stoppered, 5-liter Pyrex reaction flask *B*, the rate of feed being observable through the dropping tube sealed into the supply line. Flask *B* is about four-fifths full of 85 per cent phosphoric acid, and is maintained at 170 C. Heat is supplied electrically at a maximum rate of 1700 watts through a coil of chromel wire held between two layers of asbestos paper, the latter being molded while wet to a snug fit around the flask. The flask is supported by its ring neck and housed in a metal container filled with 85 per cent magnesia powder. A thermocouple immersed in the phosphoric acid is connected to a pyrometer controller, giving automatic regulation of the heat supplied to the generator. The gaseous products, carbon monoxide and steam, pass through a 16 mm Pyrex tube to the water-cooled glass condenser *C*, also of 16 mm Pyrex. The condensed liquid escapes through a trap and the cool gas then passes up through the scrubbing tower *D*, filled with short sections of glass tubing, while a 5 per cent sodium-hydroxide solution from aspirator bottle *E* trickles down and escapes through a

trap. Rubber tubing connected to the legs of the trap permits a variable pressure up to 12 in. of water in the generator. Since this type of trap is subject to blowoff under sudden rise of pressure, a mercury safety trap F with a pilot flame at the outlet is included to regulate the maximum pressure in the generator; the mercury trap is set to blow at a pressure less than the liquid heads in the drain traps or the water-sealed gasometer when the bell has risen to its upper limit. With the exception of bottles A and E, the entire generator and the gasometer are completely enclosed under a laboratory hood.

The output of the generator is 20 cu ft of carbon monoxide per hour, being limited not by the power input, as was the case with Thompson's generator, but by the increasing tendency of formic acid to pass through undecomposed if this rate is exceeded. Analysis of the carbon monoxide leaving the scrubber showed that it contained no impurity except water vapor.

The pyrometric control of heat input at a relatively high rate and the addition of an automatic trap have produced a generator of high output that is both easier and safer to operate than those previously reported.

Burner

The burner shown at G is of rectangular shape; it has a nickel grid of the Méker type $15^3/_4$ in. long and $^{13}/_{16}$ in. wide, giving a free port area of 7.7 sq in. The casing is brazed to the sides of the grid to increase the effectiveness of the water cooling. A metal slide H, for changing the burner length, operates in slots along the top of the casing. A flared manifold distributes the gas sufficiently to give flames of uniform height. The burner inlet has been divided into two sections, all of the gas being made to pass through one or the other by the butterfly valve J. For most of the experiments, the gas was passed through the lower section for the introduction of brine spray used in measuring the flame temperature, and through the upper section during the radiation measurements, this procedure being adopted to permit radiation measurements on flames containing no sodium chloride or water vapor.

Temperature and Radiation Measurements

Spectral reversal of the sodium resonance doublet is used to measure the temperature of the gas flames. Although the accuracy of this method has been questioned lately by David (17) the objections raised seem to have been answered satisfactorily by Lewis and von Elbe (18). The continuous source L, Fig. 1, is a G.E. 4-volt, 20-amp, No. T-20, SR-8 tungsten lamp with filament 0.080 in. wide and 0.0025 in. thick; a vee is cut in one side of the filament to insure use of the same portion in all measurements. The lamp is heated by storage batteries, the current input being controlled with variable resistances, and measured accurately with the deflection-potentiometer principle of Forsythe (19) across the fixed resistance O. Images of the filament are formed at the center of the burner and at the slit of the spectroscope M by the achromatic lenses N. The spectroscope is a Gartner L250 quartz spectrograph, in which the camera is replaced by a tube for holding the eyepiece, and the Cornu prism by one of flint glass. The red brightness temperature of the tungsten lamp is measured with the precision optical pyrometer P (20). The temperatures measured in these experiments were sufficiently low to cause no rapid aging of the band filament, conveniently permitting a transfer of the optical pyrometer calibration to a temperature-current plot for the band lamp.

Two methods are used to introduce sodium into the flames. The first consists of forming a spray in the gas inlet when a small, high-velocity jet of brine from tank Q impinges against the inside of the pipe at R. A better method, in that it eliminates the undesirable effect of water vapor on both the flame speed and total radiation from the flame, is the volatilization of the salt in an electric arc between carbon electrodes immersed in a crucible of salt S. A small stream of air or nitrogen passing through drying tower U, pressure regulator T, flowmeter V, and the enclosed, water-cooled arc chamber S assists in sweeping the volatilized salt into the burner manifold, as well as preventing flow of the gas mixture into the arc chamber with resulting ignition. If air is passed through the arc a correction is made for CO_2 formed at the electrodes.

The radiant energy emitted by the flames is measured with a reflecting-type, total-radiation thermopile K, focused on the center of the flame. The latter consists of a single spot-welded junction of copper and constantan wires, 0.001 in. in diameter, the free ends of which are fastened into two slotted copper leads cemented firmly in a celluloid block $^9/_{16}$ in. in diameter. These leads also form the cold junction. The target is 0.050 in. in diameter of tinfoil 0.001 in. thick, thoroughly coated with lampblack on the front, and cemented in close contact with the junction on the back surface. The mirror is a bright, opaque film of gold sputtered on the concave front surface of quartz; it is $^3/_4$ in. in diameter and has a focal length of 5 in. The thermopile, mounted in a telescope for focusing, is housed with the mirror in a wooden box K to which a water-cooled shield and shutter are fastened. Trays of soda-lime and calcium chloride are placed on the bottom of the box, and a slow stream of air, dry and free of CO_2, is passed through the box during measurements.

A Leeds and Northrup type-HS reflecting galvanometer, mounted on a Julius suspension and the whole enclosed in a compartment to protect it from air currents, is connected to the thermopile leads. The scale, placed at 3.5 m, is readable to 0.1 mm through a high-magnification telescope; the sensitivity of the galvanometer viewed at this distance is 101 cm deflection per microampere.

Two black bodies X of the type described by Coblentz (21), the temperatures of which are measured by carefully calibrated thermocouples, are used to calibrate the thermopile. These bodies are held at constant temperatures of about 730 F and 1820 F; over the thirteenfold range of variation of radiation intensity represented by these two radiation standards, the calibration constant of the thermopile-galvanometer system varied no more than 3 per cent, and the average was much less. A calibration is made before and after each group of flame experiments, the arithmetic mean of the constants so obtained being used for the calculations in the group.

In view of the marked dependence of radiation upon temperature, special experimental care is required to make the two properly related, particularly in a flame where temperature gradients may be great. Therefore, the band lamp, lenses, and spectroscope are mounted on an optical bench which is supported by two sturdy rods fastened into a steel base; the base is fastened to the desk top with hinges so that this system or the thermopile can be placed in line with the burner. Once in correct alignment and clamped, the separate parts undergo no relative motion and no further adjustment is required. The thermopile housing is mounted similarly on a solid base which slides back and forth transversely between fixed stops on a metal track. Once properly aligned and the stop fastened, the thermopile can also be moved and returned to the correct position.

In order to minimize the effect of temperature gradients, the flames are made as large as possible and the distance from the burner grid to the optical axis is chosen so as to place the latter in the most uniform temperature range. In addition, diaphragm W limits the cone of rays viewed during the temperature measurements, and is of such size that any ray drawn from the eyepiece image through the optical system falls well within lens N_2. The limitation of field of view of the thermopile system is accomplished

by two diaphragms of 0.125 and 0.030 in. in diameter, placed immediately in front of the mirror and the target, respectively, in the thermopile housing. The pencil of rays through the flame is thereby restricted to a diameter of 0.15 in. at the image plane near the center of the burner grid, and a maximum of 0.23 in. at the back edge of the grid.

Control of Gas Mixture

In order to avoid variation in mixture ratio while radiation and temperature measurements are being made, a $^3/_8$-in. type-*A* Reliance pressure regulator is placed in the carbon-monoxide line, and $^3/_8$-in. type-*H* regulators are placed in the other gas lines. The rates of flow are measured on calibrated orifice meters *V*. In almost all cases the total rate is such that the flame is just beginning to lift away from the grid. The gases, dried in the calcium-chloride towers if required, are tested for water vapor by aspirating a stream of gas from the manifold sampling tube through a dew-point apparatus.

Procedure

The thermopile is calibrated against the black bodies previously heated to constant temperatures of about 750 F and 1800 F; the carbon-monoxide generator, already up to operating temperature, is started; the mixture ratio is adjusted to give the kind of flame desired; the dew point of the mixture is determined; the thermopile is brought into position and galvanometer readings taken for about 15 successive 15-sec periods with the shutter alternately opened and closed; the thermopile is pushed aside; with the lamp already hot the optical bench is swung into position, the sodium generator is started, and three or four reversals made in the spectroscope, the potentiometer being read for each. This procedure, usually repeated as a check, is followed for each mixture ratio and burner length.

Calculations

The recorded brightness temperatures at $\lambda = 0.665\mu$, without the lens interposed, are corrected to those at $\lambda = 0.589\mu$, with the lens, by substituting appropriate values in Equation [1].

$$\frac{1}{T_R} - \frac{1}{T_{y\cdot L}} = \frac{0.589 \ln ABp_Y - 0.665 \ln Ap_R}{14{,}330} \quad \ldots\ldots [1]$$

where T_R = brightness temp, deg K, at $\lambda = 0.665\mu$, viewed through the bulb but without a lens

$T_{y\cdot L}$ = brightness temperature, deg K, at $\lambda = 0.589\mu$, viewed through the bulb and lens

A = transmissivity of the lamp bulb

B = transmissivity of the lens

p_R = emissivity of tungsten at $\lambda = 0.665\mu$ and true filament temperature, obtainable from T_R (22)

p_Y = emissivity of tungsten at $\lambda = 0.589\mu$ and true filament temperature.

The transmissivity of the lens is found experimentally by measuring the red-brightness temperature of the band lamp, with and without the lens between it and the optical pyrometer. For a fixed lamp temperature

$$\ln B = -\frac{14{,}330}{0.665}\frac{(T_1 - T_2)}{(T_1 T_2)} \quad \ldots\ldots [2]$$

where B = the transmissivity of the lens

T_1 = red brightness temperature of lamp, deg K, without lens

T_2 = red brightness temperature of lamp, deg K, with lens

Substitution into [2] of corresponding values obtained at several temperatures give an average value of 0.92 for *B*. This is adopted also for the transmissivity *A* of the lamp bulb and is used throughout for calculating the correction.

Values of p_R and p_y are taken from the data of Forsythe and Worthing (22).

The correction varies from +7 C at 1670 K to +14.6 C at 2200 K.

Safe Operation of High-Speed Locomotives

By B. S. CAIN,[1] ERIE, PA.

In this paper are presented the basic theories, test information, and the chief conclusions of an investigation of factors entering into the mechanical design of locomotives for high-speed operation. The author points out that (1) recent trends in railroad operation have been toward higher speeds over longer distances and (2) the development of electric and oil-electric power, and lightweight equipment have changed many of the conditions under which these higher speeds are attained. In view of the radically new types of equipment available, the increased severity of requirements both as to performance and cost of equipment, and the necessity for preserving the railroad's record for safety, it has been necessary to make an extended theoretical and experimental analysis of high-speed locomotive operation. Such an analysis is given in this paper.

THE fundamental problem in regard to the safe operation of high-speed locomotives has been to explain, and to learn to control by design means, the oscillations of locomotives which develop at high speeds, and which place a definite limit on the safe speed at which any particular design of locomotive can be operated over a given section of track. These oscillations consist partly of nosing and rolling motions produced by the sidewise components of the wheel-friction and flange-impact forces when the wheels are out of exact line with the track. Instability occurs when these forces increase the energy of oscillation faster than the damping forces can reduce it. Other oscillations are due to rough track. It is the problem of the designer to control the design, the wheel arrangement, the spring constants, the weight distribution, and the clearances so as to minimize the tendency to instability and to obtain ample margins of safety under varying conditions of track.

Testing of locomotives has been improved during recent years. Stresses in the track can be accurately measured with electric strain gages. The author has used these gages extensively to make continuous records of lateral pressures between locomotive axles and frames on a number of locomotives up to very high speeds. The development of theories to determine the stresses and motions of locomotives at high speeds has proceeded before and coincidently with the test program. The theory as now developed logically explains the test results in so far as the fundamentals are concerned. Some of the principal results of this work are outlined in this paper, reference being made particularly to the high-speed electric locomotives on which the most complete experimental information exists.

General Theory

It is a matter of frequent observation that high-speed equipment may oscillate continuously of its own accord. The only source of energy available to keep these oscillations going is the driving energy which maintains the speed. In a balanced machine, the only way in which this energy can be tapped to produce a sustained oscillation is through friction at the tread of the wheels. Whenever the locomotive wheel base makes a small angle with the track, friction makes it run sideways until the wheel flanges hit the rail. As a result of the impact, the wheel base may become pointed toward the other rail. If this motion persists or increases there is an ever-present tendency to breakage or derailment.

A study of the friction at the head of the rail shows that for oscillations at high speed the frictional force is not constant, but actually approaches a creepage force, varying with the amount of slip. Theoretical calculations which have been made of this creepage force are fairly representative of test data.

The initial motion which starts an oscillation may be due either to inherent instability of the wheel base or to rough track. Both cases have been reduced to calculations by which the tendency of locomotives to start oscillation may be compared. The calculation of the oscillation itself has been divided into two parts.

First, assuming some reasonable type of oscillation, it is possible to calculate the speed at which the oscillation will just sustain itself because the losses and gains of energy are equal. Further details of these calculations are given in the Appendix. This speed is proportional to the frequency of the oscillation, which is still unknown. Other factors, such as the lag of the rear end behind the front end in side motions, can be calculated to give the lowest critical speed.

After this energy calculation is made, a study of the motion in more detail is made to determine the frequency and to ascertain whether the forces resulting from such a motion will approximate those required to produce it. The calculation is essentially one of successive approximations. It is practical because the frequency is not affected much by the friction and damping. Therefore, the calculation of frequency can, after some experience, be made quite simply in many cases.

These calculations apply chiefly to straight track. On curves, it is usually sufficient to draw a diagram of the locomotive in the curve showing the locomotive in equilibrium and to see whether, with large variations in friction, the position is stable. The author has found it most useful to use a diagram in which a reduced scale is used for the direction corresponding approximately to the length of the locomotive and to use a full scale at right angles to this direction. Then clearances are approximately full size and the diagram is accurate at all points.

These calculations, particularly the energy method of studying oscillations on straight track and the layout method for curves, generally allow a steady locomotive to be designed or indicate the reason for observed instability. If severe flange pressures cannot be avoided, their values can be estimated by following these methods further. The allowable limits of pressure have been investigated in an elementary way to bring out the important factors, and some methods of calculation have been outlined, relat-

[1] Locomotive Division, General Electric Co., Erie, Pa. Mem. A.S.M.E. Mr. Cain was born in Manchester, England. He received the degree of M.A. from the University of Cambridge and B.Sc. from the University of London. Since 1921 he has been employed by the British Thomson-Houston Co., the International General Electric Co., and the General Electric Co. He has held his present position since 1925 and has specialized on the mechanical design of electric locomotives. Since 1930 he has conducted numerous tests on high-speed locomotive operation.

Contributed by the Applied Mechanics and Railroad Divisions for presentation at the Annual Meeting of The American Society of Mechanical Engineers to be held in New York, N. Y., December 2 to 6, 1935.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until January 10, 1936, for publication at a later date.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

ing to derailment and lateral shifting of track. These methods of calculation are given in the Appendix.

Test Methods

Most of the author's tests have been made to record lateral pressure between the axles and the locomotive frame. This is done by modifying the journal boxes so that the axles are restrained laterally by steel "weigh-bars" one on each side, these bars being adjustable to give the required clearances. Lateral pressure bends one of these bars, and an electromagnetic strain gage on the bar records the pressure on an oscillograph record. The bars are calibrated statically in a testing machine. Records have been obtained both on films and on paper rolls 100 ft long. Pressures on all axles of a locomotive may be recorded simultaneously.

Tests have also been made in which truck motion, acceleration, rail stress, and rail pressure have been recorded. The author has also had access to numerous tests of this nature made by other investigators in this field.

Conclusions

In order to keep a locomotive of conventional type from exerting high flange pressures on straight track when moving at high speed, the wheel base should be long and the clearances small to reduce angularity in the track. The independent swiveling of trucks on straight track should be prevented. Wheels near the center of the locomotive should be flanged and should preferably have lateral freedom in the frame, so that they guide themselves and do not reduce the stability of the wheel base.

Springs should be as soft as is practical to cushion blows and reduce the forces due to oscillation.

On high-speed curves, truck restraints and wheel bases should be studied to avoid instability. On sharp curves the long wheel base should be able to adjust itself to reduce angularity between flanges and rail, and to avoid high flange pressures.

The height of the center of gravity of the locomotive is a compromise. In general the height should be reduced where the locomotive is well guided and where the track is good.

Excessive axle weights should be avoided. In actual designs, these ideals can only be approached. Long rigid-frame locomotives tend to oscillate on high-speed curves and to derail on sharp curves. Therefore, designs must aim particularly at reducing these tendencies. Because articulated locomotives tend to oscillate on straight track at high speed, restraining devices are used to eliminate this tendency. Truck restraints with decreasing characteristics may also be necessary to avoid excessive flange pressures on sharp curves.

Good track maintenance and uniform construction and stiffness with the minimum practical flange clearance are always of great importance.

It is very desirable to obtain more measurements of forces produced by different locomotives and particularly to make further tests on the limiting forces which track can safely withstand.

An energy method of calculating locomotive oscillations has been developed by B. F. Langer and J. P. Shamberger,[2] but their calculations do not agree with those given in this paper.

Acknowledgment

The author is indebted to many engineers for information and suggestions. Particular reference should be made to E. G. Keller who, while with the General Electric Company in 1931 and 1932, cooperated with the author in devising methods for detailed calculation of locomotive oscillations. Dr. Keller worked out these methods in numerical detail, thereby providing clear representations of locomotive behavior and suggesting practical approximate methods. The author is indebted to F. M. Graham for information on track and for results of tests on which the theory of track movement is based. R. Eksergian and P. L. Alger have made valuable suggestions in regard to the subject matter and presentation of the paper.

Appendix

Friction and Creepage Between Wheels and Rails

According to a common theory, a wheel will roll on a rail without slipping until the tangential force at the point of contact is sufficient to overcome the friction, given by the load on the rail multiplied by the coefficient of friction. As long as the force retains this value, the wheel will continue to slip. The coefficient varies greatly with the conditions. Usual typical values are given in Table 1.

TABLE 1 COEFFICIENTS OF FRICTION FOR DIFFERENT RAIL CONDITIONS

Condition	Coefficient
Good dry conditions, no slipping	0.35
Wet surfaces, no slipping	0.25
Dry surfaces, slow speed and slight slipping	0.25
Dry surfaces, high speed and slight slipping	0.15
Dry surfaces, wheel spinning	0.05

If the wheel and rail were rubber, the rolling wheel could creep in the direction of any tangential force, due to the elasticity of the materials in contact. Steel being elastic, the same creep must occur to a reduced extent and theoretical studies indicate that the amount of the creep is sufficient to allow many of the

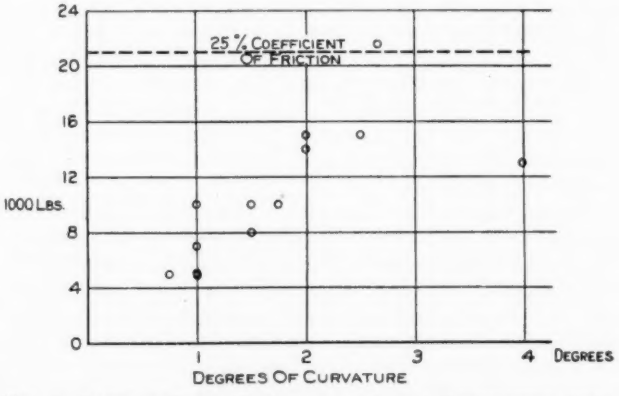

Fig. 1 Lateral Force Required to Slip a Locomotive Axle Laterally as Obtained From Tests at Speeds From 25 to 60 Mph

motions of actual locomotive wheels without requiring the whole area of contact to slip. The creepage is defined as the ratio of creeping to rolling displacement of the wheel. The creepage coefficient is the ratio of tangential force at the point of contact to the creepage.

The creepage coefficient has been calculated for a particular case of F. W. Carter,[3,4] who gives the formula

$$f = \text{creepage coefficient, lb} = 3500 \text{ (wheel diameter, in.} \times \text{axle load, lb)}^{0.5}$$

The present author has made about 50 measurements of the lateral force required to hold an axle with blind tires while going

[3] "On the Action of a Locomotive Driving Wheel," by F. W. Carter, Proceedings, Royal Society of London, series A, vol. 112, 1926, p. 151.

[4] "The Running of Locomotives With Reference to Their Tendencies to Derail," by F. W. Carter, Selected Engineering Paper No. 91, The Institution of Civil Engineers, 1930.

around various curves. The results are rough, due to such conditions as fluctuations in the force and uncertainty as to superelevation, but the results plotted in Fig. 1 for speeds of 25 to 60 mph and in Fig. 2 for speeds of 60 to 70 mph show a marked tendency for the lateral force to decrease to zero with the curvature, for curves less than about 3 deg. The angularity of the axle to the track radius can be estimated for the locomotive on which these tests were made. It increases roughly with the curvature. Calculations in the range from 1 to 2 deg give an approximate angularity (and therefore creepage) of from 0.0007 to 0.0017 and an average creepage coefficient of about 8,500,000 lb. Dr. Carter's[3] formula gives a creepage coefficient in this particular case of 8,600,000 lb. The difference is less than the probable error of either figure.

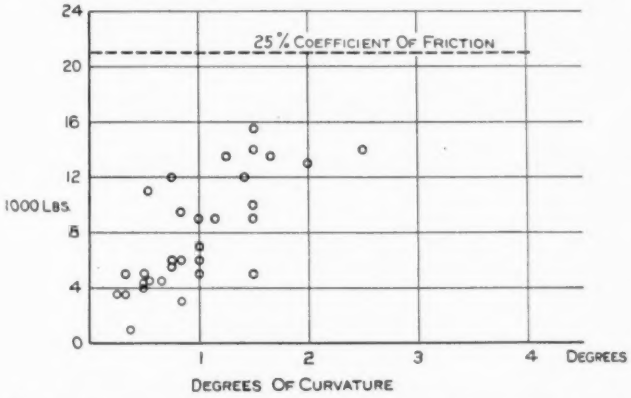

Fig. 2 Lateral Force Required to Slip a Locomotive Axle Laterally as Obtained From Tests at Speeds From 60 to 70 Mph

The creepages required to allow the oscillation of locomotives at high speeds on tangent track are within the range of these tests and the author therefore believes that the creepage theory is a legitimate one to use in such studies.

It should be noted that J. Buchli[5] made model tests and concluded that: "To cause lateral movement of a hauled wheel from its neutral position, a force of definite magnitude is necessary, the value of which is equal to the product of the load on the wheel multiplied by the coefficient of friction. . . . "

Applying Carter's formula to the loaded wheel used by Buchli (about 12-in. diameter with less than 1000 lb load) the maximum creep before complete slippage would be of the order of 0.04 per cent, which would be inappreciable in the test. Buchli's result applies to wheels running with considerable angularity on sharp curves and does not contradict the author's observations at high speed, where the angularity of wheels is very small.

Oscillations Started by Inherent Instability

There are some locomotives which are unstable on perfect track, even before the flange forces come into play. Such a locomotive will always start to deviate from steady motion down the track. When the flanges hit the rail, the resulting oscillation may sustain itself or may decrease, but if it decreases a new one will start, resulting in more flange impacts and so on indefinitely. This natural instability has been studied by F. W. Carter.[3,4] Broadly there are two causes of instability.

The first is the tendency of certain combinations of wheel bases to get out of line. A 4-4-0 locomotive with sufficient guiding force in the engine truck will follow that truck and tend to straighten itself. The same locomotive reversed, 0-4-4, will buckle because the rear truck tends to run in its own direction, which causes the drivers to become more and more out of line with the truck. A stable locomotive, from this point of view, will tend to straighten its wheel base and proceed in a straight line, but this line will not necessarily be the center line of the track. The angular deviation will be that produced by an accidental disturbance and will not be increased by buckling of the wheel base.

The second cause of instability is the coning of wheel treads. A rigid truck wheel base with all wheels equal and coned, moving slowly down uniform track will, if given a slight displacement, tend to move sinuously, the motion repeating after a certain distance. As the speed increases, the motion becomes unstable, due to the mass and moment of inertia of the truck. If the wheels are of different diameters, a truck with smaller wheels leading tends to run more stably and one with smaller wheels trailing tends to run more unstably.

In the author's opinion the effects of coning on large locomotives are generally small, because (1) the coning of new wheels is generally small, (2) the coning of new wheels is quickly worn down, and (3) the clearances between axles and truck frames usually tend to reduce its effect. On the trucks of light-weight high-speed cars, the effect of coning is considerable.

Oscillation Started by Rough Track

If track is poorly surfaced it will start a motion of the locomotive. A rolling motion results from variations in the level of the two rails. In general, this roll is reduced by giving the engine a long natural period of roll on its spring system and by increasing the locomotive length, so that the various axles produce their effects at different times and interfere with each other. If the surface irregularity is very short, the effect on each axle is to produce an angular velocity

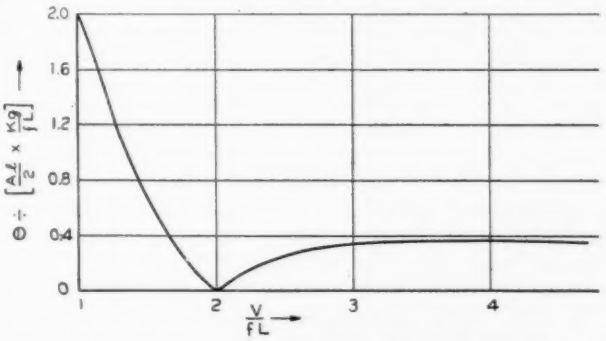

Fig. 3 Angle of Roll of a Vehicle After Passing Over a Track Irregularity

$$(Al/2) \times (kg/I) \times (1/V)$$

Where A = maximum cross-tilt of the track at the irregularity; l = the length of the irregularity which is assumed to have the shape, $A[1 - \cos(2\pi x/l)]$; k = moment acting on the body of the locomotive, due to the springs, per unit angular movement of the axle; g = acceleration due to gravity; I = the moment of inertia of the locomotive body in roll about an axis through the centers of the axles; and V = the speed of the locomotive. The angular velocity can be represented by a vector rotating with angular velocity equal to 2π times the natural frequency of the locomotive in roll.

If the next axle is a distance L behind the first one, it will receive its impulse after a time L/V and the subsequent motion is represented by adding to the first vector a second of a magnitude calculated for the second axle and lagging a time L/V

[5] "Behavior and Movement of Locomotive Wheels on the Track," by J. Buchli, Bulletin of the International Railway Congress, new series, vol. 6, no. 6, June, 1924, pp. 417–437.

behind the first. The effects of successive axles can be added in a similar way. If the locomotive springs are heavily damped, the resultant vector can have this damping applied to it during its rotation.

This vector diagram will show the rolling motion completely. It will be clear from inspection that if a locomotive has n similar axles which are equally spaced, it will leave the irregularity with no roll at all if the time taken to pass over it is just equal to $(n-1)/n$ times the natural period of the locomotive in roll (assuming undamped springs). Fig. 3 shows the relation between the final roll and the speed of a symmetrical two-axle truck plotted in dimensionless coordinates. As V/fL increases above 2, the roll

$$\theta/[(Al/2) \times (kg/fL)]$$

increases to about 0.36 and then decreases steadily toward zero.

Roll in itself will not always start any other oscillation, but it constitutes a reservoir of stored energy which produces nosing if any accidental angularity occurs.

Flange Impacts

When a wheel flange runs against the rail, its lateral motion is quickly stopped. The locomotive begins to roll and the flange tends to bounce back away from the rail. If the center of gravity of the locomotive continues to move in the same direction after the impact, the springs, in bringing the locomotive back from its roll, will pull the flange back again and a second impact will take place. On the other hand, if the center of gravity is low, so that the impact reverses the direction of its motion, the flange may not come in contact with the rail again until the whole locomotive has completed another oscillation. Actually, the impact is reduced by the effect of the increasing diameter in the throat of the wheel flange, which tends to prevent direct impact on the flange. The detail calculations of multiple flange impact are not difficult, but may be very laborious because of the repeated discontinuities in the forces. In many cases where the locomotive as a whole is being studied it will be found convenient to make the following simplifying assumptions:

With the flange hitting the rail, consider a point above the axle situated on the longitudinal axis through the center of gravity of the locomotive body. If, after impact, this point moves away from the impact point, then subsequent impacts are neglected. If this point moves toward the impact point, then the impact is recalculated, assuming that the flange is guided along the rail smoothly as the result of an inelastic impact. For the dividing line, where the point is stationary, the two assumptions do not give the same result, but the actual motion is considerably affected by small variations, so that it is not unreasonable to have a case where the solution is uncertain between two limits. When spring friction or damping is taken into account, the impacts are usually simplified, the approximations become more accurate and agree well among themselves. If necessary, the more exact calculations of multiple impact can always be made.

The theory of multiple impact is borne out by the nature of actual blows as recorded in high-speed oscillograms. Under varying conditions, particularly of spring friction, these show (1) single blows, (2) fluctuating blows, and (3) blows in which the rebound actually divides the blow into two parts, an initial peak, falling to zero and followed by a fluctuating pressure of longer duration. Calculation of impact for a single unit is made as follows:

If h = the height of the center of gravity above the centers of the axles, k_x = radius of gyration about a longitudinal axis, k_z = radius of gyration about a vertical axis, l = distance of impact ahead of the center of gravity, W = weight of the body, u = lateral velocity of the center of gravity, ω_z = angular velocity of the nosing action, and ω_x = angular velocity of roll, then the equivalent mass at the point of impact is

$$\frac{W}{g}\left[\frac{1}{1+(h^2/k_x^2)+(l^2/k_z^2)}\right]$$

and the impact is

$$\frac{W}{g}\left[\frac{2}{1+(h^2/k_x^2)+(l^2/k_z^2)}\right](u+l\omega_z-h\omega_x)$$

Therefore, after the impact, the velocity of the point $x = l$, $y = 0$, and $z = 0$ is

$$\left[u-\frac{2(u+l\omega_z-h\omega_x)}{1+(h^2/k_x^2)+(l^2/k_z^2)}\right] + l\left[\omega_z-\frac{2l}{k_z^2}\left\{\frac{u+l\omega_z-h\omega_x}{1+(h^2/k_x^2)+(l^2/k_z^2)}\right\}\right]$$

$$= u+l\omega_z-\left\{\frac{2[1+(l^2/k_z^2)]\,(u+l\omega_z-h\omega_x)}{1+(h^2/k_x^2)+(l^2/k_z^2)}\right\}$$

Critical Speed on Tangent Track

The energy method of calculating critical speed is similar to other energy methods used in engineering calculations. A reasonable sinuous motion is first assumed and the loss or gain of energy of the locomotive is calculated for this motion. The loss and gain depend on the speed of the locomotive, and the lowest speed at which they balance is called the critical speed. Subject to reasonable limitations the shape of the assumed path can be varied to obtain a minimum critical speed.

Assuming a constant forward speed V, the locomotive can dissipate energy (*a*) by lateral and angular oscillations which cause the wheel treads to slip or creep on the rail, (*b*) by rolling, due to friction and damping in the springs, (*c*) by the operation of such devices as internal friction plates and dampers, (*d*) by impacts between flanges and rails, and (*e*) by rough track where this reduces existing oscillations. It can gain energy by (*f*) the tendency of any angularity of the wheel base to give the engine a lateral velocity and (*g*) rough track where this starts or increases oscillations. It is easier to consider first (*a*) and (*f*), the forces at the head of the rail. It is clear that with perfect uniform track it is not possible to gain or lose energy in flange impacts because these are uniformly elastic and the only forces left are those of slip or creep between the head of the rail and the tread of the wheels.

The calculation is based on the fact that the rate of gain of energy at each point of contact is equal to the force acting on the wheel multiplied by the velocity of motion of the point of application in the direction of the force. If the motion is in a direction opposite to the force, the gain becomes a loss of energy. First assume that the wheels creep, with a creepage coefficient f.

Let an arbitrary reference point o shown in Fig. 4, be taken which moves down the center of the track with velocity V. Let the wheel base be deflected a distance y to o' and rotated an amount θ. Then the lateral deviation of an axle distant l ahead of the reference point is $y + l\theta$. The lateral velocity is

$$\dot{y} + l\dot{\theta}$$

Of this velocity, $V\theta$ is due to rolling displacement of the wheel, and the velocity of creep is

$$\dot{y} + l\dot{\theta} - V\theta$$

The creepage force is

$$-(f/V)(\dot{y} + l\dot{\theta} - V\theta)$$

The rate of gain of energy is creepage force times lateral velocity

$$= -(f/V)(\dot{y} + l\dot{\theta} - V\theta)(\dot{y} + l\dot{\theta})$$

Now assume that y and θ are sinusoidal, which is a reasonable first approximation, and let $\omega = 2\pi f$, where f is the frequency. Then

$$y = Y \sin \omega t$$

θ may be written $\theta \cos(\omega t + \epsilon)$, θ being now the maximum value, and the average rate of gain of energy

$$= -(f/V)[(Y^2\omega^2/2) + Yl\theta\omega^2 \sin \epsilon + (l^2\omega^2\theta^2/2)] + f(\theta Y\omega \cos \epsilon/2)$$

For the whole wheel base, summing over various axles

$$\text{Gain of energy} = -\Sigma(f\omega^2/2V)[Y^2 + 2lY\theta \sin \epsilon + l^2\theta^2 - (V/\omega)Y\theta \cos \epsilon]$$

For the critical speed, this must be zero, or

$$V_{cr} = \omega\left[\frac{\Sigma f(Y^2 + 2lY\theta \sin \epsilon + l^2\theta^2)}{\Sigma fY\theta \cos \epsilon}\right]$$

$$= \omega\left[\frac{Y}{\theta \cos \epsilon} + \frac{2\Sigma fl}{\Sigma f}\tan \epsilon + \frac{\Sigma fl^2}{\Sigma f}\frac{\theta}{Y \cos \epsilon}\right]$$

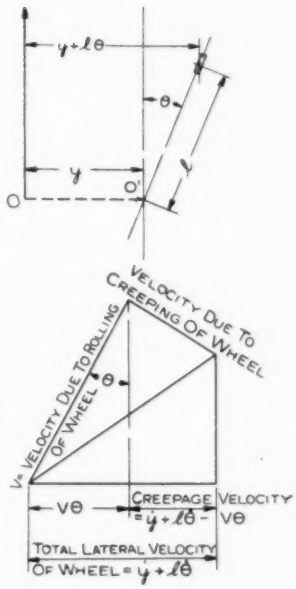

FIG. 4a POSITION DIAGRAM FOR A SIMPLIFIED TRUCK WHEEL

FIG. 4b VELOCITY DIAGRAM FOR A SIMPLIFIED TRUCK WHEEL

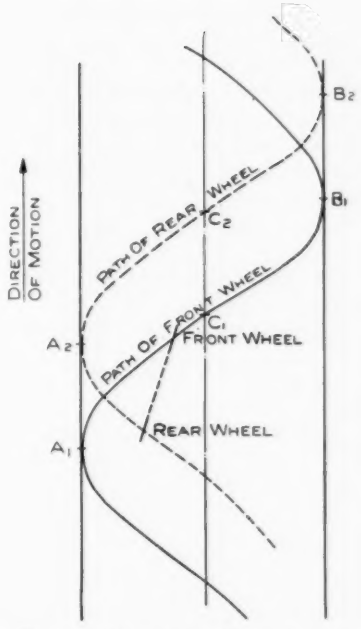

FIG. 5 DIAGRAM OF MOTION OF A SIMPLIFIED TRUCK

Choose the origin of the coordinates so the $\Sigma fl = 0$. This makes the second term vanish, making it obvious that the least value of critical velocity V_{cr} is given by the $\cos \epsilon = 1$, so that

$$V_{cr} = \omega[(Y/\theta) + (\Sigma fl^2/\Sigma f)(\theta/Y)]$$

which is a minimum when

$$Y/\theta = (\Sigma fl^2/\Sigma f)(\theta/Y)$$

Therefore

$$Y/\theta = \sqrt{(\Sigma fl^2/\Sigma f)}$$

giving

$$V_{cr} = 2\omega\sqrt{(\Sigma fl^2/\Sigma f)}$$

This calculation neglects the effect of the track gage, although it can be taken into account by adding the effect of longitudinal forces due to the different longitudinal speed of the two wheels on one axle.

The rate of gain of energy is increased by

$$-0.25(f/V)S^2\dot{\theta}^2$$

where S = the track gage measured between center lines of the tread contacts. Therefore, the speed

$$V = 2\omega\sqrt{\frac{\Sigma f[l^2 + (S^2/4)]}{\Sigma f}}$$

Finally, the effect of lateral clearances in the locomotive has to be taken into account. This theory is a first approximation, the motion of all parts being assumed sinusoidal. It follows that a proper assumption to make with regard to axles with clearance in the journal boxes is to take their motion as sinusoidal and to make the assumed positions coincide with the real positions at the extreme points of the cycle, where impacts take place. Therefore, assume that the motion of the frame laterally with respect to the axle is proportional to the motion of the axle laterally with respect to the track and that the internal clearance is taken up at the same time as the track clearance. In any oscillatory motion this will give very closely the same extreme conditions, the same track impacts and the same net energy transfer at the head of the rail as in the real motion.

As a second approximation, if necessary, the motion calculated in this way can be plotted and corrections made graphically.

Let C_i = the internal clearance between axle and frame, C_t = the track clearance between flanges and rail, and μ = the ratio of track clearance to total clearance, so that

$$\mu = C_t/(C_i + C_t)$$

First assume that μ is the same for all axles. Then

$$V_{cr} = 2\mu\omega\sqrt{\frac{\Sigma f[l^2 + (S^2/4\mu^2)]}{\Sigma f}} = 2\omega\sqrt{\frac{\Sigma f[\mu^2l^2 + (S^2/4)]}{\Sigma f}}$$

so that internal clearance is equivalent to a reduction in wheel base.

If different axles have different clearances, so that each axle has its own value of μ, then the origin of the coordinates is to be taken so that $\Sigma f\mu^2 l = 0$ and

$$V_{cr} = 2\omega\sqrt{\frac{\Sigma f\mu^2 \times \Sigma f[\mu^2l^2 + (S^2/4)]}{(\Sigma f\mu)^2}}$$

Losses due to spring friction and the effects of coning may be included similarly. These formulas depend on the creepage theory of wheel action. It is worth while to show that if slippage with constant friction is assumed, the results do not differ greatly.

Take the simple case of a truck with two equal axles and assume that the motions are sinusoidal. In Fig. 5 consider the motion of the front wheel across the track, along the path A_1B_1. The motion is uniformly to the right, so that if the friction force is also to the right, the front wheel will gain energy, but if it is to the left the front wheel will lose energy. In the position shown, both wheels are losing energy and will continue to do so until they become tangent to their paths or their directions of motion

change. An examination will show that the lowest critical speed is obtained by letting the rear wheel touch the left rail as the front wheel crosses the center line of the track tangentially to its path. Then, when the front wheel passes C_1 its loss will become gain. Similarly, the rear wheel will start to gain energy after it passes A_2. Each wheel gains energy over half its lateral path and loses it over the other half so that the gain and loss are balanced. This condition for minimum critical speed is expressed by the formula

$$2l = V_{cr}/\omega \text{ or } V_{cr} = 2l\omega$$

which is the same formula as was obtained by the creepage theory for this case.

More complicated wheel-base arrangements can be calculated

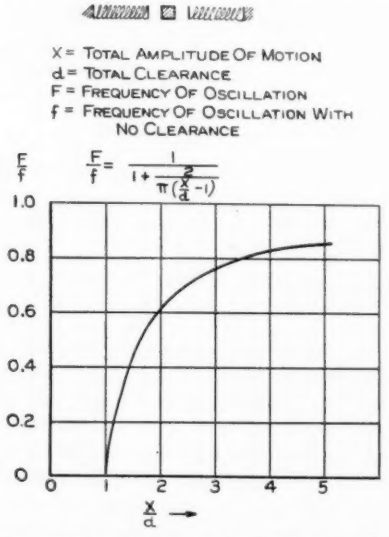

Fig. 6 Effect of Clearance and Amplitude on Frequency of Oscillation

analytically if required, using vector diagrams to portray phase relationships.

Frequency of Locomotive Oscillations

The frequency of roll is given by the well-known formula

$$f = (1/2\pi)\sqrt{[(M - Wh)g/Wk^2]}$$

where f = frequency, cycles per sec; M = the restoring moment, ft-lb per radian; W = the weight of the rolling part, lb; h = the height of the center of gravity of the rolling part above the center of rotation (center line of the axles), ft; k = the radius of gyration of the rolling part about a longitudinal axis through the center of rotation, ft; and g = acceleration due to gravity, 32 ft per sec per sec.

The ratio M/W is called the metacentric height h_m, and therefore the last given equation can be written

$$f = (1/2\pi)\sqrt{[(h_m - h)g/k^2]}$$

In some cases, the natural frequency of roll is also the frequency of nosing oscillations. This is true particularly of locomotives consisting of a single rigid frame, with a high center of gravity and a fairly low frequency of roll. When the flange of the rear driver of such a locomotive hits the rail, the rolling oscillation keeps this flange in contact until the return of the center of gravity allows the flange to leave the rail and the axle to move quickly across the track, where a roll in the opposite direction takes place.

If the frequency of roll is very high, the time taken by the roll will be short and the time taken by the axle to pass through the clearance will become important. To illustrate this, Fig. 6 shows the great effect which amplitude of motion has on frequency for the simplified case of a weight moving between springs, with clearance.

At the other extreme is a locomotive with an extremely low center of gravity, in which case the flange impacts do not produce any appreciable rolling and the frequency depends entirely on the speed with which the axles traverse the clearance. In the study of critical speed, it was shown that for a self-sustaining oscillation

$$V = Cf/\cos \epsilon$$

where V = speed, C = a constant depending on the type of locomotive, f = frequency of motion, and $(\pi/2) - \epsilon$ = phase difference between lateral and rotational motions. If $\cos \epsilon = 1$, then

$$f = (1/C)V$$

so that the frequency would increase with speed. The lateral blows on the flanges, which produce the necessary acceleration would be roughly proportional to the square of the speed. Actually, with extreme oscillation, the locomotive would tend to be thrown more nearly broadside onto the flanges, i.e., the lateral and rotational motions would come more nearly into phase. Then $\cos \epsilon$ would be less than unity and the frequency of sustained oscillations would no longer be proportional to speed. Nevertheless, the highest frequency oscillation which could be sustained is given by $f = (1/C)V$ and this will give an upper limit to the severity of the blows at any speed if rolling or other lateral motions in the locomotive are negligible. Detail calculations are necessary to proceed further. In starting the study of a locomotive, vector diagrams are very useful, as long as their limitations are recognized.

Another useful approximation is to consider the front end of the locomotive fixed against one rail and to calculate the period of swing of the wheel base as a damped pendulum, under the effect of the creepage forces. In some cases the motion can be divided into two types, to each of which an approximation applies.

Operation on Curves

Locomotives may oscillate at high speeds on curves of long radius. The energy methods of calculation are frequently useful but there are other ways of attacking the problem which are often more direct. The first stage in any study is to find the equilibrium position of the locomotive on the curve. For curves of very long radii the creepage theory is probably the most correct to use. For sharp curves, the theory of slipping is more correct. For preliminary studies it is generally very enlightening to take, for convenience, the theory of constant slipping force and to neglect the effect of the width of the gage. Then any wheel which slips is subject to a lateral force equal to the weight on the axle multiplied by the coefficient of friction. This coefficient may conventionally be taken as 25 per cent for slow speed on sharp curves (roughly up to 40 mph and on 6-deg curves and sharper), and 15 per cent for high speed on long-radius curves (roughly above 60 mph and up to 4-deg curves).

The locomotive wheel base is laid out in a possible position on the curve in question and the forces are evaluated. If the forces are in equilibrium the position has been correctly chosen. If the forces have a resultant, the locomotive is moved in the direction which this resultant indicates until finally an equilibrium position is located.[5]

When the equilibrium position is obtained it should be examined to see if it is stable. Stability is shown particularly by

two well-defined points at which the locomotive is held against the rail, these points being well separated to give a long base. If there is only one definite point and the locomotive is balanced by slipping wheels, guiding-truck restraints which are not locked, etc. the locomotive will be unstable at even slow speeds, because the frictional and other forces are not actually constant. Every slipping wheel will, if it can, roll and slip alternately, following a saw-tooth path. Therefore, the equilibrium position must be independent of large changes in the coefficient of friction. Also, wheels which make considerable angles with the rail should be able to execute small rapid oscillations without forcing the main mass of the locomotive to follow them, otherwise major oscillations will be started by small track irregularities.

A frequent cause of oscillation is due to excessive speed where the centrifugal force becomes sufficient to shift one or more axles from the inner to the outer rail, thus upsetting the balance and causing the locomotive to oscillate. More detailed calculations of any kind of motion which is indicated by this preliminary study can be made using energy methods as used for critical speed on tangent track.

Safety

Lateral pressure on an axle may (1) cause derailment, (2) spread or overturn the rail, (3) move the track bodily through the ballast, (4) break the axle, frame or other parts of the locomotive, or (5) may overturn the locomotive.

Derailment. The formula for the maximum lateral pressure on an axle which can be exerted before the wheel flange will climb the rail is,[6] for a positive angle of attack

$$H/W = [(\tan \alpha - f)/(1 + f \tan \alpha)] - (W'/W)f$$

For the flange tangent to the rail

$$H/W = \tan \alpha$$

The formula for the positive angle should be used in order to be safe. For a negative angle of attack

$$H/W = [(\tan \alpha + f)/(1 - f \tan \alpha)] + (W'/W)f$$

In these formulas H = the lateral force on the axle to produce derailment, W = the vertical load at the rail on the wheel which derails, W' = the vertical load at the rail on the other wheel of the same axle, α = the inclination to the horizontal of the plane of contact between the flange and the rail, and f = the coefficient of friction. The vertical loads are not the static loads but are those actually existing at the time of derailment.

The coefficient of friction is conventionally taken as 0.25. For high speed and small angles of attack it will probably be less although for slow speed on very sharp curves it may be more. It is suggested that for negative angles of attack, where decreased coefficient of friction decreases the allowable lateral load, 0.15 should be used for high speeds and small negative angles of attack.

The angle α, which is the inclination of the plane of contact between flange and rail, depends on the contour of the flange and of the rail, and on the angle of attack.

While the contour of the flange can be drawn, it is very laborious to determine graphically the effect of angularity between the plane of the wheel and the plane of the rail. The following semigraphical method can be used where the angularity is enough to make it worth while.

The contour of the tire is drawn. Any convenient point on the contour is chosen as the origin of the coordinates and the contour is then a curve connecting x and y as shown in Fig. 7.

[6] "Traité de Stabilité du Matériel des Chemins de Fer," by Georges Marié, Ch. Béranger, Paris, France, 1924, pp. 288–299.

If the wheel is now turned through an angle θ about a vertical axis, the projected contour becomes a new curve, determined by X and Y as before and also by Z, perpendicular to the plane of projection.

Then, corresponding to any original point (x, y) there is a new point on the projected contour (X, Y, Z) given by

$$(R - Y)^2 = (R - y)^2[1 - (y^1 \tan \theta)^2]$$
$$X = \cos \theta[x + (R - y)y^1 \tan^2 \theta]$$
$$Z = -\sin \theta[x - (R - y)y^1]$$

where R = the radius of the wheel measured to the point on the tire which is taken as the origin of the coordinates, and $y^1 = dy/dx$ in the original curve $y = f(x)$.

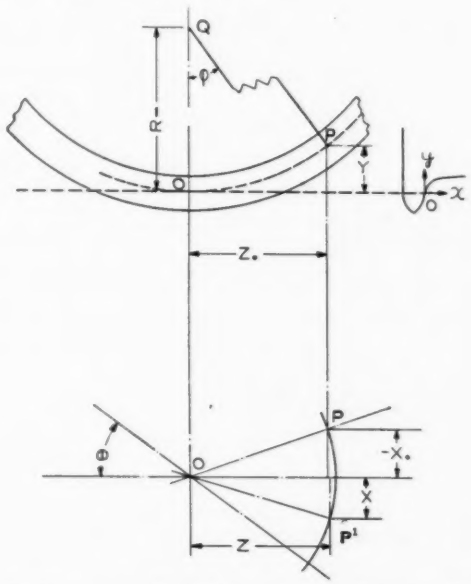

Fig. 7 Diagram of Tire Contour on an Inclined Wheel

Take a number of points (x, y) on the original contour, calculate X and Y by the latter three formulas, and plot Y against X. This will be the projected contour of the tire when turned through an angle θ. The projected contour can then be laid against a section of the rail to determine where they touch, and the slope of the tangent at the point of contact can be measured or calculated. If required, Z can also be calculated for this point to ascertain how far ahead of or behind the center of the wheel the point of flange contact is located. To prove the validity of these formulas refer to Fig. 7. Take the origin of coordinates at a point O on the tire. Let P be any point on the surface of the tire, with coordinates X_o, Y, Z_o. In the normal cross-section of the tire, P would have coordinates x, y.

Now rotate the wheel about a vertical axis OQ through an angle θ so that P moves to P^1. The coordinates of P^1 are X, Y, and Z. Then

$$X_o = x$$
$$QP^2 = (R - y)^2 = Z_o^2 + (R - Y)^2 \quad [1]$$
$$X_o^2 + Z_o^2 = X^2 + Z^2 \quad [2]$$
$$\tan \theta = \frac{(-X_o/Z_o) + (X/Z)}{1 + (X_oX/Z_oZ)} \quad [3]$$

A condition when X, Y, and Z are on the projected contour of the tire is expressed by

$$(\partial X/\partial Z)_{Y = \text{const}} = 0 \quad [4]$$

From Equations [1], [2], and [3]

$$(R - y)^2 - (R - Y)^2 = (Z \cos\theta + X \sin\theta)^2$$

and

$$x = X \cos\theta - Z \sin\theta$$

Differentiating with respect to Z, keeping Y constant and putting $(\partial X/\partial Z)_Y = 0$

$$-2(R - y)(\partial y/\partial Z)_Y = 2 \cos\theta(Z \cos\theta + X \sin\theta)$$

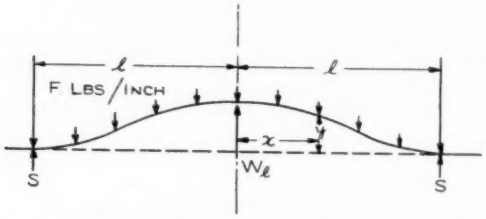

FIG. 8 TRACK DISPLACED BY A STATIONARY LOAD

and

$$(dx/dy)(\partial y/\partial Z)_Y = -\sin\theta$$

Eliminating $(\partial y/\partial Z)_Y$

$$(R - y)(dy/dx) \tan\theta = Z \cos\theta + X \sin\theta$$

Therefore

$$(R - Y)^2 = (R - y)^2[1 - (y' \tan\theta)^2] \quad [5]$$

$$X = \cos\theta[x + (R - y)y' \tan^2\theta] \quad [6]$$

$$Z = -\sin\theta[x - (R - y)y'] \quad [7]$$

If the contour can be expressed by a formula, the projection can be calculated directly. For example, if the contour is conical $y = x \tan\alpha$ and the slope of the projected cone is

$$\tan\alpha/\cos\theta \sqrt{(1 + \tan^2\alpha \tan^2\theta)}$$

MOVING TRACK

An excessive lateral load may move the track bodily through the ballast. The resistance to this motion is the friction between the ballast and the bottom of the ties.

A certain amount of side thrust can be exerted without any motion of the ties because the bending and twisting of the rail and compression of the ballast will distribute the thrust over a number of ties and the thrust on at least one tie must overcome the total friction on that tie. There is little data available as to the distribution of lateral pressure between ties up to the point where they slip. After slipping starts, the following simplified calculation is useful.

Assume the frictional force resisting side motion is constant and equal to F lb per in. Consider also, the case where deflection is all in one direction. In order for this to be possible, with a single applied load, reaction forces S are required at the points where deflection starts. Let the total length of deflected track be $2l$ in. Let the lateral load be W_l. Then $S = Fl - (W_l/2)$ as can be observed from Fig. 8.

For equilibrium and positive values of x, taking the origin at the point of application of the lateral load to the undeflected rail

$$y = \frac{9}{2048} \frac{W_l^4}{F^3 E I_l} \left[1 - 6\left(\frac{x}{l}\right)^2 + 8\left(\frac{x}{l}\right)^3 - 3\left(\frac{x}{l}\right)^4\right]$$

where E = the modulus of elasticity of rail steel, I_l = lateral moment of inertia of the track (two rails), $l = 0.75(W_l/F)$, and y = the lateral deflection of the track.

The maximum deflection at the load is

$$y_o = 0.0044(W_l^4/F^3 E I_l)$$

Field tests show that this equation represents the facts fairly accurately for deflections from 0.25 in. to 1 in. For small deflections, the loads are less than given by the equation. It appears that deflections up to approximately the order of 0.25 in. can be produced in heavily loaded track without causing permanent slip. In field tests, track was shifted considerably under a load and returned practically to the original position when the load was removed.

If the vertical load on an axle is W_v, the vertical force on the ballast per inch at a distance x is known to be

$$P = (\pi/8)(W_v/x_l)e^{-(\pi x/4x_l)}[\cos(\pi x/4x_l) + \sin(\pi x/4x_l)]$$

where $x_l = (\pi/4) \sqrt[4]{(4EI_v/U)}$, I_v = the vertical moment of inertia of one rail, and U = the modulus of foundation of one rail.

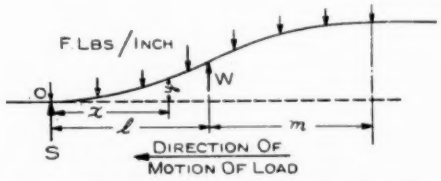

FIG. 9 TRACK DISPLACED BY A MOVING LOAD

The maximum pressure under load is

$$P_o = (\pi/8)(W_V/x_l)$$

Dividing the frictional force F by the vertical force P_o, an index of the nature of a coefficient of friction is obtained. Numerous tests on good track with wooden ties in stone ballast show values of F/P_o ranging from approximately 0.9 to 1.9 according to the condition of the track. The value increases with age up to the point where the ties decay if the track is undisturbed. If the track is raised and the ballast disturbed, the index is reduced. Observations on some metal ties indicate a materially lower resistance to lateral motion. Except on newly laid track or metal ties, it seems reasonable to rely on a ratio of at least 1.0.

Actually, the lateral friction force F will not be constant along the rail but will decrease as the vertical pressure on the ties decreases and will be affected by adjacent wheels. Except on the first wheel of a locomotive, however, the adjacent wheels tend to keep the track uniformly loaded and therefore the assumption of a constant force F per inch is reasonable. A leading wheel will move track a little more easily than these approximate formulas indicate. The previous discussion refers to static conditions. When the locomotive is moving, less lateral force is required to shift the track.

In Fig. 9, let O be the origin of the coordinates. Consider the track moving in one direction only and remaining shifted after the lateral load has passed. Let the coordinates move with the same speed as the load. Then, for the moving section

$$EI(d^2y/dx^2) = Sx + W\{x - l\} - (Fx^2/2)$$

where $\{\ldots\}$ are Macauley brackets, i.e., the bracket is taken as zero whenever the bracketed term is negative.

But

$$S = F(l + m) - W$$

Therefore

$$EI(d^2y/dx^2) = [F(l + m) - W]x + W\{x - l\} - (Fx^2/2)$$

and since $(dy/dx) = 0$ when $x = 0$

$$EI(dy/dx) = [F(l + m) - W](x^2/2) + (W/2)\{x - l\}^2 - (Fx^3/6)$$

Also putting $(dy/dx) = 0$ when $x = l + m$

$$(F/3)(l + m)^3 = (Wl/2)(l + 2m)$$

and taking moments about the origin

$$Wl = (F/2)(l + m)^2$$

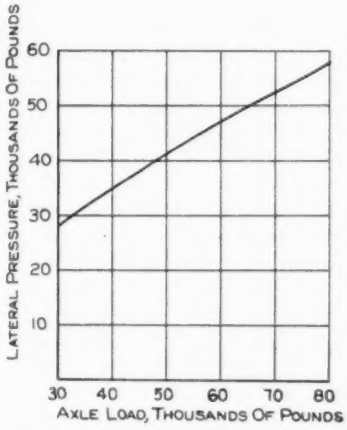

FIG. 10 LATERAL PRESSURE FROM A MOVING LOAD REQUIRED TO PRODUCE 0.25-IN. TRACK MOVEMENT
$(F/P_o = 1;\ Wl = 12.2W_v^{3/4}.)$

whence $l = 2m = (8/9)(W/F)$

Integrating again and putting $x = l + m$, the maximum deflection is found to be

$$y_{max} = (32/2187)(W^4/F^3) = 0.0146(W_l^4/F^3EI_l)$$

Otherwise, for the same maximum deflection, the ratio of moving force to static force will be

$$\sqrt[4]{(0.0044/0.0146)} = 0.74$$

The lateral force exerted by a moving locomotive axle to produce a 0.25-in. displacement of the track may be used as a convenient index. According to the previously given formulas

$$0.25 = (0.0146W_l^4/(F^3EI_l)$$

and

$$F = (F/P_o)(W_v/2)\sqrt[4]{(U/4EI_v)}$$

Therefore

$$W_l = (E^{1/16}/1.07)(F/P_o)^{\frac{3}{4}}(I_l^{\frac{1}{4}}/I_v^{3/16})U^{3/16}\,W_v^{\frac{3}{4}}$$

and if $E = 30{,}000{,}000$ lb per sq in. and $(F/P_o) = 1$

$$W_l = 2.74(I_l^{\frac{1}{4}}/I_v^{3/16})U^{3/16}\,W_v^{\frac{3}{4}}$$

The latter formula indicates that the weight of the rail has very little influence, that the modulus of foundation, i.e., the stiffness of the ballast, is quite important, and that, other things being equal, the allowable ratio of lateral to vertical load on an axle decreases as the axle load increases.

Taking typical values for good track with 131-lb rail, $I_l = 16.1 \times 2 = 32.2$, $I_v = 89$, and $U = 2500$. These values substituted in the last given equation give

$$W_l = 12.2W_v^{\frac{3}{4}}$$

the curve for which equation is plotted in Fig. 10.

In this discussion, the moment of inertia of the track I_l has been taken as being due to the rails alone, which is not strictly accurate inasmuch as other factors enter into it. Before these factors can be taken into consideration, additional experimental data is required, which is not available at the present time.

Lateral Oscillations of Rail Vehicles

By B. F. LANGER[1] and J. P. SHAMBERGER,[2] EAST PITTSBURGH, PA.

The authors point out in this paper that lateral oscillations, which either do not occur or are negligible at slow train speeds, are of vital importance at the high train speeds now demanded by the railroads in order for them to compete successfully with the swiftly moving automobile and the much swifter airplane. Aside from collisions and broken rails, practically all railroad accidents result from lateral derailments, since vertical derailments occur only on those rare occasions when a bridge or trestle collapses from flood or storm. Lateral derailments are caused by lateral pressure of wheel flanges against the rail. Therefore, the prevention of lateral derailments requires a knowledge of both the conditions which cause high lateral forces and of the conditions which must prevail in order to keep the lateral forces below some indicated safe value.

The literature on the subject of lateral oscillations of rail vehicles is rather meager. Nadal[3] and Marie[4] discuss the type of oscillations that are forced. Boedecker,[5] as well as the authors previously mentioned, discusses the weaving motion of the wheel base due to the conicality of the wheel treads. The weaving action which Boedecker discusses must be started by an initial disturbance and, in the absence of further periodic disturbances, can neither build up to a higher amplitude than that produced by the initial conditions nor be sustained, but must quickly die away. Carter[6] develops the stability condition for a rail vehicle as determined by the slippage at the treads.

The essential difference between the previous studies[3,4,5,6] and the present one is that the previous ones discussed forced oscillations the life of which depended upon the application of some periodic force, such as that from cylinder action or rail joints, whereas the present discussion describes and explains a type of oscillation which, after an initial disturbance, even though a minor one, may build up to dangerous proportions and sustain itself indefinitely on absolutely perfect track. This type of oscillation is frequently encountered and is commonly known as "nosing." It is only one phase of the whole problem, but it represents the most serious menace to the safe operation of rail vehicles at high speed.

1—FUNDAMENTAL CONSIDERATIONS

IN ORDER to investigate the possibilities of self-induced lateral oscillations in rail vehicles, the simple case of a symmetrical vehicle with two axles in a rigid frame supporting a spring-borne mass as shown in Fig. 1, will be considered first. It runs on a track the vertical flexibility of which is small compared to that of the springs of the vehicle, but which allows lateral motion of the wheels and axles, partly through flange clearance, partly through the riding-up of the wheel onto the throat of the flange, and partly through elastic distortion of the track itself. The springs of the vehicle allow vertical motion of the sprung mass relative to the unsprung mass. They also allow a sidewise rolling motion and a fore-and-aft pitching motion, but no relative rotation about a vertical axis. This system has six degrees of freedom, three of which are motions of sprung mass relative to unsprung mass, and three of which are motions of unsprung mass relative to the ground. The three motions of sprung mass relative to unsprung mass are (1) vertical motion, (2) rotational motion about a transverse axis which is defined as "pitching," and (3) rotational motion about a longitudinal axis which is defined as "rolling." (Since the height of this longitudinal axis above the rail is less than the height of the center of gravity, the roll results in a lateral displacement of the center of gravity of the sprung mass relative to the unsprung mass.) The three motions of the unsprung mass relative to the ground are (1) lateral motion, (2) longitudinal motion, and (3) rotational motion about a vertical axis. The system is not linear, the principal nonlinearity being in the lateral spring scale of the track.

As a first step in the investigation of the possibilities of self-induced oscillations, the system can be simplified considerably in order to determine which features of it are essential to the existence of the oscillations. Consider the case of a vehicle without any springs and no flange clearance. This eliminates the first three of the six degrees of freedom, which are the three motions of sprung mass relative to unsprung mass, and makes the lateral spring scale of the track linear. There are now just two possible types of lateral motion. One is a rotation about some vertical axis and the other is lateral translation of the wheel base. As far as lateral motions are concerned there are just two degrees of freedom. In order to have self-sustained oscillations in a system with two degrees of freedom there must be transfer of energy between the two degrees of freedom and also net energy input to the system. In other words, the following three conditions must all be satisfied: (1) The rotational motion must produce lateral translation; (2) the lateral translation must produce rotation; and (3) a periodic force must have a component in phase with the velocity of lateral translation and a periodic moment must have a component in phase with the velocity of rotation.

[6] "On the Stability of Running of Locomotives," by F. W. Carter, Proceedings, Royal Society of London, vol. 121, 1928, p. 585.

As long as there is forward velocity and friction at the treads of the wheels, the first condition is satisfied. The vehicle tends to travel in the direction of its own center line rather than in the direction of the track center line, because of the friction at the treads. Thus, whenever there is an angular displacement between the track and vehicle center lines, the forward motion has a lateral component of which all points on the vehicle partake equally or, in other words, a lateral translation. Therefore condition (1) is satisfied.

In order to ascertain if the second condition is satisfied, see Fig. 2. Here the wheel base is in an angular position and the track is bowed out on one or both sides. There is a moment exerted by the track tending to restore the wheel base to its neutral position. Note, however, that this moment is a function of only the angular

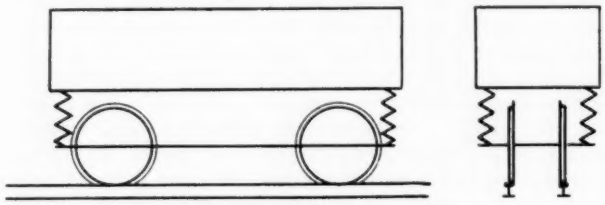

FIG. 1 SIMPLE RAIL VEHICLE

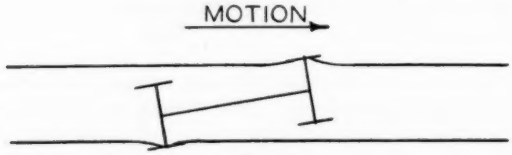

FIG. 2

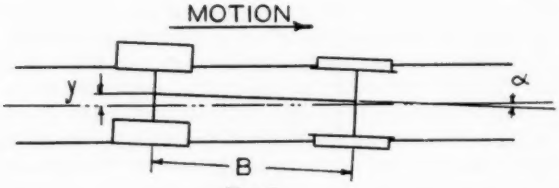

FIG. 3

position of the wheel base and lateral translation does not affect it. If the wheel base is translated laterally, say upward, in Fig. 2, the force at the leading axle increases but the force at the trailing axle decreases by the same amount and the moment remains the same. Inspection readily shows that this holds true for any position of the wheel base. Consequently, condition (2) is not satisfied. The lateral translation does not affect the angular motion and no self-induced oscillations are possible in this simplified system.

Now retrace one of these steps and replace the nonlinearity of the lateral resistance of the track. Actually, this nonlinearity is always present, except under very special conditions, because of the flange clearance. The spring scale may be considered as one which increases with displacement. Condition (1) is still satisfied. In Fig. 2, however, if the whole wheel base shifts upward, the leading axle moves in the direction of increasing spring scale, and the trailing axle moves in the direction of decreasing spring scale. Therefore, the force at the leading axle increases more than the force at the trailing axle decreases, and the moment is changed. This change in moment occurs for any positions of the wheel base except those in which its center line is parallel with that of the track.

Thus one condition is disclosed which is essential to the existence of self-induced lateral oscillations in rail vehicles. *The lateral resistance of the track must increase with the lateral displacement of the wheel from its neutral position. This condition is satisfied if flange clearance is present.*

It has been shown that for a conventional rail vehicle the nonlinearity of the track spring scale must be considered since it furnishes the coupling between lateral and rotational motion. The differential equations which exactly represent such a system are nonlinear and impossible to solve for the general case. As an approach to the problem it is interesting to consider a rigid two-axle rail vehicle with flanges on only the leading pair of wheels. Such a vehicle can sustain its oscillations on a linear track without clearance, and the equations which represent its motion are solvable.

In Fig. 3, let y = the lateral displacement between the center of the trailing axle and the center line of the track, α = the angular displacement between the track center line and the vehicle center line, V = the forward velocity of the vehicle, J = the polar moment of inertia of the vehicle about a vertical axis through the center of gravity, M = the mass of the vehicle, K = the lateral spring scale of the track, B = the wheel base of the vehicle, and c = the track damping constant.

In Fig. 3 let positive forces and displacements be upward and positive moments and angles counterclockwise. The lateral forces at the leading axle are $-K(y + B\alpha) - c(\dot{y} + B\dot{\alpha} - V\alpha)$. The lateral forces at the trailing axle are $-c(\dot{y} - V\alpha)$.

Note that the sliding velocity of a wheel is not its total lateral velocity, but the difference between the total lateral velocity and $V\alpha$. Longitudinal sliding has been disregarded.

The equilibrium of lateral forces gives

$$M[\ddot{y} + (B/2)\ddot{\alpha}] = -K(y + B\alpha) - c(2\dot{y} + B\dot{\alpha} - 2V\alpha) \quad [1]$$

The equilibrium of moments about the rear axle gives

$$\ddot{\alpha}[J + (MB^2/4)] + (MB/2)\ddot{y} = -BK(y + B\alpha) - cB(\dot{y} + B\dot{\alpha} - V\alpha) \quad [2]$$

These equations can be solved completely, but this is not necessary for our present purpose. By the application of Routh's criteria of stability[7] the conditions under which the motion is unstable can be determined. We find that for stability

$$V < \frac{B[2Jc^2B^2 + 2KJ^2 + (1/2)Mc^2B^4 + (1/8)M^2KB^4]}{4J^2c + 2cB^2JM + (1/4)B^4M^2c} \quad [3]$$

If $J = (B^2M)/4$, the case of the mass concentrated at the axles, then

$$V < B[(c/M) + (K/4c)] \quad [3a]$$

If $J = 0$, the case of a light swivel truck, then

$$V < 2B[(c/M) + (K/4c)] \quad [3b]$$

It is interesting to note that this critical speed, below which oscillations will die out and above which they will increase indefinitely, is directly proportional to the length of the wheel base. It also increases with increasing track stiffness and decreases with increasing mass of the vehicle. Combining these last two statements we may say that the higher the natural frequency of the vehicle on the track the higher the critical speed. The term "critical speed" as here used does not mean the speed at which the oscillations are a maximum, but merely a border-line value above which oscillations build up and below which they die out.

2—APPROXIMATE SOLUTION

The next step will be to develop an approximate solution for a more conventional type of vehicle. Take a two-axle vehicle the mass of which is supported on springs and the unsprung mass of

[7] "Mechanical Vibrations," by J. P. Den Hartog, McGraw Hill Book Co., New York, 1934, chap. 7.

which is negligible. It has flanges on all four wheels and has lateral flange clearance in the track. The lateral spring scale of the track is high compared to the stiffness of the springs in the vehicle. The friction between the wheel and the rail is constant, not proportional to velocity.

The difficulty in solving the problem lies with the nonuniformity of the track resistance, which changes from zero to a large value when a flange hits the rail. It is known, however, that whatever the nature of the track resistance, it is such as to transform lateral motion of the wheel base into angular motion. Therefore, if the wheel base has a periodic lateral motion, it will also have a periodic angular motion. Let it be assumed that this angular motion can be expressed by the function $\alpha = A\cos\omega t$. The effect on the following solution if α is some other function of t is discussed in Appendix 3.

Fig. 4 shows six successive positions of the wheel base and the body. Wherever the rotation is in such a direction as to make a pair of wheels move to the same side of the track as that to which the vehicle is pointed, that pair of wheels may be sliding in either direction, or else rolling. If the rotation is in the opposite direction, the wheels must be sliding in the direction of rotation. Thus the direction of sliding of the rear wheels is indeterminate in I and IV and that of the front wheels is indeterminate in III and VI.

Let Y_1, Y_2 = the flange pressure on the leading and trailing axles, respectively, G_1, G_2 = the friction forces at the leading and trailing axles, d = the lateral displacement of the body relative to the wheel base due to roll, Q = the vertical load on a wheel, μ = the coefficient of friction between a wheel and the rail, and K = the lateral spring scale of the body on the wheel base.

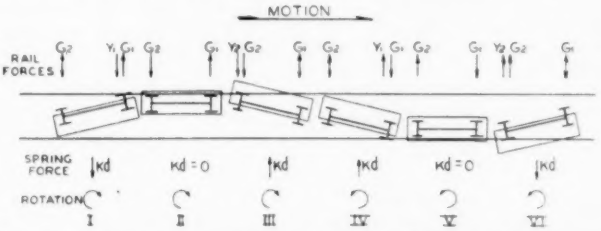

FIG. 4 SUCCESSIVE POSITIONS OF A VEHICLE DURING OSCILLATION, SHOWING DIRECTION OF ROTATION AND DIRECTION OF FORCES EXERTED BY THE TRACK OR BODY ON THE AXLES

The equilibrium equation for the forces on the wheel base is

$$Y_1 + Y_2 + G_1 + G_2 + Kd = 0 \quad [4]$$

For condition I, $Y_2 = 0$, $G_1 = 2\mu Q$. Then $Y_1 + 2\mu Q + G_2 + Kd = 0$, or $Y_1 = -2\mu Q - G_2 - Kd$.

Since Y_1 must be negative, and d is at this time negative, and G_2 cannot exceed $2\mu Q$, then Kd must, in absolute magnitude, be equal to or less than $4\mu Q$. If the amplitude of roll is such that Kd exceeds this value, then both pairs of wheels will slide to the right and $Y_1 = 0$. At the instant when Kd decreases to the value $4\mu Q$, the leading flange hits the left rail and period I can start. Thus, the wheel base cannot turn until a definite point in the cycle of the body's oscillation is reached. Therefore, the rolling of the body on its springs acts as an escapement, controlling the frequency of the oscillation of the wheel base, and in the expression $\alpha = A\cos\omega t$, ω is 2π times the natural frequency of body roll.

The mass of the body will tend, on the average, to rotate about its center of gravity. During I and IV the friction forces will tend to throw the center of rotation toward the rear, and during III and VI toward the front, but during the whole cycle the net effect will be that of the center of rotation in the middle of the wheel base. If y is called the lateral displacement of the center of the wheel base, then the assumption can be made that $\dot{y} = V\alpha$. This assumption is based on the idea that the lateral translation, y, is produced by forward motion, V at a small angle α. $V\alpha$ is probably not the correct value for $\dot{y}$, but it represents an upper limit and gives the lowest possible value for critical speed.

$$\text{If} \qquad \dot{y} = V\alpha, \; y = \int_0^t VA\cos\omega t = (VA/\omega)\sin\omega t$$

Since y is the purely translatory motion of the point under the center of gravity of the body, it is y which excites the rolling oscillation of the body. When a damped system is forced to oscillate at its natural frequency, the vibration lags the disturbing force by 90 deg. Therefore, $d = -d_{max}\cos\omega t$, and the relative positions shown in Fig. 4 are correct.

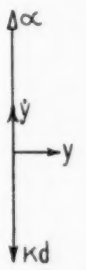

FIG. 5

The question of whether or not the oscillation can sustain itself is dependent upon the relation between energy input and energy loss. Fig. 5 shows the vector relationships between the various motions and forces which have been considered. The sum of all the rail forces, Y_1, Y_2, G_1, and G_2 is equal and opposite to Kd. Therefore, the rail forces are in phase with $\dot{y}$, the velocity of lateral translation, and they constitute the input force.

The energy input per cycle of a periodic force in phase with a velocity is equal to π times maximum force times amplitude.[8] Therefore

$$\text{input per cycle} = \pi Kd_{max}VA/\omega \quad [5]$$

If, during any part of the oscillation, $Kd > 4\mu Q$ then during such time the motion y is not taking place and there is an interim during which there is no input. Therefore, $4\mu Q$ can be substituted for Kd_{max} in calculating the true input, provided $Kd_{max} > 4\mu Q$, and

$$\text{input per cycle} = 4\pi\mu QVA/\omega \quad [5a]$$

The losses at the rail which drain energy from the oscillation consist of frictional losses due to sliding at the wheel treads. This sliding is due to (1) the angular oscillation about the center of the wheel base and (2) the lateral slippage of the whole wheel base when $Kd > 4\mu Q$. Considering (1) first, the force at each wheel is μQ and the distance through which it acts is $BA/2$ during each quarter cycle. Therefore

$$\text{loss per cycle} = 4(BA/2)\;4\mu Q = 8BA\mu Q$$

The loss due to lateral slippage may be calculated by the curves of Appendix 1. In using these curves it must be remembered that the amount of slipping may be limited by the flange clearances.

Let us now study what happens for various amplitudes of roll, that is, various values of Kd_{max}.

If $Kd_{max} = 4\mu Q$

$$\text{input per cycle} = 4\pi\mu QVA/\omega \quad [6]$$

$$\text{loss per cycle} = 8BA\mu Q \quad [7]$$

For stability, $8BA\mu Q > 4\pi\mu QVA/\omega$, or

$$V < 2\omega B/\pi \quad [8]$$

If $Kd_{max} < 4\mu Q$, the loss is the same as for $Kd_{max} = 4\mu Q$, but the input is smaller. Therefore, the critical speed is higher.

If $Kd_{max} > 4\mu Q$, the input is the same as for $Kd_{max} = 4\mu Q$,

[8] "Mechanical Vibrations," by J. P. Den Hartog, McGraw Hill Book Co., New York, 1934, p. 19.

but the loss is increased by the lateral slipping of the whole wheel base. Therefore, the critical speed is again higher.

This whole phenomenon may be illustrated by a curve such as that shown in Fig. 6, which was calculated for an actual locomotive. The curve ABC represents the critical speed for various initial amplitudes of roll. If the initial conditions for this locomotive are represented by either L_1 or L_3, the oscillation will die out. If they are represented by either L_2 or L_4, the conditions will change until the steady condition L_5 is reached, at which the input is equal to the loss.

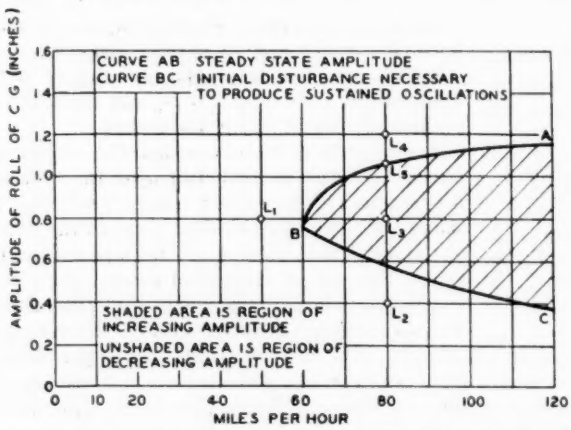

FIG. 6 AMPLITUDE OF ROLL OF AN ATLANTIC-TYPE LOCOMOTIVE

The most important critical speed is, of course, the lowest one, given in Equation [8]. Note that exactly the same conclusions regarding the effect of wheel base and natural frequency on critical speed can be drawn from Equation [8] as have already been drawn from Equations [3a] and [3b], which give the critical speed for the rigid vehicle with flanges on only the leading pair of wheels.

These same methods as were used can be applied to the case of a vehicle with more than two axles in a rigid wheel base. It is not necessary to follow the whole line of reasoning here. In Equation [9], the additional friction loss due to longitudinal sliding of the wheels is considered. The center of rotation should be taken at the center of the wheel base. Any other assumption would increase the friction loss and result in a higher critical speed.

If f = the natural frequency of the roll of the body, n = the number of axles in the rigid wheel base, x_i = the longitudinal distance from the center of rotation to an axle, s = the track gage, and the subscript i refers to the i-th axle in the wheel base, then

$$V_{cr} = [8f/n]\sum_{i=n}^{i=1}\sqrt{[x_i^2 + (s/2)^2]} \quad \ldots\ldots [9]$$

Values of $\sqrt{[x^2_i + (s/2)^2]}$ for various values of x_i are given in Table 1, Appendix 2.

In applying Equation [9] to a nonsymmetrical wheel base, the question of where to take the center of rotation arises. The safest assumption to make would be the one which gave the lowest value to $\Sigma\sqrt{[x^2_i + (s/2)^2]}$. As far as the oscillations discussed in this paper are concerned, there seems to be no inherent advantage or disadvantage in the use of a nonsymmetrical as compared to a symmetrical axle arrangement.

The symbol f is defined as the natural frequency of the roll of the body. This is approximately the correct frequency to use for most simple vehicles of the rigid-frame type and can be calculated according to the equation

$$f = [1/2\pi]\sqrt{[(K_s b^2 - 2Wh)/2I_r]} \quad \ldots\ldots [10]$$

where K_s = the spring scale for one side of the vehicle, neglecting cross-equalized springs, W = the sprung weight of the vehicle, I_r = the polar moment of inertia of the sprung weight about a longitudinal axis through the axle centers, h = the height of center of gravity of sprung mass above axle centers, and b = the lateral distance between springs.

Measurements have shown that the actual frequency at which the oscillation occurs is affected to a certain extent by the natural frequency of the locomotive in the track. The theoretical evaluation of this factor would require a much more detailed analysis than has been developed here; one which would take account of all possible degrees of freedom. It is highly advisable to use experimental data wherever possible in choosing a value of f for use in Equation [9].

Equation [9] was developed primarily for use on vehicles of the type of the rigid-frame locomotive. There is no reason why the same theory would not apply, however, to any individual rigid wheel base in a more complicated system, such as an articulated locomotive or a vehicle with swivel trucks. The only difference would be in the determination of the natural frequency which controls the oscillation. The authors' casual observations on street-railway cars with swivel trucks have led to the conclusion that the oscillations of the body are almost entirely angular about a vertical axis. Thus, the natural frequency would be determined not by the roll, but by the polar moment of inertia of the body about a vertical axis and the lateral restraint at the truck center pins.

If harmonic motion is assumed at all points of the vehicle, the center of rotation at a fixed point on the center line of the wheel base, and a known maximum lateral amplitude for a wheel, it is possible to solve the kinematics of the problem completely. This is done most easily by vector representation.

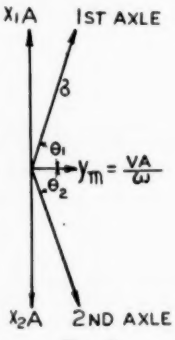

FIG. 7

Let 2δ = the maximum possible full amplitude for a wheel (flange clearance plus rail deflection); A = the maximum value of α during a cycle; θ_i = the phase angle of i-th axle referred to center of rotation; and the other symbols the same as given previously.

Fig. 7 shows the vector diagram for a two-axle wheel base with the center of rotation in the middle. The value of y_{max} has already been determined. It is

$$y_{max} = VA/\omega \quad \ldots\ldots [11]$$

The total amplitude of the i-th axle is seen to be

$$2VA/\omega \cos \theta_i \quad \ldots\ldots [12]$$

Also, if the leading axle has the full amplitude 2δ,

$$\delta = VA/\omega \cos \theta_1 \quad \ldots\ldots [13]$$

and hence

$$A = \delta\omega \cos \theta_1/V \quad \ldots\ldots [14]$$

However

$$\cos \theta_1 = \frac{VA/\omega}{\sqrt{[(V^2A^2/\omega^2) + x_1^2A^2]}} = \sqrt{[V^2/(x_1^2\omega^2 + V^2)]} \quad \ldots [15]$$

Substituting Equation [15] in Equation [14], we obtain

$$A = \delta\omega/\sqrt{(x_1^2\omega^2 + V^2)} \quad \ldots\ldots [16]$$

It is also of interest to know the expressions for energy input

and energy loss in terms of the known constants of the vehicle. These are found to be:

$$\text{Input per cycle} = \pi k d_{\max} V\delta / \sqrt{(x_1^2\omega^2 + V^2)} \quad [17]$$

or, at the critical speed, when $Kd_{\max} = 2n\mu Q$

$$\text{input per cycle} = 2\pi n\mu Q V\delta / \sqrt{(x_1^2\omega^2 + V^2)} \quad [18]$$

and due to rotation the

$$\text{loss per cycle} = \frac{8\mu Q\delta\omega}{\sqrt{(x_1^2\omega^2 + V^2)}} \sum_{i=n}^{i=1} \sqrt{[x_i^2 + (s/2)^2]} \quad [19]$$

3—DESIGN REQUIREMENTS FOR A HIGH-SPEED LOCOMOTIVE

The basic design requirement for a high-speed locomotive is that its critical speed be considerably above the highest speed at which the locomotive is expected to operate. The critical speed as given by Equation [9] is in error on the side of safety in that it assumes $\dot{y} = V\alpha$ and does not consider the energy loss from the friction in the equalization springs and at other rubbing surfaces that tend to damp the oscillation. The experience of the authors has been that the factor of safety introduced by these simplifying assumptions is sufficient for good practice, so that a locomotive can operate safely up to its calculated critical speed. The design features that influence steady performance at high speed are indicated in Equation [9], which is the equation for critical speed. For a given track gage s and a given number of axles n in the rigid wheel base, it is observed from Equation [9] that the inherent critical speed is a function of (1) the frequency of roll, and (2) the length of the rigid wheel base. A high frequency of roll and a long rigid wheel base produce a high critical speed. The critical speed of a locomotive may be raised or lowered to the extent that the designer can vary (1) the frequency of roll, and (2) the length of the rigid wheel base, these two factors being the ones which dominate the critical speed.

Equalization System

The equalization system is an important design feature as regards critical speed because of its influence on the frequency of roll. The equalization system influences the frequency of roll by (1) the scale of the spring, (2) the lateral distance between spring supports, and (3) the ratio between cross-equalization and side-equalization. The relative influence of these three factors on frequency is indicated by Equation [10] for natural frequency of roll. Other things remaining constant, the critical speed is raised by (1) increasing the stiffness of the springs, (2) by increasing the lateral distance between spring supports, and (3) by increasing the amount of side-equalization.

Stiff springs are desirable from a consideration of critical speed but are undesirable from a consideration of resulting forces on vehicle and track. Springs are employed in the equalization system in order to shield both the sprung weight and the track from forces in excess of those existing under static conditions. From the consideration of reducing forces on sprung weight and track, the softer the supporting springs the more effective they become. To stiffen the springs defeats the purpose for which they are used. The fact is that the designer can vary the stiffness of the equalization springs only within rather well-defined limits. To stiffen them defeats their purpose, to soften them beyond a certain limit introduces complications on account of the large vertical movement in the pedestal guides. It would seem, then, that the logical procedure to follow is to employ springs as soft as can be used from practical considerations without too great a sacrifice of frequency. From Equation [10], it is observed that the frequency of roll varies directly as the square root of spring stiffness. Because of this relationship between frequency and spring stiffness, it is possible to soften the springs of a locomotive considerably without producing more than a minor change in frequency.

The type of spring employed in the equalization system, that is, whether leaf-type or coil-type, is as important as the spring scale. Considerable frictional damping is introduced by leaf springs which is absent when coil springs are used. A satisfactory arrangement results from a combination of low-frequency leaf springs in series with high-frequency coil springs. In this arrangement the low-frequency leaf springs practically determine the period of roll and provide frictional damping while the high-frequency coil springs are placed directly over the journal boxes and absorb the high-frequency shocks from the road bed.

The lateral distance between supporting springs is fixed by the location of journal boxes. For a given angularity of roll, the greater the lateral distance between springs, the greater will be the variation in vertical load under the drivers, but as regards critical speed, the greater the lateral distance between springs, the higher will be the frequency of roll and the higher the critical speed. Other things remaining constant, outside journal boxes will produce a higher critical speed than will inside boxes. For steam locomotives, however, outside boxes are possible only with inside cranks, and in this country inside cranks are unknown except for three-cylinder locomotives. In Europe, inside cranks for steam locomotives are common. For electric locomotives, both in this country and elsewhere, outside boxes predominate.

With respect to the ratio between the amounts of cross-equalization and side-equalization, it is probable that the need for cross-equalization has been somewhat overemphasized in the past. The object of cross-equalization is to prevent a wide difference in the vertical loads under the two wheels of a given axle. But field tests have shown that cross-equalization of itself is unable to achieve this objective. Field tests indicate that for a locomotive with the customary amount of cross-equalization the vertical loads under the two wheels on the same axle vary the greatest under the condition of nosing. The prevention of nosing, then, should accomplish more toward equalizing vertical loads than does cross-equalization, and nosing is prevented not by cross-equalization but by side-equalization which, by influencing the frequency of roll, raises the critical speed.

From the standpoint, then, of critical speed and rail loads, the equalization system (1) should employ relatively soft leaf springs in series with stiff coil springs directly over the boxes, (2) the lateral distance between springs should be made large by placing the journal boxes outside the drivers if possible, and (3) the amount of side-equalization should be a maximum, and, if cross-equalization is insisted upon, restrict its amount to 25 per cent or less of the sprung weight.

Weight of Spring-Borne Parts

To determine the influence on critical speed, the absolute weight of the spring-borne parts must be considered in conjunction with the height of the center of gravity above the axle and the stiffness of the equalization springs. The weight of the spring-borne parts influences critical speed by influencing the frequency of roll. However, for a given center of gravity, the weight of the spring-borne parts may be varied at will without changing the critical speed provided the stiffness of the equalization springs is also varied. The spring-borne parts may thus be said to exert a neutral influence so far as critical speed is concerned. Furthermore, the weight of spring-borne parts is one of the design features that can be varied only within rather narrow limits when once the general characteristics of the locomotive have been determined. Hence, it becomes apparent that a varia-

tion of the sprung weight may as well be left out of consideration in the search for means of raising the critical speed.

Location of Center of Gravity of Spring-Borne Parts

The location of the center of gravity of the sprung mass is a most important factor in determining the critical speed, but like the absolute weight of the sprung mass, it is a design feature which can be varied only within exceedingly small limits for a locomotive with prescribed characteristics. Any consideration of the location of the center of gravity of the sprung mass is thus nonessential in the search for means for raising the critical speed. The higher the center of gravity of the spring-borne parts, the lower becomes the frequency of roll and the lower the critical speed. But, what can be done about it?

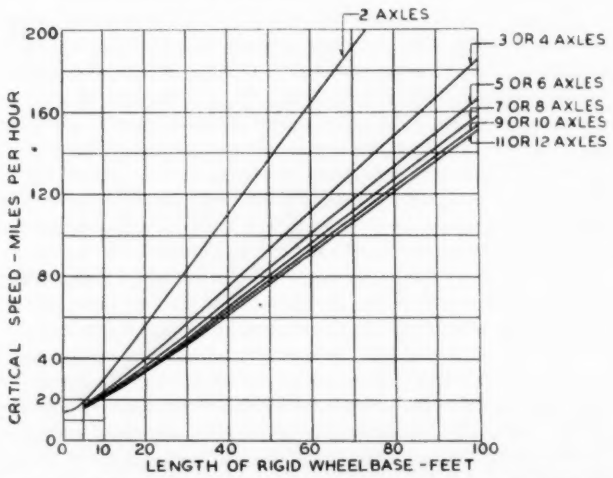

Fig. 8 Effect of the Length of a Rigid Wheel Base on Critical Speed for Various Numbers of Equally Spaced Axles Calculated From Equation [9], $f = 1.0$

The center of gravity of the sprung parts of an electric locomotive is usually somewhat lower than that for a steam locomotive. This lower center of gravity for the electric locomotive is frequently considered a disadvantage, but an analysis of the influence of the center of gravity on locomotive performance does not justify this belief. To determine the tendency from raising or lowering the center of gravity, let us assume extreme conditions. Assume first that the center of gravity is very high above the rail. For this condition the frequency of roll would be very low with a corresponding low critical speed, also a very small amount of roll would throw all of the weight on one rail and bring the center of gravity outside the gage, thus causing the locomotive to tip over. Now, assume that the center of gravity is on line with the center line of the axle. For this condition a lateral force would produce an unbalance of vertical loads at the rail, but this motion of the sprung mass would be purely rotational with no roll at all at the center of gravity. Hence, there would be no lateral translation of the center of gravity and, therefore, for this condition, lateral oscillations would be impossible because lateral translation of the sprung mass is absolutely necessary if the lateral oscillations are to be sustained. Finally, assume that the center of gravity is on line with the rail. For this condition, there is lateral rolling and lateral oscillations are possible but lateral forces now produce no change in the vertical wheel loads at the rail. Thus, the center of gravity of the sprung mass, from a consideration of lateral oscillations, should be located on the center line of the axle, but from a consideration of the unbalance of vertical loads at the rail, the center of gravity should be on line with the rail; that is, it should be in the plane in which the lateral force reacts on the locomotive. The conclusion is reached then that lateral oscillations would be impossible and there would be no unbalance in rail loads from lateral forces if the center of gravity of the sprung mass and the reaction on the locomotive from lateral forces both occurred at the center line of the axle.

For the conventional locomotive, the location of the center of gravity of the sprung mass is practically beyond the control of the designer. However, if possible to do so, move the center of gravity downward, not upward. Lowering the center of gravity raises the critical speed and decreases the amount of vertical-load unbalance at the rail. The lower center of gravity of the electric locomotive, as compared to the steam locomotive, is a distinct advantage.

Wheel Base

The length of the rigid wheel base is the most important design feature influencing critical speed. It has been stated by various writers in the past that a high-speed locomotive should have a long rigid wheel base, but the reason for this requirement has hitherto been unknown. This reason is revealed by an inspection of Equations [18] and [19] which are the equations for energy input and frictional losses during oscillations. These equations show that lengthening the rigid wheel base decreases the available energy input for sustaining oscillations and at the same time increases the frictional losses for damping them out. Hence, a long rigid wheel base becomes the principal requisite for every high-speed locomotive. The effect of increasing the length of the rigid wheel base is illustrated in Fig. 8.

Guiding Trucks

With the exception of the permanently rigid wheel base, the guiding trucks become the most important design feature determining critical speed. The guiding trucks determine critical speed because of their influence on the length of the rigid wheel base. The importance of guiding-truck design is best illustrated by considering two extreme values for the force necessary to produced initial lateral displacement of the truck, commonly known as truck crack-off.

Assume, first, that the crack-off is 10 per cent of the bolster load. For a truck with the usual amount of weight below the center pin, this would represent a lateral force at the rail of about 8.75 per cent of the vertical rail load. For truck wheels, with no tractive effort, the coefficient of friction against lateral slippage at the rail is considerably greater than 8.75 per cent for all normal operating conditions. This means it is possible to swing the truck bolster laterally without sliding the truck wheels. If the locomotive starts to oscillate laterally, the truck bolster will swing laterally within the truck frame without offering any damping force against the oscillations unless the guiding characteristic is so steep that the rail coefficient of friction against lateral slippage is exceeded during part of the oscillation cycle. The reason the lateral swing of the bolster offers no damping resistance is because the energy loss of the sprung weight in overcoming the truck resistance from central position to the extreme swing is immediately restored on the return swing so that the net effect is zero.

Assume now that the truck crack-off is 40 per cent of the bolster load. This represents a lateral force at the rail of about $35^1/_2$ per cent of the vertical rail load. A lateral force of this magnitude at the rail should be capable of sliding the truck wheels laterally across the head of the rail against the highest coefficient of friction that might be expected with the locomotive at speed. Experiments indicate that the coefficient of friction against the lateral sliding of a wheel in motion decreases with speed. Hence, a lateral force at the rail equal to $35^1/_2$ per cent of the vertical rail load should cause the wheels to slide laterally even at quite a

low speed. If the locomotive oscillates laterally, the truck wheels are slipped laterally across the rail head thus introducing an enormous damping force. So far as lateral oscillations are concerned, it is thus seen that a guiding truck with a crack-off high enough to slide the truck wheels laterally across the rail has the effect of lengthening the rigid wheel base to the truck center pin.

It is customary to design electric locomotives for two-way operation. Practically, though not necessarily, the specification for two-way operation demands a symmetrical-type locomotive. It is usual, then, for electric locomotives to have identical guiding trucks at both ends. From the standpoint of providing a turning moment on curves, this arrangement is more effective than might appear at first sight. The location of the center of rotation of a locomotive rigid wheel base is always such as to make the lever arm of the leading truck, with respect to the driver against the inner rail, longer than the corresponding lever arm of the trailing truck. This difference in lever arms produces a net guiding moment even for the condition in which both guiding trucks have the same amount of guiding, which is the case for trucks of the constant-resistance type. Therefore, it is evident that for electric locomotives it is possible to extend the rigid wheel base from truck center pin to truck center pin by employing trucks at both ends with a crack-off, with respect to the rail, greater than the lateral coefficient of friction without sacrificing adequate guiding for curves. If this initial crack-off resistance is too high for operation on sharp curves it is possible to give the truck restraint a drooping characteristic.

It is thus seen that a high-restraint truck possesses very great value as a means of extending the rigid wheel base, but this advantage of high restraint has been shown by experience to be virtually lost if the truck is free to swivel about its center pin, as is usually the case with four-wheel engine trucks. When free to swivel, the truck itself goes through an oscillation similar to that of the main wheel base and consequently runs back and forth through the track clearance without much sliding friction. This freedom of a four-wheel truck to run back and forth without sliding can be prevented by the application of an antiswiveling device such as a radius bar. To limit the flange pressures on extremely sharp curves and turnouts, the restraint of the radius bar on a four-wheel truck should be limited so that it becomes possible for the truck to swivel when its swiveling torque reaches some selected value.

In Equation [9] it is assumed that all axles have the same loading. If this is not the case, then the term $\sqrt{[x_i^2 + (s/2)^2]}$ for each axle must be given a weighting factor equal to the ratio between its actual load and the average load for all the axles being considered, and the symbol n instead of representing the actual number of axles represents the sum of the weighting factors. Letting k represent the weighting factor, Equation [9] may be written

$$V_{cr} = 8f\left[\frac{k_1\sqrt{[x_1^2 + (s/2)^2]} + k_2\sqrt{[x_2^2 + (s/2)^2]} + \ldots.}{k_1 + k_2 + \ldots\ldots\ldots}\right] \quad \ldots\ldots\ldots [20]$$

Since the expression $\sqrt{[x_i^2 + (s/2)^2]}$ increases in value with the increase in distance from the center of rotation, it follows that the heavier the axles at the ends of the locomotive, the higher becomes the critical speed. Since the end axles on a locomotive are usually truck axles, this means that the trucks should carry as much of the total load as is possible, considering wheel-load limitations and the weight requirements of the drivers for adhesion. The influence of changing the ratio between driver load and truck load is illustrated by curves A and B of Fig. 9. Another method for increasing the equivalent rigid wheel base of a locomotive is to give unrestrained lateral play to the intermediate axles of a rigid wheel base.[9] Unrestrained lateral play eliminates both the input and the loss from these axles. Since the input from an axle is fixed regardless of its position in the wheel base, and its loss is proportional to its distance from the center of rotation, this arrangement produces a considerable increase in the critical speed. The magnitude of the increase in critical speed, for a particular locomotive, by the use of unrestrained lateral is illustrated by a comparison between curves A and B of Fig. 9. In this figure, curve B represents the critical speed for a locomotive having the wheel arrangement as shown and for the condition of no free

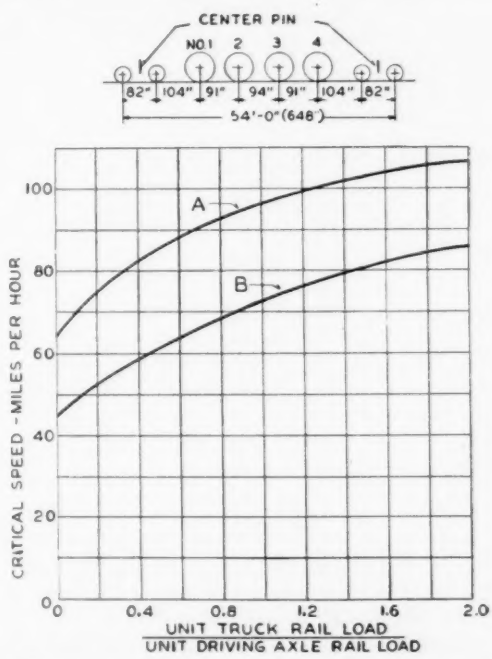

FIG. 9 EFFECT OF WEIGHT DISTRIBUTION ON CRITICAL SPEED CALCULATED FROM EQUATION [20], $f = 1.0$
(Curve A—Unrestrained lateral play at second and third drivers, Curve B—Normal minimum lateral play at all axles.)

lateral, while curve A represents the critical speed for the condition of unrestrained lateral in driving axles No. 2 and No. 3.

RAIL LOAD

The absolute value of the rail load is not a factor in determining critical speed. The axle loading influences critical speed only to the extent that the weight of the sprung mass influences the frequency of roll.

GYROSCOPIC ACTION

The revolving wheels and axles of a locomotive give rise to gyroscopic forces whenever their axes are subjected to angular rotation. On an electric locomotive, the motor armatures constitute additional rotating masses to those of the wheels and axles.

A rotating mass which is part of the deadweight does not have any gyroscopic effect whatever on the oscillations described in this report. The rotation of the wheel base α may cause a shifting of load from one side to the other, but there can be no rolling oscillation of the deadweight, so the shifting of load does not result in an oscillation.

Spring-borne motors in an electric locomotive, however, can affect the oscillation because the rotation α of the wheel base causes the motors to exert gyroscopic forces which aid the rolling of the cab. Calculations show the magnitude of this effect to be small.

[9] Suggested to the authors by B. S. Cain.

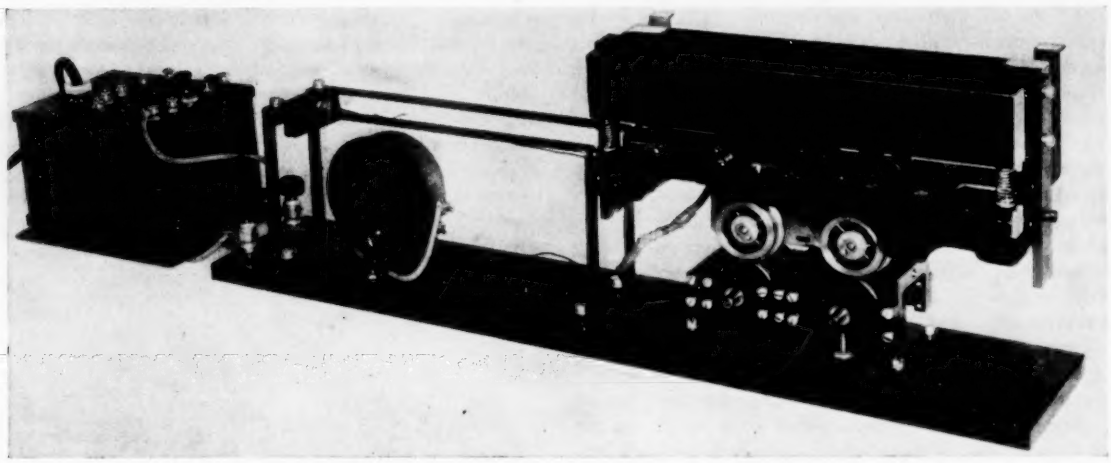

FIG. 10 MODEL FOR ILLUSTRATING LATERAL OSCILLATIONS

RAIL AND TIRE CONTOUR

There has been discussion in the past concerning the effect of conical wheel treads on locomotive and car performance. In this paper, the coning of the wheel tread is not considered and the wheel is treated as having a tread that is a true cylinder. No matter what the contour may be on leaving the shop, under service conditions, the tread surface quickly conforms to the contour of the rail head.

TRACK CLEARANCE

It is very important to keep the track clearance as small as possible. Although this quantity does not appear directly in the formula for critical speed, it does appear in the expressions for energy input and energy loss, both of which are directly proportional to track clearance δ. Therefore, at speeds above the critical, the larger the clearance the larger the amount of energy available to sustain and increase the oscillation. Thus, when the clearance is large there is less possibility of the spring friction being sufficient to control the oscillation.

Probably the most serious result of large track clearance is not shown by the equations, that is, its effect on the magnitude of the rail forces. The amplitude of the leading axle is equal to the track clearance. In any oscillation, velocity and acceleration increase proportionately to amplitude, and therefore the flange pressure increases in proportion to the track clearance, since it is the flange pressure that produces the lateral acceleration.

Therefore the smaller the track clearance the less the possibility of sustained oscillations and the less the damage they can do to the track if they do start. For the condition of zero track clearance, oscillations of the type discussed in this paper become impossible.

COEFFICIENT OF FRICTION

The effect of a low coefficient of friction is twofold. First, it lowers both the input and the loss energies and thus decreases the energy available to sustain oscillations. At the same time, however, it decreases the disturbance necessary to start sustained oscillation and thus makes the vehicle less stable. A low coefficient of friction against lateral slippage may be produced by wet rails or high tractive effort.[10] A very high coefficient of friction may be found in rubber-tired rail vehicles, which have recently been tried out.

4—MODEL TESTS

In order to bring experimental evidence to bear upon the conclusions drawn from the theory without going at once to the expense of making tests on actual locomotives, a small model was constructed.

The critical speed of a model rail vehicle, according to Equation [9], is proportional to the natural frequency of roll of the sprung weight and the linear dimensions of the model. Therefore, if the natural frequency were made the same as that of a full-scale locomotive, the critical speed would be reduced in the same ratio as the scale of the model, and oscillations would occur at easily obtainable speeds.

An illustration of the model used is shown in Fig. 10. The first trials showed that it was not practical to run the model on a track. The track could not easily be made smooth enough nor the straight stretches long enough. Also, the forward motion of the model along the track made it difficult to study the lateral oscillations in detail. It was found that a much better arrangement was obtained by mounting the model on rollers. The model was restrained from longitudinal motion by a wire similar to a drawbar.

The model contained all the parts which, according to the theory, were necessary for the existence of lateral oscillations. It had two axles, both driven through gears by a single motor, and both mounted in the same rigid frame. It had a sprung weight supported from the frame by four helical springs, one at each corner. The center of roll of the sprung weight was made to coincide with the height of the axles by means of a pin and clevis arrangement at each end. The model had a wheel gage of $1^1/_4$ in., a wheel base of $2^5/_{16}$ in., a total length of 9 in., an unsprung weight of 2.6 lb, a sprung weight of 9.5 lb, a natural period of roll of 0.6 sec, and a critical speed of 1.9 fps.

The wheels had flanges and cylindrical treads. The rollers consisted of two cylinders, one under each axle. Each cylinder had two beads spaced $1^1/_4$ in. center to center for the wheel treads to run on and the flanges to bear against. These beads represented the rails. In order to equalize the weight on the four wheels, one roller was mounted on trunions.

The speed of rotation of the wheels, which represented the forward velocity of the model, could be varied by changing the voltage supplied to the motor. By the use of a rheostat any speed up to about 7 fps could be obtained.

OBSERVED OSCILLATIONS

At speeds above 3 fps a rolling oscillation started by hand be-

came self-sustaining and was accompanied by lateral oscillations of the running gear at the same frequency. At speeds below 3 fps the oscillation would die out. It died out quickly at very low speeds but more and more gradually as the speed was increased. Therefore, 3 fps was the actual critical speed. This was higher than the calculated value of 1.9 fps, but this discrepancy was to be expected due to the various frictional losses in the mechanism not considered in the theory.

It was observed that the oscillation of the model was of the same nature as that predicted by the theory, but no exact comparison could be made by mere visual observation. In order to study the motion quantitatively and in detail, a motion-picture camera was used.

There were four points where the motion had to be measured. They were at the front and the back of the sprung and the unsprung weights. The camera was placed so as to look directly down on the model. The four points in which the authors were interested were brought into the same focal plane by bringing up extensions from each end of the unsprung frame to the level of the top of the sprung weight. Spots of white paint located the four points to be observed. Pictures were taken at the rate of about 30 per second, which gave a sufficient number of readings during the 0.6 second period of the oscillation to enable the authors to plot the curves of the motion. The time scale was determined by placing a stop watch in the picture alongside the model. Fig. 11 shows a portion of a strip of pictures from which readings were taken.

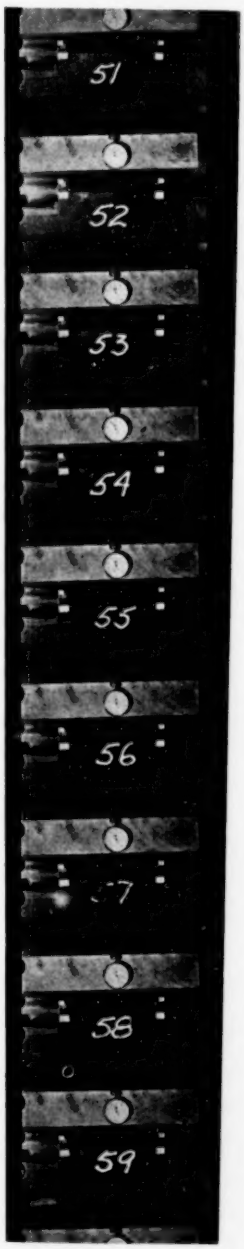

FIG. 11 SECTION OF MOTION-PICTURE FILM OF MODEL DURING OSCILLATION

The motions observed were (*a*) lateral motion of the front of the unsprung weight, (*b*) lateral motion of the rear of the unsprung weight, (*c*) lateral motion of the front of the sprung weight at the top of the model, and (*d*) lateral motion of the rear of the sprung weight at the top of the model. By means of these directly measured values, it was possible to derive (*e*) lateral motion of the top of the model due to roll by subtracting (*a*) from (*c*) or (*b*) from (*d*); (*f*) angularity of the wheel base α by subtracting (*b*) from (*a*) and dividing the result by the length of the model; (*g*) lateral motion of the center of rotation, which was approximately $\frac{1}{2}[(a) + (b)]$.

The primary motions are (*a*), (*b*), (*e*), (*f*), and (*g*). These five motions are plotted for one representative cycle in Fig. 12. It is interesting to note how well the experimental results check with the theory. The theoretical values of motions (*a*), (*b*), (*f*), and (*g*) are shown in Fig. 12 along with the experimental results. Motion (*e*), the roll, was not correctly represented by the model as far as its amplitude was concerned because the theoretical value greatly exceeded the solid position of the springs. The other motions, however, show a remarkably good check between theory and experiment. Note that the lateral slippage of the wheel base occurring at

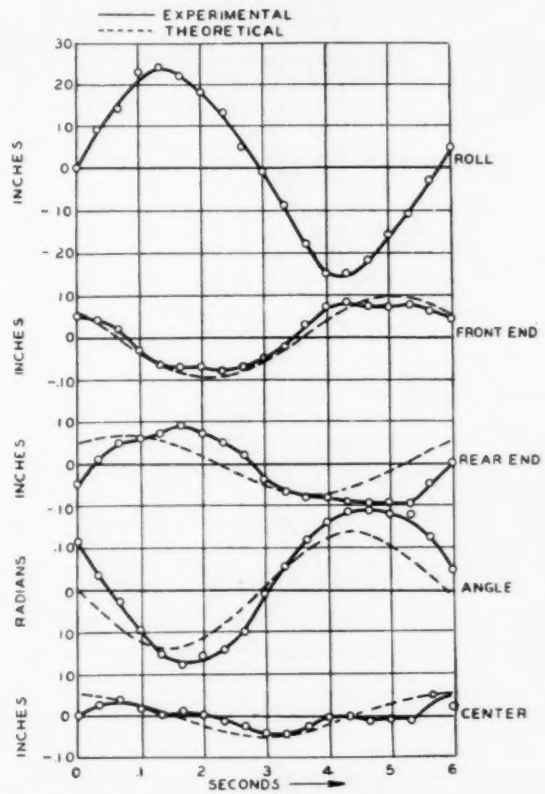

FIG. 12 LATERAL OSCILLATIONS OF LOCOMOTIVE MODEL

the instant of maximum roll shows up quite plainly in the experimental curves. This slippage was not considered in calculating the theoretical curves.

Other tests on the model showed that the critical speed was proportional to the frequency of the oscillation, as predicted by the theory.

5—CONCLUSIONS

In this paper the authors have offered a mathematical theory which explains the self-sustained lateral oscillations of rail vehicles. The formulas derived from this mathematical analysis check with all available experimental data.

The conclusions to which the theory leads may be summarized as follows:

1 For satisfactory operation at high speed, a rail vehicle should have a critical speed, as calculated from Equation [9], no lower than its highest operating speed.

2 Recommended tendencies in design are: (*a*) as high a natural frequency of roll as is possible without sacrificing adequate vertical resiliency; (*b*) a long rigid wheel base; (*c*) high-resistance guiding trucks with limited swivel restraint. This applies to four-wheel trucks; two-wheel trucks are inherently nonswiveling; (*d*) loads concentrated as much as feasible on the end axles; (*e*) unrestrained lateral motion in axles near the center of the wheel base.

3 Recommended tendencies in track maintenance include:

(*a*) the elimination of irregularities. (*b*) The narrowing of the gage to decrease the clearance between flange and rail.

There are three factors to be considered in determining whether or not the performance of a vehicle will be satisfactory in a given service. These factors are (1) the inherent critical speed of the vehicle, (2) the maximum speed at which it will operate, and (3) the condition of the track. For the most satisfactory operation, the calculated critical speed should be well above the operating range, say 30 per cent above the maximum speed. The vehicle should then operate safely on ordinary track. For track that is better than ordinary, the ratio between critical and operating speed may be reduced. On perfect track, any vehicle can operate at any speed. However, it is not safe to rely entirely on a good track condition to maintain satisfactory operation, since the best of track may develop an occasional rough spot.

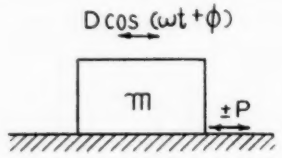

FIG. 13

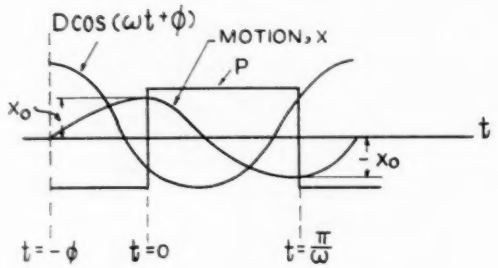

FIG. 14

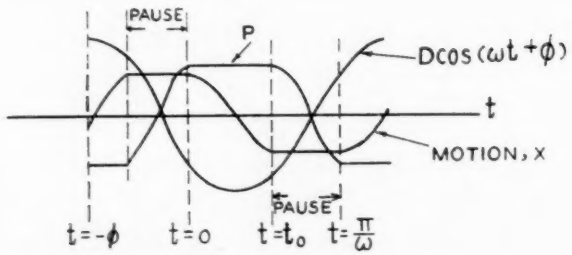

FIG. 15

The design of railway vehicles becomes of increasing importance with every increase in the speed of railway trains because the higher the train speed the greater becomes the effect on vehicle performance from track irregularities. However, in so far as self-sustained oscillations are concerned, it is believed that with proper vehicle design and with good track maintenance, it will be possible, with safety, to appreciably increase train speed above the general level now prevailing.

Appendix 1

Lateral Sliding of Wheels Due to Rolling of Body

The amount of lateral sliding of the wheel base which can be produced by the rolling of the cab may be calculated if the problem is simplified to that shown in Fig. 13. Here a mass m representing the total mass of the vehicle, is resting on a surface which resists any horizontal motion of the mass with a force P. A reciprocating force $D \cos(\omega t + \phi)$, representing the inertia force of the body, is applied to the mass. What is the motion of the mass m for various values of the ratio D/P?

Obviously, if $D/P < 1$ there is no motion at all. If D/P is slightly greater than unity there will be an intermittent motion with a pause during each half cycle. If D/P becomes quite large, the mass can be conceived as having a continuous reciprocating motion with no pauses.

First consider the case where the motion is continuous, Fig. 14. If x is the displacement of the mass m from its mean position, the equilibrium conditions for the mass during its motion in one direction can be expressed as

$$m(d^2x/dt^2) - P = D\cos(\omega t + \phi)$$
$$\text{or, } d^2x/dt^2 = P/m + (D/m)\cos(\omega t + \phi) \ldots [a]$$

Integrating

$$dx/dt = Ft/m + (D/m\omega) \sin(\omega t + \phi) + C' \ldots\ldots [b]$$

Integrating again

$$x = Ft^2/2m - (D/m\omega^2) \cos(\omega t + \phi) + C't + C'' \ldots [c]$$

The following conditions are known: When $t = 0$

$$x = x_0, \text{ and } dx/dt = 0 \ldots [d]$$

and when $t = \pi/\omega$

$$x = -x_0, \text{ and } dx/dt = 0 \ldots [e]$$

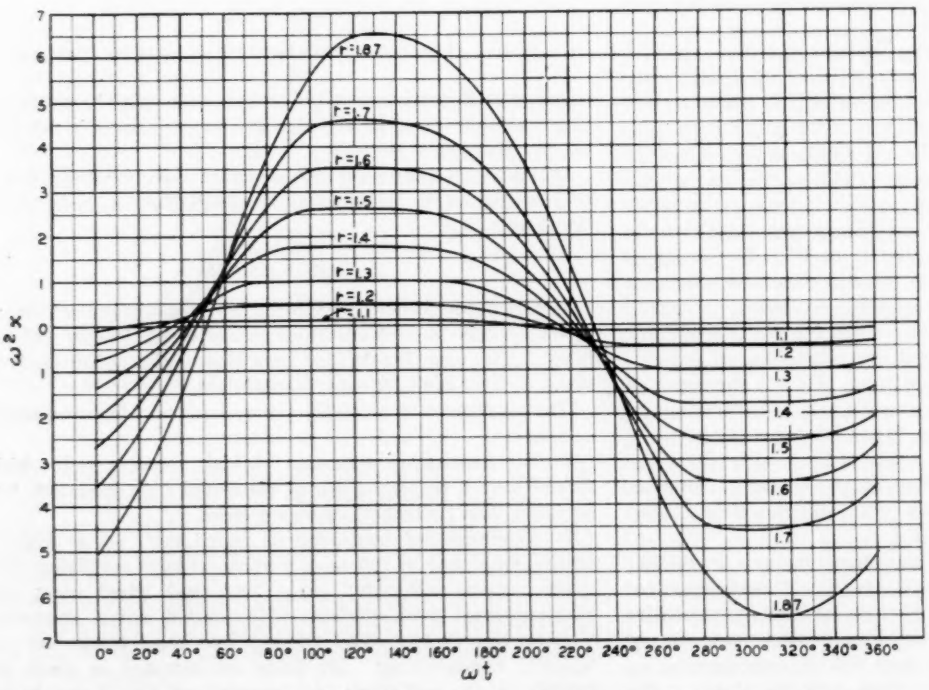

FIG. 16 LATERAL SLIDING OF A MASS (VEHICLE) ON A DRY SURFACE (RAIL) UNDER THE ACTION OF A HARMONIC FORCE (ROLL OF SPRUNG MASS)
(r = maximum exciting force/friction force.)

By using Equation [b] and condition [d], C' may be solved for, whence

$$C' = -(D/m\omega) \sin \phi \quad \ldots\ldots [f]$$

By using Equation [c] and condition [d], C'' may be solved for, whence

$$C'' = x_0 + (D/m\omega^2) \cos \phi \quad \ldots\ldots [g]$$

By using Equations [b] and [f] and condition [e] we can obtain

$$\sin \phi = P\pi/2D \quad \ldots\ldots [h]$$

By using Equations [c], [f], [g], and [h] and condition [e] we may solve for x and obtain the final solution

$$x = \frac{Pt}{2m}\left(t - \frac{\pi}{\omega}\right) + \frac{P}{2m\omega^2}\left(\sqrt{\frac{4D^2}{P^2} - \pi^2}\cos \omega t + \pi \sin \omega t\right) \quad \ldots\ldots [i]$$

Now consider the case where the motion is intermittent, Fig. 15. During motion of the mass in one direction Equations [a], [b], and [c] still hold. However, the end conditions now, when $t = 0$, are

$$x = x_0,\ dx/dt = 0, \text{ and } d^2x/dt^2 = 0 \quad \ldots\ldots [j]$$

and when $t = t_0$

$$x = -x_0, \text{ and } dx/dt = 0 \quad \ldots\ldots [k]$$

We find that our values of C' and C'' are the same as before and are given by Equations [f] and [g]. By using Equation [a] and condition [j] we find that

$$\cos \phi = -P/D \quad \ldots\ldots [l]$$

Now substitute condition [k] into Equation [b], using the known values of the constants for which we have already solved. We obtain

$$\omega t_0 - \sin \omega t_0 + \sqrt{(D^2/P^2) - 1}\,(\cos \omega t_0 - 1) = 0 \quad \ldots [m]$$

Using the same procedure with Equation [c] instead of [b] we obtain

$$x_0 = \frac{t_0}{2m\omega}\sqrt{D^2 - P^2} - \frac{Pt_0^2}{4m} - \frac{P}{2m\omega^2}\left(\cos \omega t_0 + \sqrt{\frac{D^2}{P^2} - 1}\sin \omega t_0 - 1\right) \quad \ldots\ldots [n]$$

The procedure should now be to solve [m] for t_0, substitute the value obtained into Equation [n], and assume that all of our unknown constants had been evaluated. Unfortunately, however, Equation [m] cannot be solved explicitly for t_0, so the best analytical solution we can give is that

$$x = \frac{Pt}{2m}\left(t - \frac{2}{\omega}\sqrt{\frac{D^2}{P^2} - 1}\right) + \frac{P}{m\omega^2}\left(\cos \omega t - 1 + \sqrt{\frac{D^2}{P^2} - 1}\sin \omega t\right) + x_0 \quad \ldots\ldots [o]$$

where x_0 is given by Equations [n] and [m].

For any practical problem, however, the solution can be completed graphically. This has been done for several values of the ratio D/P, and the results are shown in Fig. 16. This chart may be used to find the lateral sliding of the wheel base for any D/P ratio, and no use need be made of the equation given in this Appendix.

It is of interest to know the value of D/P at which the motion changes from intermittent to continuous. This may be found by putting $\omega t_0 = \pi$ in Equation [m]. Solving for D/P we find

$$D/P = (1/2)\sqrt{(\pi^2 + 4)} = 1.87 \quad \ldots\ldots [h]$$

Appendix 2

Values of $\sqrt{[x_i^2 + (s/2)^2]}$ for use in applying Equation [9]

x_i	$\sqrt{x_i^2+(s/2)^2}$	$\sqrt{x_i^2+(s/2)^2} - x_i$	x_i	$\sqrt{x_i^2+(s/2)^2}$	$\sqrt{x_i^2+(s/2)^2} - x_i$	x_i	$\sqrt{x_i^2+(s/2)^2}$	$\sqrt{x_i^2+(s/2)^2} - x_i$	x_i	$\sqrt{x_i^2+(s/2)^2}$	$\sqrt{x_i^2+(s/2)^2} - x_i$

Appendix 3

Effect of Nonsinusoidal Lateral Motion of Wheel Base

The theory described in this paper assumes that all displacements, velocities, and accelerations vary harmonically. This assumption is reasonable for the motions of the sprung weight on its supporting springs, since the scales of the springs are linear and the predominating forces are spring forces and inertia forces. Also, accelerometer records taken in the cabs of oscillating locomotives appear sinusoidal, which shows that the velocities and displacements must have been very close to following pure sine waves. The unsprung mass, however, has its lateral motion resisted partly by friction and partly by flange pressure, the latter coming into play only near the maximum displacement positions. Therefore, it cannot be assumed that the lateral motions of the unsprung mass will be harmonic. Let us determine the effect that nonharmonic motion will have on the theory.

At the critical speed, the energy input per cycle is

$$4\int_0^{\pi/2\omega} 4\mu QV\alpha dt = 16\mu QV\int_0^{\pi/2\omega} \alpha dt \ldots\ldots [a]$$

The energy loss per cycle is

$$8BA\mu Q \ldots\ldots [b]$$

Equating input to loss and solving for V, we obtain

$$V_{cr} = BA/2\int_0^{\pi/2\omega} \alpha dt \ldots\ldots [c]$$

The determination of the critical speed is thus dependent on the determination of an expression for α as a function of t. If, as a first approximation we take $\alpha = A\cos\omega t$, as done before, we obtain

$$V_{cr} = 2B\omega/\pi \ldots\ldots [d]$$

Consider that α is some function other than $A\cos\omega t$. The turning action on the vehicle comes from the flanges, which act during only a portion of each cycle. Therefore, the angularity may change rather quickly, remain constant, and then change back again. The angularity α plotted against the time t Fig. 17 will be a sine wave flattened at the peaks. The limit of such a tendency is the square wave form, Fig. 17, which could not exist, but is a limit which could be approached. It represents the most unfavorable condition because it produces the largest possible value of input.

If the wave form of α were square, then α would be constant and equal to $\pm A$ during each half cycle. Substituting A for α in Equation [c] of this Appendix, we obtain

$$V_{cr} = B\omega/2 \ldots\ldots [e]$$

If the wave form of the variation of α were sharper at the peaks than a sine wave, then the input would be smaller and the critical speed would be higher. However, this is too favorable an assumption. If the tendency exists at all it comes as a result of the speed and flange pressure being too small to turn the locomotive fast enough. High speeds and severe oscillations both tend to produce the square rather than the pointed wave form.

As a result of the foregoing analysis we find that the critical-speed theory advanced in this paper no longer depends on the

assumption of sinusoidal motion. If the motion of the wheel base is not sinusoidal, the critical speed may be reduced by the factor $\pi/4$ or 0.785 as the limit.

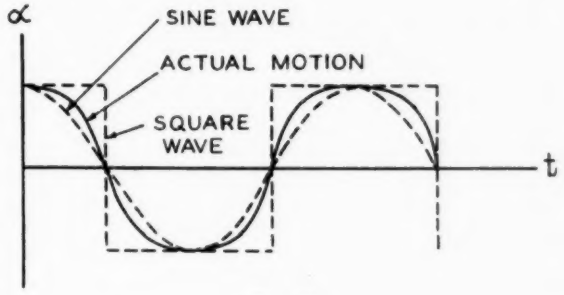

FIG. 17

Appendix 4

NOMENCLATURE AND IMPORTANT EQUATIONS

α = the variable angle between the center line of the vehicle and the center line of the track
A = the peak value of α during a cycle of the oscillation
B = the wheel base of a vehicle
b = the lateral distance between the springs supporting the sprung weight of a rail vehicle
C' and C'' = constants of integration
c = track damping constant
D = disturbing force (see Appendix 1)
d = lateral displacement of the center of gravity of the sprung weight relative to the unsprung weight due to roll
f = natural frequency of roll of a vehicle
G = the lateral component of the friction force at the tread which opposes rotation of the wheel base
h = height of the center of gravity of the sprung mass above the center line of the axle
I_r = the polar moment of inertia of the sprung weight about a longitudinal axis through the axle centers
J = the polar moment of inertia of a vehicle about a vertical axis through the center of gravity
i = a general subscript designating the i-th axle of a wheel base
K_s = the spring scale for one side of a vehicle, neglecting cross-equalized springs
K = the lateral spring scale of a vehicle
k = axle load/average axle load
M = the mass of the sprung weight of a vehicle
μ = the coefficient of friction
n = the number of axles in a wheel base
ϕ = the phase angle between the lateral slippage of the wheel base and the rolling of the sprung weight (see Appendix 1)
P = the frictional resistance to the lateral slippage of the wheel base (see Appendix 1)
Q = static wheel load
s = track gage
δ = half the maximum lateral amplitude of the wheel base allowed by the track and bearing clearances
θ_i = phase angle of motion of i-th axle referred to phase of center of rotation
t = time
V = the forward velocity of the vehicle
ω = 2π times the frequency of the oscillation
W = the sprung weight of a vehicle
x = lateral slippage of wheel base due to roll of body (see Appendix 1)
x_i = the longitudinal distance between the i-th axle and the center of rotation
x_1 = same for the first axle
Y = the flange pressure on an axle
y = lateral translation of a vehicle.

Natural frequency of roll

$$f = [1/2\pi]\ \sqrt{[(K_s b^2 - 2Wh)/2I_r]} \quad \ldots\ldots [10]$$

Angularity of wheel base

$$A = \delta\omega \cos\theta_1/V = \delta\omega/\sqrt{(x_1^2\omega^2 + V^2)} \quad \ldots [14] \text{ and } [16]$$

Amplitude of lateral translation of wheel base

$$2y = 2VA/\omega \quad \ldots\ldots [11]$$

Total amplitude of the i-th axle

$$= 2VA/\omega \cos\theta_i \quad \ldots\ldots [12]$$

Input per cycle

$$= 2\pi n\mu QV\delta/\sqrt{(x_1^2\omega^2 + V^2)} \quad \ldots\ldots [18]$$

Loss per cycle

$$= [8\mu Q\omega\delta/\sqrt{(x_1^2\omega^2 + V^2)}] \sum_{i=n}^{i=1} \sqrt{[x_i^2 + (s/2)^2]} \quad \ldots [19]$$

Critical speed

$$V_{cr} = [8f/n] \sum_{i=n}^{i=1} \sqrt{[x_{i1}^2 + (s/2)^2]} \quad \ldots\ldots [9]$$

Critical speed for nonuniform axle load

$$V_{cr} = 8f\left[\frac{k_1\sqrt{[x_1^2 + (s/2)^2]} + k_2\sqrt{[x_2^2 + (s/2)^2]} + \ldots}{k_1 + k_2 + \ldots\ldots}\right] \ldots [20]$$

Measurement of Steam Rate and Indicated Horsepower of Locomotives

By ARTHUR WILLIAMS,[1] EAST CHICAGO, IND.

It has been the customary procedure to determine the steam rate and indicated horsepower of locomotives and other reciprocating steam engines from indicator cards. This paper points out that particularly at high locomotive speeds, the obtainment of indicator cards is subject to gross errors, and that the expense of rigging up for such tests is hardly warranted by the results that can be expected. The paper discusses in detail another method of determining the steam rate and indicated horsepower of a locomotive, which other writers have referred to as the "heat-drop method." The paper proves both the simplicity of the method as well as its relative accuracy. The method is applicable to such locomotives only in which the exhaust steam is at least dry, and only in the absence of moisture, the Btu contents per pound of both admitted and exhausted steam can be accurately determined through pressure and temperature measurement. The paper contains detailed suggestions for successfully applying the method on the locomotive. Thus it contains data on the construction and location of the thermocouples, and the manner in which these thermocouples are applied and wired up to the instrument with which the pyroelectric force is determined. The results of the tests carried out with this method on two different locomotives, are presented in the paper and, in general, it is shown what advantages this simple method has for the test and analysis of all those design factors or devices which are liable to affect the steam rate of a locomotive.

Toward the conclusion of the paper, reference is made to a suggestion by L. K. Botteron, which appeared in the *Railway Mechanical Engineer* of July, 1930, to the effect that the exhaust nozzle of a locomotive could be considered a flowmeter nozzle for the determination of the quantity of steam that the locomotive exhausts. The paper proceeds to show how the specific volume and velocity of the steam, while passing through the mouth of the locomotive exhaust tip (which quantities are essential for the Botteron method), are derived from the exhaust-steam temperature and pressure measurements that are incidental to the carrying out of the heat-drop determination.

THE overall efficiency of a locomotive may be divided into three parts: The engine or cylinder efficiency, the boiler-combustion efficiency, and the machine efficiency. A measure of the cylinder efficiency is the steam rate, or steam consumption per indicated horsepower-hour. In the past this has been determined by measuring the indicated horsepower, and the steam to the engines, and dividing the second by the first. It is somewhat difficult on a road test to determine these values accurately. The indicated horsepower can be calculated when the mean effective pressure in the cylinders and the speed are known. The mean effective pressure in the cylinders is found by means of an indicator. The accuracy of the indicator depends in the first place upon the accuracy of the reducing motion from the crosshead to the indicator drum, the pencil motion on the indicator, the spring, and the area of the piston. With careful workmanship and calibration these errors can be made fairly small. It is more difficult, particularly at high speeds, to guard against errors due to the inertia of the moving parts and vibration of the apparatus.

Having obtained the mean effective pressure it is necessary to know the speed in order to calculate the indicated horsepower. A speed indicator is again a source of error, and if speeds are obtained by taking the time between mileposts the speed at the time at which the indicator card is taken may be different from the average time between mileposts.

The next step in the calculation of the steam rate is to measure the steam to the engines. This is usually done by measuring the water fed to the boiler from the tender tank and subtracting the steam to the auxiliaries, such as the air compressor, boiler feed pump, stoker, steam used for heating the train, or for other train services, and the steam wasted from the safety valve, injector overflow, and blower. Errors arise, of course, in the measurement or calculation of each of these quantities.

Since the accurate measurement of the steam rate depends upon the accurate measurement of the mean effective pressure, speed, boiler evaporation, steam to auxiliaries, and steam wasted, it can readily be seen that the correct determination of the steam rate on a road test, using the test procedure outlined, is difficult. The suggestion has been made[2] that the steam rate be determined by means of the observation of the difference in heat content of the steam in the steam pipe and the exhaust. It is the purpose of this paper to show that, with reasonable precautions this can be done on most locomotives with good accuracy and far less trouble than by using the indicator.

Theory of Measurement

The first law of thermodynamics states that "heat and mechanical energy are interconvertible and can neither be created nor destroyed. For steady-flow conditions, such as are obtained with an engine, it follows that "For any prime mover operating under these conditions the energy delivered by this apparatus in any unit of time is equal to the difference of the heat contents at entrance and exit from the apparatus, for the entire amount of

working substance flowing in this unit of time, minus the radiation and conduction losses from the apparatus."[3]

With superheated steam, if the temperature and pressure are known, the heat content can be obtained from steam tables. With saturated steam it is necessary to know the percentage of moisture. To measure the temperature of the exhaust steam from locomotive cylinders, when it is superheated, is simple. To measure the amount of moisture in the exhaust steam accurately, when it is saturated, is difficult, if not impossible. Accordingly, the method described in this paper is limited to those cases where there is superheat in the exhaust steam. Since most locomotives in main-line service have some superheat in their exhaust, this limitation is not very important. It is one, however, that must always be borne in mind.

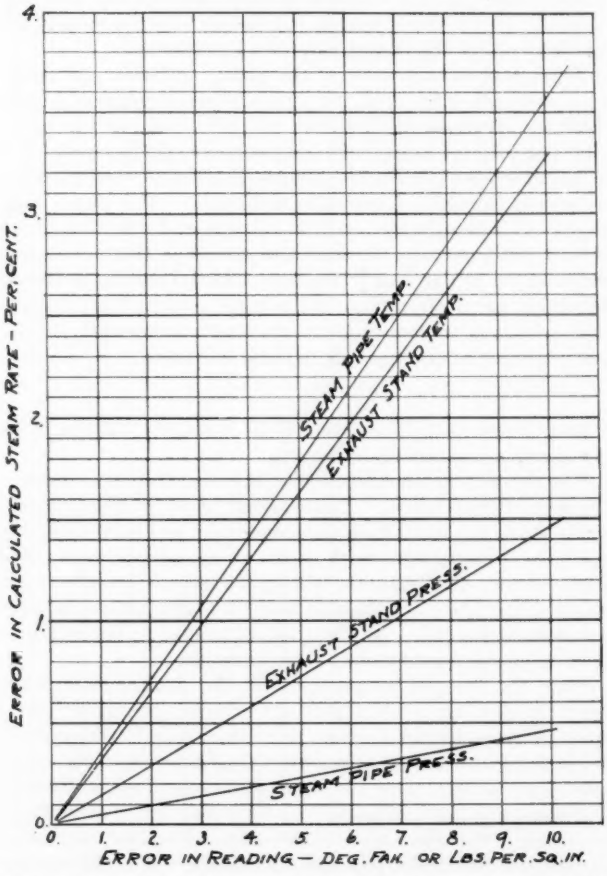

FIG. 1 EFFECT OF ERRORS IN READINGS ON CALCULATED STEAM RATE

Knowing the temperature and pressure of the admitted steam and of the exhaust steam, the two heat contents can be obtained from steam tables. The difference between the two gives the heat drop in Btu per pound of steam. This heat drop is equal to the work done in the cylinders per pound of steam, plus the heat lost through radiation. The radiation loss is relatively small and, if desired, can be allowed for. One horsepower-hour is equal to 2545 Btu. Dividing 2545 by the heat drop per pound of steam will give directly the pounds of steam per indicated horsepower hour. It makes no difference what processes are taking place in the cylinder, whether they are adiabatic, isothermal, or, as is actually the case, a turbulent process which does not follow any definite law. In the extreme case, where steam is leaking by the piston, with no work being done, the heat content would be the same in the steam pipe and in the exhaust, with due allowance for radiation. This case is the same as that of the well-known throttling calorimeter.

VALUE OF METHOD FOR LOCOMOTIVE TESTS

Since it is only necessary to measure the temperature and pressure in the steam pipe and in the exhaust of the locomotive cylinders, the test apparatus is relatively simple. It is possible for one man to ride in the cab of a locomotive and take all of the necessary readings. This may be contrasted with the test apparatus and test crew necessary for determining the steam rate using indicators.

It is obvious that where a complete test by taking indicator cards would not be justified, a test using the heat-drop method can be run with a low expenditure, and the various design features which influence cylinder performance can be studied as often as desired.

The following are the design features commonly in question:

(1) Boiler pressure, since it controls the steam pressure in the steam pipe.

(2) The throttle and dry pipe. The pressure drop through these affects the pressure in the steam pipe.

(3) The steam temperature in the steam pipe and superheater design.

(4) The size and design of the valves and cylinders.

(5) The valve setting.

(6) The exhaust nozzle, both size and shape.

The necessary readings for obtaining the steam rate can be taken at frequent intervals, so that a complete picture is easily obtained of the locomotive performance, at various speeds and rates of working. Even when tests are being made on the combustion efficiency of, and heat transfer in, the boiler, it is desirable to measure the steam rate and cylinder efficiency, so that the results may be more closely analyzed.

METHODS OF MEASUREMENT AND SOURCES OF ERROR

The instruments used in measuring the temperature and pressure should be as accurate as possible and suitable for use in road tests on locomotives. In order to obtain a better understanding of the relation between errors and accuracy, Fig. 1 has been prepared. In this figure the four curves show the effect of errors in measurement of the steam-pipe temperature, steam-pipe pressure, exhaust-steam temperature, and exhaust-steam pressure, on the steam rate. An error of 2 lb per sq in. in measuring the steam-pipe pressure will cause an error of 0.1 per cent in the calculated steam rate. An error of 1 lb per sq in. in the measurement of the exhaust pressure will cause an error of 0.14 per cent in the steam rate. To measure the steam-pipe pressure to within 2 lb per sq in. and the exhaust pressure to within 1 lb per sq in. only calls for reasonably accurate test gages. It may be necessary to make a correction for the hydrostatic head, due to the water in the pipe connecting the pressure gage and the point where it is tapped into the steam pipe or exhaust pipe.

The measurement of the steam pipe and exhaust-steam temperatures calls for more careful consideration. If they can be measured with a maximum error in each of 1 F, the resulting error in the steam rate will be 0.68 per cent. If they are measured with a maximum error in each of 2 F, the error in the steam rate will be 1.35 per cent. Adding to these figures the errors due to the steam-pressure measurements gives a total error of 0.92 per cent if the temperatures are measured to within 1 F and 1.59 per cent if the steam temperatures are measured to within 2 F.

It is possible to use instruments suitable for road tests on locomotives that will give results which will average somewhere between these two figures.

The apparatus described in this paper has been used by the author with good results. This statement is not meant to infer that this is the only apparatus suitable for measuring temperatures to within 1 or 2 F. Other means of temperature measurement will be mentioned later.

The temperatures are measured with thermocouples constructed as shown in Fig. 2. Wires used are iron and constantan, purchased in lengths. Samples of each length are calibrated, with reference to a thermometer which has been certificated by the Bureau of Standards. The wires are led through porcelain insulators to a steel plug welded in the end of a piece of $^1/_4$-in. pipe. The wires are brought through small holes drilled in the steel plug, bent over, and the ends then covered with silver solder. This gives a thermocouple which is tight against the steam pressure and will follow any change in steam temperature rapidly. The thermocouple is screwed into a socket, which, in turn, is screwed into the steam pipe. This gives a steam space surrounding the thermocouple all the way up to the thermocouple head, which serves to minimize any errors due to conduction along the thermocouple pipe. The steam-pipe thermocouple, illustrated in Fig. 2, is screwed into the steam pipe in any convenient place.

The exhaust-steam temperature is measured, not in the exhaust passage, but in the exhaust stand. It has been the common practice in the past to measure the exhaust-steam temperature in the exhaust passage close to the steam chest. This has been standard practice on the Pennsylvania Railroad in their tests, at Altoona, in their locomotive test plant. It is stated in sev-

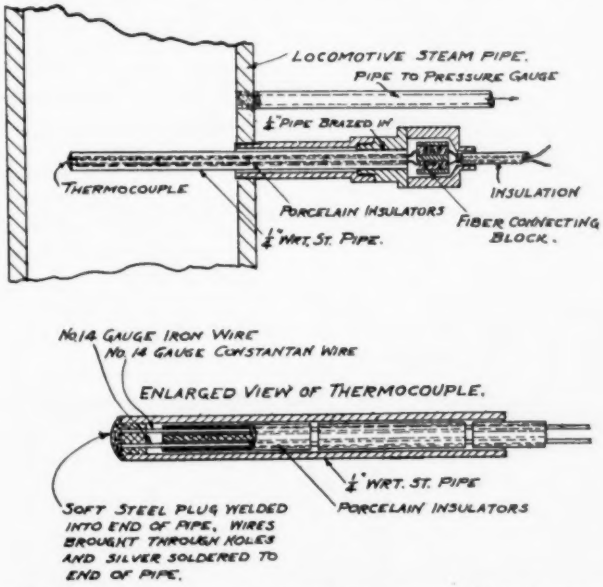

FIG. 2 STEAM-PIPE THERMOCOUPLE AND PRESSURE-GAGE CONNECTION

eral of the railroad's publications, that the exhaust-steam temperature measurements are believed to be higher than the true temperatures. The reason given is as follows:

> During admission of the steam into the cylinder, heat is transferred from the steam to the cylinder walls and head. As the steam expands and becomes cooler this heat transfer stops and then reverses, so that during the exhaust stroke heat is being transferred from the cylinder to the exhaust steam. After release, when the pressure in the cylinder is higher than the average exhaust pressure, there occurs a sudden rush of steam, which by reason of its high velocity does not have time to absorb very much heat from the cylinder walls. As the piston moves on the exhaust stroke the steam, which is now moving more slowly, is heated up by the cylinder walls, with a rise in temperature.

The Pennsylvania Railroad states that it believes the sudden rush of relatively cool steam at release does not register properly on the thermometer in the exhaust passage and that this thermometer is influenced more by the slow-velocity high-temperature steam during the exhaust stroke.

In measuring any fluctuating steam temperature it is desirable to provide for as much mixing of the steam as possible. Accord-

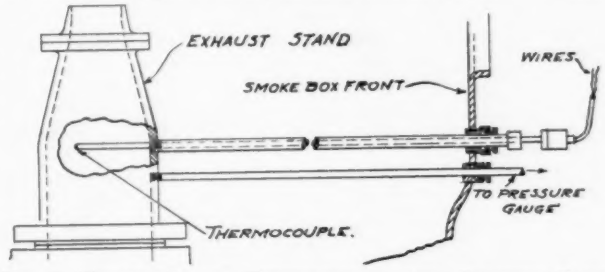

FIG. 3 EXHAUST-STAND THERMOCOUPLE AND PRESSURE-GAGE CONNECTION

ingly, the exhaust-steam thermocouple is located in the exhaust stand so that the steam passes through a chamber of some volume and with several bends before the temperature is measured. Also a thermocouple applied in one side of the exhaust stand will measure the temperature of the exhaust from both ends of one side of the engine, and thermocouples applied in both sides of the exhaust stand will measure the exhaust-steam temperatures from all four ends of the locomotive cylinders.

The accuracy of the assumption that better temperature measurements could be made in the exhaust stand than in the exhaust passage was tested on a locomotive in main-line service. On this particular test an observer was riding on the front of the locomotive and simultaneous readings were taken of the exhaust-steam temperature with a thermometer in the exhaust passage close to the steam chest, and a thermocouple in the exhaust stand. The average of a number of readings showed the observed exhaust-passage temperature, as indicated by the thermometer, to be 345 F and the observed exhaust-stand temperature, as indicated by the thermocouple, to be 325 F. In other words, if the exhaust-stand temperature is taken as being accurate the temperature measured in the exhaust passage close to the steam chest was reading 20 deg high. This figure would vary no doubt with the class of engine and conditions of working, but it is evident that measurements taken of the exhaust-steam temperature in the exhaust passage close to the steam chest are subject to considerable error.

The application of the thermocouple to the exhaust stand is shown in Fig. 3. The thermocouple is constructed in the same way as that shown in Fig. 2. A $^1/_2$-in. standard pipe is screwed in the exhaust stand and brought out through the smokebox front. The thermocouple is slid into this $^1/_2$-in. pipe, which provides an insulating steam jacket and also permits easy removal.

The thermocouple electromotive force is measured with a Leeds and Northrup potentiometer. The potentiometer is a well-known means of measuring temperatures in connection with thermocouples, and is suitable for locomotive testing. Because of severe vibration it is always possible to obtain a broken strand in one of the thermocouple wires, or a bad contact. With a direct-reading pyrometer this would throw the instrument off but with a potentiometer it would make no difference, as long as the wiring was good enough to provide a circuit.

With the galvanometer mounted in the potentiometer case as sent out by the makers, the vibration of the locomotive is sufficient to upset the galvanometer needle. In order to obviate this difficulty, the galvanometer is mounted on a board with a spring suspension as shown in Fig. 4. This board also serves for writing down the data and is held by the observer. The observer's body will absorb most of the shocks and vibration of the locomotive, and with the spring mounting of the galvanometer no trouble will be found in taking readings. The potentiometer is mounted on a bracket and the galvanometer wired to

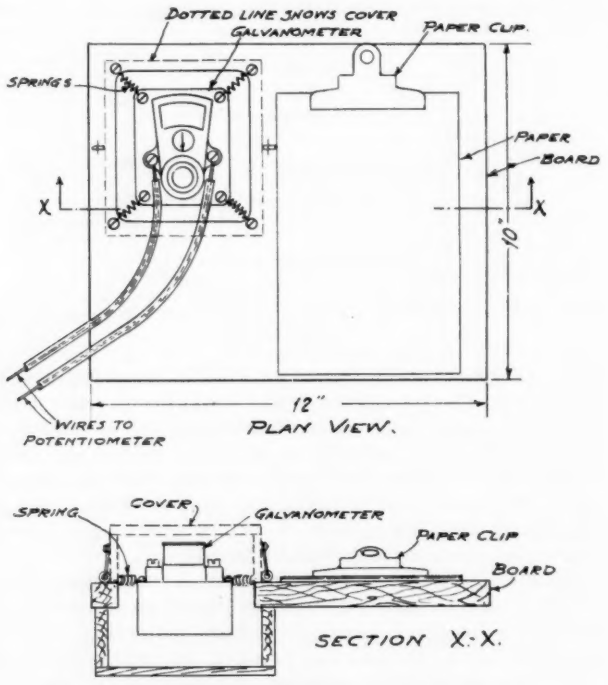

FIG. 4 GALVANOMETER MOUNTING OF DATA BOARD

the potentiometer by means of two copper wires of sufficient length to allow freedom of movement to the observer.

The thermocouples are connected to a rotary switch in the cab by means of which each one in turn may be put into the potentiometer circuit. The wiring diagram is shown in Fig. 5. A thermocouple measures the difference between the temperatures of the hot and cold junctions and consequently it is necessary to know the temperature of the cold junction and to connect the hot and cold junctions in such a way that no other electromotive force is set up. As in Fig. 5, the thermocouples are connected with special extension leads to a connecting strip which is located at some convenient spot near the front of the locomotive. These extension leads are of the same material as the thermocouple wire, so that no electromotive force is set up at their junction. This connecting strip is mounted in a closed metal box, so that all the junctions will be at the same temperature. From the connecting strip copper leads are run to the rotary switch in the cab. The common wires from the rotary switch, which are connected to each thermocouple in turn, are connected with copper leads forward to the connecting strip and from there connected with the special extension leads back to the cab. The ends of these leads are joined to copper wire, which is connected to the potentiometer. This junction of the extension lead and the copper wire forms the cold junction and is placed in a piece of $^3/_8$ in. pipe. The thermometer and cold junction will be at the same temperature and will not be affected by stray air currents. As many thermocouples as desired can be wired with extension leads to the connecting strip at the front of the engine and the single extension lead going back to the cold junction will automatically refer the cold junction from the connecting strip to the cab.

For best accuracy in measuring the steam rate it is desirable to have thermocouples in both steam pipes and both sides of the exhaust stand. The temperatures should not vary much from side to side, but with the two sets of thermocouples variations can be seen and a true average obtained.

Instead of using the thermocouples the temperatures can

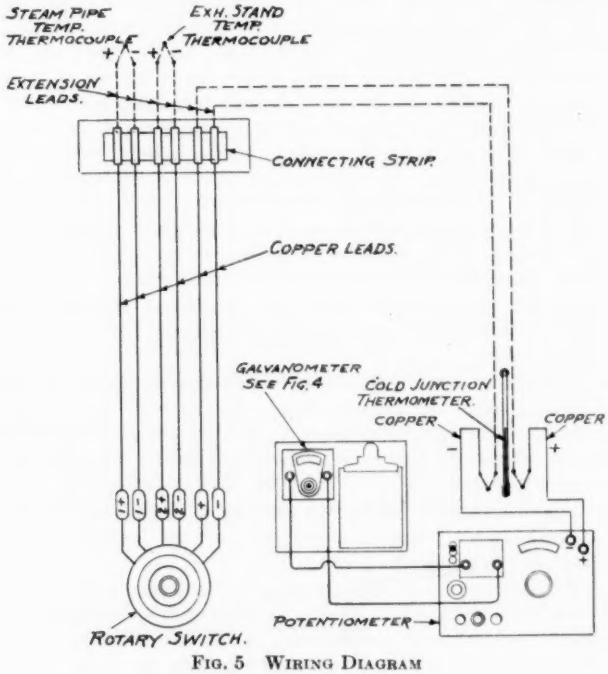

FIG. 5 WIRING DIAGRAM

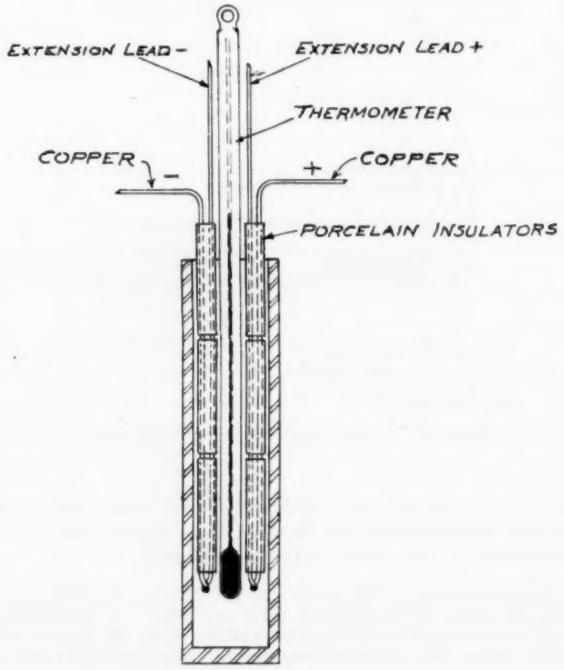

FIG. 6 COLD JUNCTION

be measured with even greater accuracy by using platinum-resistance thermometers.

It has already been pointed out that the heat drop from the steam pipe to the exhaust includes radiation from the steam pipes, steam chests, cylinders, and exhaust passages. For a typical Pacific-type locomotive, this radiation loss has been calculated to be approximately 0.42 per cent of the heat drop with the engine standing still and 0.83 per cent of the heat drop with the engine running at 100 mph. This radiation loss can be allowed for, but it is obvious that inaccuracies in its determination will be negligible in its effect on the calculation of the steam rate.

Road Tests of Locomotives

Table 1 shows the results obtained on road tests of a 2-8-2-type locomotive in fast freight service. The object of the test was to determine the effect on the engine performance of a special design of superheater unit. Tests were first run with the standard type-*A* superheater in place. The special superheater was then installed in place of the type-*A* and further tests were run. No attempt was made to obtain special conditions with reference to the running. The engine was in regular service, pulling whatever trains were assigned to it with various engine crews. The locomotive would run for half a division, then take on water, and then finish the run to the end of the division. Each test, shown in Table 1, is the average of readings taken every two miles for about 40 to 50 miles, representing about half a division. After starting, several miles were allowed before readings were commenced, in order that conditions might become reasonably constant. A caboose was carried back of the locomotive as a test car. The thermocouples were all wired to the caboose, where the temperatures were read by an observer with the potentiometer and rotary switch. The wiring connection between the caboose and tender was arranged to be easily connected and disconnected. Temperatures were measured on the left side of the engine only.

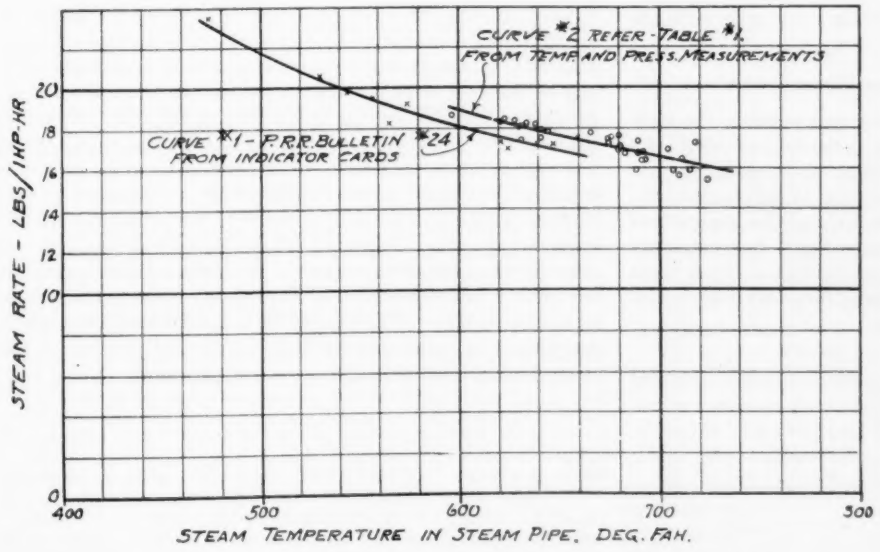

Fig. 7 Relation of Steam Rate and Steam Temperature

The method of testing was successful and the readings obtained were consistent and reasonable. The increase in steam temperature with the special type of superheater showed a decrease in steam rate, in line with other tests. This will be referred to later, when the accuracy of the heat-drop method is discussed.

Table 2 shows the results obtained in a similar test on a 4-6-2-type locomotive in fast passenger service. In this case temperatures were measured in both steam pipes and in both sides of the exhaust stand. The variation from side to side was not very great, but was enough to be significant. The potentiometer and rotary switch were mounted in the cab and even at the highest of speeds the galvanometer mounting shown in Fig. 4 was satisfactory. As in the test recorded in Table 1 the increase in steam-

pipe temperature showed a decrease in steam rate, as would be expected. The readings of the steam-pipe temperature, exhaust-stand temperature, and steam rate are more consistent than those shown in Table 1. This is because the weight of the train did not vary much. Only two crews were used for all of the tests, and the time-table schedule was kept more closely.

Accuracy of Heat-Drop Measurement of Steam Rate

It is difficult to estimate the absolute accuracy of the steam rate as determined by the proposed method. In a number of locomotive tests, particularly those made at the Altoona testing plant of the Pennsylvania Railroad, measurements were taken of the exhaust-steam temperature. This temperature was always measured in the exhaust-steam passage close to the steam chest, and, as already pointed out, the readings cannot be taken as being accurate. Consequently, it is not possible to compare the steam rate as obtained in these tests from the heat drop and, as obtained from the indicator cards, except in a general way.

Some idea of the possible accuracy of the heat-drop method can be obtained from Fig. 7. In this figure steam rate is plotted against temperature in the steam pipe. Curve 1 is taken from Pennsylvania Railroad bulletin No. 24, published in 1914, entitled "Superheater Tests." In this bulletin tests are described which were made on a Pacific-type locomotive. The only changes throughout the test were the length and arrangement of the superheater units. All points shown on curve 1 are for a constant cutoff of approximately 40 per cent and a consistent speed of approximately 240 rpm. The steam-pipe pressure varied from 170 to 195 lb. Curve 2 is plotted from the results given in Table 1. These tests were run at approximately 45 per cent cutoff, with a steam-pipe pressure of from 145 to 165 lb per sq in.

On account of the lower steam-pipe pressure it would be expected that curve 2 would lie above curve 1, showing a higher steam rate for the same steam temperature. The general trend of curve 2 is the same as that of curve 1. Another measure or indication of the accuracy of the results is the scattering of the points about the average line. It must be remembered that the tests for curve 1 were made on a stationary test plant, with the speed, cutoff, and horsepower being closely controlled. The tests for curve 2 were made in regular service, with a large variation in speed and tonnage, and with a number of different crews operating the locomotive. In view of this it is thought that the scattering of the points for curve 2 compares favorably with the scattering of the points for curve 1.

Measurement of Indicated Horsepower

It was pointed out by L. K. Botteron, in a paper in the *Railway Mechanical Engineer*, July, 1930, that the exhaust nozzle of a locomotive could be considered as a flowmeter. From the exhaust pressure and temperature the velocity of the steam in the exhaust-nozzle tip can be determined. Using the connections for pressure and temperature, as shown in Fig. 3, it is necessary to apply a correction for the velocity of the steam at the point where the pressure is measured. The usual formula for determining the velocity of steam in a nozzle is

$$V_2 = 223.7 \sqrt{H_1 - H_2} \quad \ldots\ldots [1]$$

where V_2 = outlet velocity, ft per sec
H_1 = inlet heat content, Btu per lb
H_2 = outlet heat content, Btu per lb.

In order to allow for the velocity of the steam at the point where the pressure is measured it is necessary to use the more exact formula

$$\frac{V_2^2 - V_1^2}{2g} = 778(H_1 - H_2) \quad \ldots\ldots [2]$$

where V_1 = inlet velocity, ft per sec

From a knowledge of the pressure and temperature in the exhaust pipe the quantity H_1 is determined. From a Mollier diagram the quantity H_2 is obtained, since the steam expands adiabatically and the entropy is the same at points 1 and 2. The pressure at point 2 is the pressure in the smokebox, and from the entropy and pressure the specific volume can be determined. Since the same weight of steam is flowing by points 1 and 2, the relation between V_1 and V_2 is

$$V_1 = V_2 \times \frac{A_2}{A_1} \times \frac{v_1}{v_2} \quad \ldots\ldots [3]$$

where A_1 = area of exhaust stand where pressure is measured, sq ft
A_2 = area of exhaust tip, sq ft
v_1 = specific volume at inlet, cu ft per lb
v_2 = specific volume at outlet, cu ft per lb.

Substituting this value of V_1 in Equation [2] gives

$$\frac{V_2^2\left[1 - \frac{A_2 V_1}{(A_1 v_2)^2}\right]}{2g} = 778\,(H_1 - H_2) \quad \ldots\ldots [4]$$

from which V_2, or the velocity in the exhaust tip, can be calculated. The flow of steam through the exhaust tip is equal to the velocity multiplied by the area, multiplied by the density, multiplied by a coefficient. It was assumed in the article by Botteron that this coefficient would be unity. Using this assumption the author has obtained some results which agreed fairly well with the measurement of water from the tender tank. It is felt that for better accuracy it would be desirable to calibrate the exhaust tip by means of a standing or blowdown test. It would be possible for any railroad to establish the coefficient for their design of exhaust tip and then to use the exhaust-stand pressure and temperature measurements to give accurate readings of the flow of steam through the exhaust tip. By making suitable corrections for the steam flowing from the exhaust to the feedwater heater or exhaust-steam injector and for the steam flowing from the auxiliaries to the exhaust passage the weight of steam to the engine can be calculated with fair accuracy. These readings would give the flow of steam to the engines at any instant during a run. When the steam rate is known, as obtained from the heat-drop measurements, the indicated horsepower, at any instant, can be obtained by dividing the steam to the engines by the steam rate. This enables the indicated horsepower to be determined by measuring the temperature and pressure of the steam in the steam pipe and in the exhaust stand.

The Correlation of Spring-Wire Bending and Torsion Fatigue Tests

By E. E. WEIBEL,[1] BERKELEY, CALIF.

The investigation reported in this paper was an attempt to correlate bending and torsion fatigue results for tempered Swedish valve-spring wire so that the torsion fatigue strength might be inferred within reasonable limits of accuracy from the fatigue values found in the simpler rotating-beam test. The original program called for (*a*) the development of suitable methods of gripping the wire for the torsion fatigue tests; (*b*) the determination of bending and torsion fatigue values for one size of wire in the as-received condition, and also after removal of the surface layer in a centerless grinder; (*c*) the determination of fatigue values for other sizes of wire between 1/8 in. and 1/4 in., as permitted by time limitations; and (*d*) a survey of the literature for data bearing on the correlation of bending and torsion results. The results of these experiments on straight specimens of tempered Swedish wire in torsion and bending fatigue may be summarized as follows:

1 Methods of gripping were developed which are satisfactory for both bending and torsion fatigue tests with the exception of torsion tests on shot-blasted wire.

2 Zero to maximum torsion fatigue values for straight specimens in the as-received condition were about 70 per cent higher than values estimated from previous tests on carefully coiled springs.

3 The smaller of two sizes of wire tested in the as-received condition had the higher torsion fatigue limit and lower ultimate torsional strength.

4 Removal of the natural surface by grinding increased the bending fatigue strength about 20 per cent, but decreased the torsion fatigue strength about 4 per cent.

5 Shot-blasting increased the bending fatigue strength about 27 per cent and increased the torsion fatigue strength an undetermined amount.

6 The zero-to-maximum torsion fatigue limits of two sizes of wire tested in the as-received condition were 1.5 and 1.6 times their respective bending fatigue limits.

7 For two sizes of wire in the as-received condition the values of 0.84 and 0.90 were obtained for the ratio of reversed torsion fatigue strength to reversed bending fatigue strength.

8 Approximate measurements of surface residual stress were made on the wire in different conditions before and after fatigue testing and before and after coiling, which may have a bearing on the fatigue properties of springs.

1—REVIEW OF THE LITERATURE

Methods of Gripping Wire in Torsion Fatigue Tests

A DESCRIPTION of gripping methods satisfactory for torsion fatigue tests on tempered carbon-steel wire could not be found.

F. C. Lea of Sheffield has developed methods of gripping which are satisfactory for cold-drawn wires. In his earlier work (1)[2] split bushings were used. These were not entirely satisfactory for tempered wires. In his later work (2) gripping shanks of an alloy with a low melting point (type metal) were cast on the ends of the wire specimen. It was found that 80 per cent of the cold-drawn-wire specimens failed at a distance from the grips.

Goodacre (3) reviews gripping methods in use in England for bending, tension, and torsion fatigue tests on ferrous and nonferrous wires. In the case of torsion Lea's casting method is mentioned.

A study of type-metal alloys by F. D. Weaver (4) was noted; also a paper by L. J. G. van Ewijk (5) on the penetration of steel by soft solder and other molten metals at temperatures up to 400 C. The latter's observations may explain why Lea's casting method, unmodified, was not successful with tempered Swedish wire.

In 1929, O. Föppl (6) obtained increased torsion and bending fatigue strengths of polished specimens by rolling the surface so as to produce local plastic flow.

A publication by P. Behrens (7) describes the rolling apparatus used by Föppl, and gives further results. An increase of 17 per cent in torsion fatigue strength of a mild steel was obtained, and increases of 20 to 50 per cent in bending fatigue strength of a low-carbon steel.

Thum and Wunderlich (8) determined the bending fatigue strength of shafts with and without a press-fitted collar. Heavy stress concentrations, microscopic rubbing with the formation of oxides and corrosion, lowered the fatigue strength considerably. By surface-rolling the shaft and shaping the collar to reduce stress concentration, an increase of 95 per cent in fatigue strength was obtained.

A paper by O. J. Horger (9) presents a considerable amount of data on the surface-rolling process. Increases in bending

[1] Instructor in Department of Mechanical Engineering, University of California. Dr. Weibel received the degree of B.Sc. in mechanical engineering at McGill University, Montreal, in 1918. During the summers, 1915 to 1917, he was employed as structural draftsman with the Dominion Bridge Company, Ltd., Montreal; and from 1918 to 1922 as mechanical designer and estimator on steam-turbine and electric-crane work. From 1922 to 1927 he was supervisor, under the mechanical engineer of the company, of the mechanical-design squad on cranes, hydroelectric regulating gates, etc. During 1928 and 1929 he studied mathematics at the University of Toronto and in 1929 returned to the Dominion Bridge Company where he was employed on mechanical standardization and as field engineer on the installation of hydroelectric equipment. In 1931 Dr. Weibel received the M.S.E. degree and in 1932 the degree of Ph.D. in engineering mechanics from the University of Michigan where he specialized in photoelastic stress determination. At the time these tests were carried out Dr. Weibel was research associate in the engineering research department of that University.

Contributed by the Research Committee for presentation at the Annual Meeting of The American Society of Mechanical Engineers to be held in New York, N. Y., December 2 to 6, 1935.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until January 10, 1936, for publication at a later date.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

fatigue strength around 30 and 40 per cent were obtained. Petersen and Wahl (10) also experimented with surface-rolling. Their paper includes a summary of Thum and Wunderlich's results.

Fatigue Results on Tempered Swedish Valve-Spring Wire

Swan, Sutton, and Douglas (11) tested straight specimens of a tempered Swedish valve-spring wire in torsion fatigue with maximum stress four times the minimum stress. When tested at full diameter of 0.128 in. the safe range was from 20,200 to 80,800 lb per sq in. When reduced to 0.100 in. diameter and polished, the safe range was from 31,400 to 125,500 lb per sq in., an increase of 56 per cent. These stress values were not measured directly but were assumed proportional to the angular travel of the gripping chucks, an assumption which will be shown later to be unjustified because of variations in the effective length of the specimen.

F. P. Zimmerli (12) tested a number of steels in the form of completed springs. The steels, numbers 4 and 7, were straight carbon pretempered Swedish wires, 0.148 in. diameter, with 0.75 and 0.65 per cent carbon content, respectively. The safe ranges decrease with increasing mean values of torsion stress in close agreement with the Goodman diagram. Probable values of zero to maximum torsion stress range extrapolated from the diagrams are 68,000 and 58,000 lb per sq in., respectively.

Bending fatigue tests were made on two sizes of Swedish valve-spring wire by Shelton and Swanger (13). The first wire, 0.162 in. diameter, 0.65 per cent carbon, had an ultimate tensile strength of 221,000 lb per sq in. and with the natural surface a fatigue strength 34 per cent of the ultimate, or ±76,000 lb per sq in. When reduced to 0.130 in. diameter and polished, the fatigue strength was 56 per cent of the ultimate or ±126,000 lb per sq in. The second wire, 0.148 in. diameter, 0.65 per cent carbon, had an ultimate strength of 217,000 lb per sq in. and a fatigue strength only 30 per cent of the ultimate or ±65,000 lb per sq in. It showed surface defects.

Other Fatigue Results

The torsion fatigue results of G. A. Hankins (14) on polished specimens of spring steel show safe stress ranges which are practically the same for alternating torsion and for zero-to-maximum torsion stress. For higher mean stresses there is a reduction in the safe range but values are always greater than would be given by the Goodman diagram.

The Correlation of Torsion and Bending Fatigue Results for Wire

No reports of experiments were found in which torsion and bending fatigue results were obtained for the same wire and compared. Considerable experimental work and some theoretical work having a bearing on the torsion fatigue strength and on the ratio of torsion to bending fatigue strengths was reviewed.

A criterion of fatigue failure of metals under any type of stress does not appear to have been found. Fahrenhorst and Schmid (15) review briefly the hypotheses as to the cause of fatigue failure of Kuntze, Haigh, Ljungberg, Ono, Ludwik, Gough, Hanson and Wright, and Schmid. These are many and various and will not be given here.

H. J. Gough (16) reported that behavior of metals was being studied under reversed bending, reversed torsion, and all possible combinations of these two types of fatigue loading. Mild steel, a ductile material, obeyed closely the distortion-energy theory of von Mises and Hencky and discussed in a paper by Nadai (17), according to which theory the safe torsion fatigue stress would be 0.577 times the safe bending fatigue stress. But an alloy steel and a cast iron exhibited other relations. He concludes that no general criterion of failure obtains under the stated stress conditions.

Fatigue experiments by A. F. Maier (18) on tubes under two types of reversed stressing obtained by means of internal pressure appeared to support the theory of maximum shear stress according to which the safe shear stress is 0.500 times the safe tensile stress. The results did not support the distortion-energy theory.

Moore and Kommers (19) list the reversed-torsion endurance limits and the reversed-bending endurance limits for polished specimens of a number of straight-carbon steels which had received widely different heat-treatments. The average of 19 values of the ratio of torsion endurance limit to bending endurance limit was 0.55. Extreme values were 0.48 and 0.64. The average of 49 values of the same ratio, from results of tests on polished specimens, listed by Gough (20), was 0.56. Extreme values were 0.44 and 0.80. These results are for presumably homogeneous and isotropic material, and surface effects have been eliminated as far as possible.

Gill and Goodacre (21) studied some aspects of the fatigue properties of patented wire. They found that wire with decarburized surface will take overloads as well as, or better than, wire not decarburized and conclude that there is no gain in removing the decarburized surface if wire will be overstressed much. The writers assume that the ratio of torsion fatigue strength to bending fatigue strength should have the value $^2/_3$, and using this value together with one of their bending fatigue results for polished wire, they calculate a hypothetical torsion fatigue strength which agrees closely with a previous experimental torsion fatigue value for polished wire obtained by Lea and Dick (22). They say, "It seems very probable therefore that the fatigue limit in bending will give a good indication of the torsional fatigue properties of polished spring wire." But they give no reasons why it should and offer only one sample calculated value, and do not check experimentally the torsion strength of the actual wire whose bending fatigue strength they used in their calculations. The arbitrary use of the ratio $^2/_3$ did not appear to be justified.

Values of stress concentration factor around spherical and cylindrical inclusions have been given by Southwell and Gough (23) and J. N. Goodier (24), and the stresses around an elliptical hole in a plate by C. E. Inglis (25).

Goodier shows that the elastic stress concentration factors at a small spherical cavity in regions of uniform pure shear and of uniform tension stress are 1.91 and 2.72, respectively. These values cannot be used in estimating the effect of such a cavity on fatigue strength in the two cases, since the first is in terms of maximum shear stress, and the second is in terms of maximum tensile stress. From Goodier's results it can be shown that for a cavity in a field of uniform tension stress, the maximum shear stress is increased just 1.91 times. If fatigue failure were known to be determined by maximum shear stress, this would lead to the practical conclusion that the ratio of torsion endurance limit to bending endurance limit is unaffected by the presence of small spherical inclusions which are not too close to the surface.

Since in wire, inclusions are probably lengthened out as a result of drawing, calculations for ellipsoidal cavities would be of interest, but none were found in the literature.[3]

For flaws at the surface of wire, the two-dimensional elastic stress concentrations for circular and for elliptical cylindrical holes might be applied assuming again an arbitrary criterion of fatigue failure. At a minute circular hole in the surface of the wire, for the case of torsion, the maximum shear stress is doubled, and for the case of bending, the maximum shear stress is trebled

[3] A paper by H. Neuber has since been noted, "Der Raümliche Spannungszustand in Umdrehungskerben," *Ingenieur Archiv*, vol. 6, no. 2, April, 1935, p. 133.

(24). Therefore, such a flaw is more effective in reducing the bending fatigue strength than in reducing the torsion fatigue strength.

Still assuming the maximum shear stress criterion, we may consider the elastic stress concentration factors for an elliptical flaw on the surface with major axis placed longitudinally and four times the length of the minor axis. For the case of bending, Inglis' formula gives a factor of 1.5. For the case of torsion, the maximum shear stress is increased by the factor $[1 + (a/2b) + (b/2a)]$, where a and b are the major and minor semiaxes, respectively. This formula is not given by Inglis, but was obtained from his results. The value of the factor in the present instance is 3.12. Hence, it is seen that a longitudinal elliptical surface flaw will reduce the torsion fatigue strength proportionately more than it will the bending fatigue strength. Numerical comparisons are limited by the lack of numerical values for notch sensitivity of the material, but it is apparent that any attempt to calculate the torsion fatigue strength from the bending fatigue strength must take account of the shape of flaws which are permitted by the specifications. A striking example of the formation of four fatigue cracks at the points of stress concentration around an approximately elliptical flaw of a torsion fatigue specimen is shown in Fig. 27.

Different materials under alternating loading react differently to stress concentration.

W. Buchmann (26) concludes that "Notch sensitivity is a utilizable property of the material, determinable by calculation." This is the same quantity which R. E. Peterson (27) calls "stress concentration index" q where

$$q = (k - 1)/(K - 1)$$

where k is the ordinary endurance limit without stress concentration divided by the endurance limit with stress concentration (fillet, hole, etc.), and K is the elastic stress concentration factor and is equal to the maximum stress at a fillet or hole divided by the average nominal stress.

W. Buchmann (26) made fatigue studies in bending and torsion on specimens about 0.3 in. diameter, with circumferential notches of 0.002 in. to 0.08 in. radii. Fatigue strength of annealed materials was practically unaffected by the presence of the notch (q practically equal to zero for very ductile materials), while for hardened steels the reduction in fatigue strength was practically proportional to the calculated increase of stress at the notch (q approximately unity for very brittle materials). For the same material the greatest difference between actual reduction of fatigue strength and reduction calculated from the elastic stress concentration factor occurred with the sharpest notches (q decreases with increased sharpness of the notch in a particular material).

Erich Scheil (28) published a paper on the origin of cracks in steel as a result of heat-treatment, and found a dependence on the internal-stress condition, the separation strength of the steel, and other factors.

The effect of internal stresses on fatigue strength were studied by Buehler and Buchholtz (29), who worked with specimens about 1 in. in diameter. They found that compressive surface stresses of about 30,000 to 50,000 lb per sq in. caused by quenching, raised the bending fatigue limit from 10 to 20 per cent. They quote results which show that large tensile surface stresses reduce the fatigue strength about 15 per cent, and that tensile stresses below 28,000 lb per sq in. have no appreciable effect on fatigue limit. They mention the gradual reduction of internal stresses as a result of fatigue stressing.

The same authors (30) studied the relation between residual temperature stresses and yield point of the material and found higher residual quenching stresses for materials with lower yield point due to the greater amount of plastic deformation which occurred during quenching.

Buehler and Scheil (31) studied the combined effect of temperature and transformation stresses in 2-in. diameter specimens of quenched steels. The nickel content was varied to give various transformation temperatures corresponding to different carbon content in straight-carbon steels. Lower transformation temperatures left tension stresses at the surface. Very high transformation temperatures left compressive stresses. Smaller-diameter specimens had smaller tension or compression surface stresses than large-diameter specimens.

Linicus and Sachs (32); in studying the effect of the die angle and degree of drawing on the internal stresses in wire, measured the internal stress by planing off half the width of the wire and noting the change of curvature. However, this gave only a qualitative measure of stress.

R. M. Brown (33), in measuring residual stresses in cold-drawn mild-steel rods, found that in general, zero stress is at an annulus 0.66 of the diameter, with tensile stress outside and compressive stress within.

General

H. J. French (34) discusses the phenomenon of delayed fractures. Hardened and slightly tempered steels which did not fail at 10 million repetitions, failed suddenly at 30 to 60 million repetitions. The steels were all nickel steels and delayed fractures were observed at hardnesses above the range 45 to 50 on the Rockwell C scale, but not at lower hardnesses. No mention of the same effect in straight-carbon steels was found in the literature.

Another delayed-fracture effect is mentioned by A. Jünger (35) who found that flat bending specimens of hardened chrome-molybdenum steel, in which stress concentration was produced by a small hole, were breaking even after 75 million repetitions, whereas unbored specimens did not break after 5 million repetitions.

2—MATERIALS INVESTIGATED

Three coils of straight-carbon tempered Swedish valve-spring wire were supplied by three different wire manufacturers for the purpose of these tests. The wire was specially selected in regard to freedom from inclusions and for as nearly a perfect surface as could be obtained.

The stress-strain curves for static tensile and torsional tests of these wires are plotted in Figs. 1, 2, and 3, while the dimensions, chemical analyses, Rockwell hardnesses, and strengths are given in Table 1. The ultimate torsion strength was calculated from the formula

$$\frac{5.1 \times \text{maximum twisting moment}}{\text{diameter}^3}$$

Carbon contents for the outer 0.001-in. thick layer were found to be 0.57, 0.59, and 0.59, respectively. Photomicrographs of the boundary material are discussed below.

Fatigue tests were made chiefly on the 0.225-in. and 0.187-in. diameter wires. Complete series of tests were not made on the 0.187-in. and 0.125-in. wires because of lack of time.

Polished longitudinal sections and cross-sections of the 0.187-in. and 0.225-in. diameter wires were examined for inclusions. At 100 magnifications, inclusions were smaller in general than about 0.015 in., and no large inclusions were observed.

The structure at 1000 magnifications of a cross-section of the 0.187-in. wire is shown in Fig. 4, and of a longitudinal section of the 0.225-in. wire in Fig. 5.

The boundary of the 0.187-in. wire at 1000 magnifications is

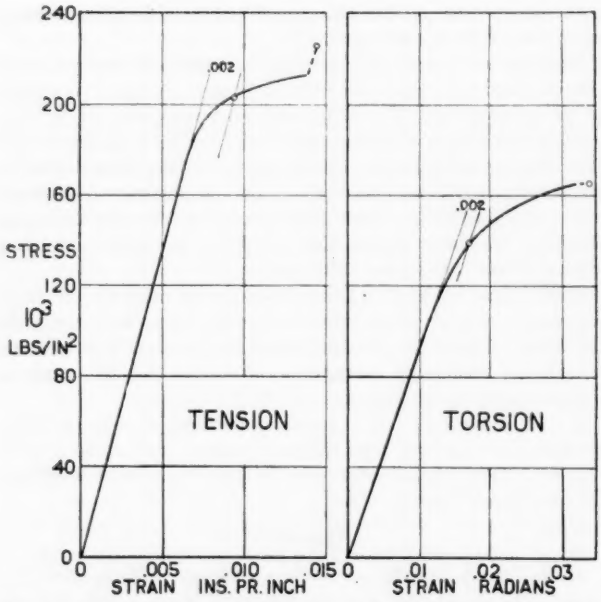

FIG. 1 CURVES FROM STATIC TESTS OF 0.125-IN. DIAMETER TEMPERED SWEDISH WIRE

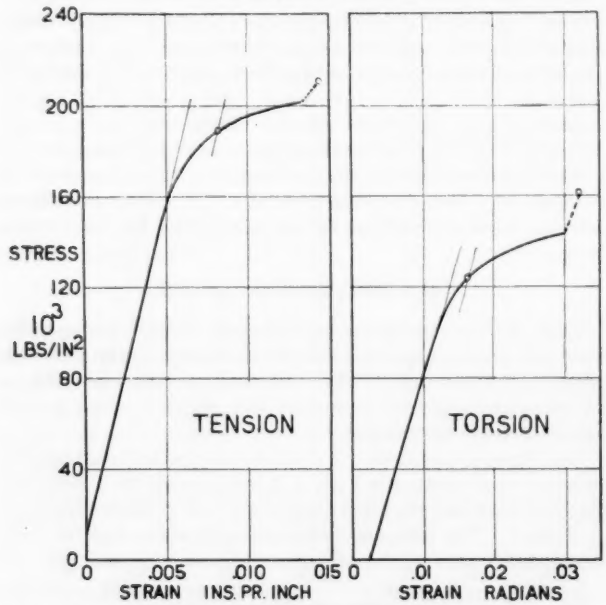

FIG. 2 CURVES FROM STATIC TESTS OF 0.187-IN. DIAMETER TEMPERED SWEDISH WIRE

shown in Fig. 6 in which decarburization to a depth of about 0.0005 in. is shown.

Fig. 7 shows decarburization at the boundary of the 0.225-in. wire, the oxide scale being in focus. Fig. 8 shows another portion of the boundary of the same wire, at which the distribution of ferrite is less disperse.

The photomicrographs show the extent of decarburization better than the carbon analyses previously given, as the latter gave the average carbon content for a layer twice as thick as the actual decarburized layer.

3—DESCRIPTION OF THE FATIGUE-TESTING MACHINES

Bending fatigue tests were made on a short-span rotating-beam-type machine, which was found to work satisfactorily for 0.225-

TABLE 1 RESULTS OF TESTS ON THREE SPECIMENS OF TEMPERED SWEDISH WIRE

Diameter of wire, in.	0.125	0.187	0.225
Coil diameters as received, in.	28	36	36
Chemical analyses:

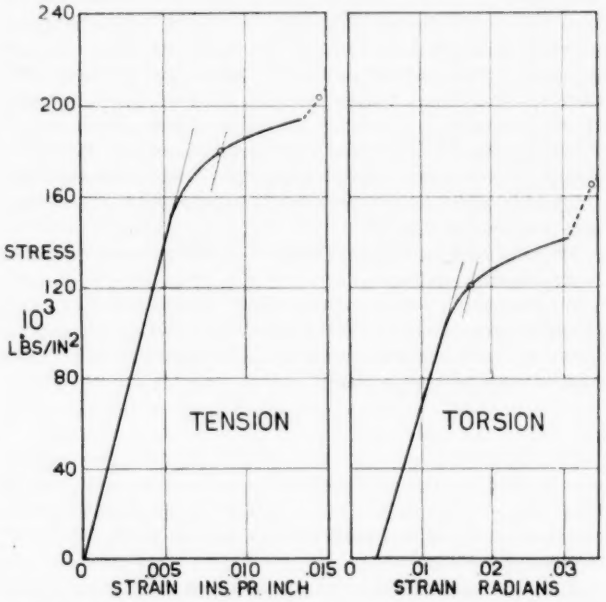

FIG. 3 CURVES FROM STATIC TESTS OF 0.225-IN. DIAMETER TEMPERED SWEDISH WIRE

in. and 0.187-in. diameter wires, but not for 0.125-in. wire. Clear lengths of specimens between $1^1/_2$ in. and $2^1/_2$ in. were used. Grips were cylindrically bored and fitted with an external cone and nut for clamping.

Torsion fatigue tests were conducted on three machines of the constant-strain type shown in Fig. 10. A $^1/_3$-hp driving motor running at 1725 rpm was coupled to a shaft with a variable eccentric. A connecting rod gives an oscillating motion to one of the gripping chucks through a rocker arm of variable radius, the maximum angular motion being about 12 deg.

The second gripping chuck was originally clamped solidly on these machines, but in order to provide a means of determining the stress range at all times while the machine was in operation, a torsion-measuring member was inserted in series with the specimen under test. Two dial indicators measured the relative rotation of the two ends of this member at the extremities of the cycle. This device was calibrated statically under known torsion moments. Inertia effects in it were negligible, the calculated error with the proportions used being 0.1 per cent. Readings of the dials for zero torque were made at the beginning of a test with the specimen in place by unclamping the dead end of the torsionmeter and giving the assembly a slight oscillatory motion to eliminate friction.

A revolution counter was connected to the eccentric shaft. The motor was controlled through a 6-volt relay circuit, a current of 0.125 amp passing through the specimen under test. A

spring was provided to shift the oscillating grip a distance of about 0.0625 in., thus opening the circuit. Relays were adjusted so as to remain open after a momentary break in the circuit. This plan did not always stop the motor since contact was often maintained through the two parts of the fractured specimen. A phosphor-bronze leaf-spring contact in series with the specimen was therefore added at the end of the oscillating shaft which positively broke the circuit with a small endwise motion of the shaft and stopped the motor as desired.

Ball-bearings were used throughout, lubrication being maintained by oiling at the end of every one or two million cycles.

Vibration was reduced to a minimum by balancing the rotating eccentric parts and mounting the machines on thick sponge-rubber pads.

For tests at values of mean stress other than zero, a rotational adjustment was provided, which could be varied during operation.

The split chucks were cylindrically bored to 0.5 in. diameter and each was clamped by means of four $^5/_{16}$-in. heat-treated bolts.

4—DEVELOPMENT OF GRIPPING METHODS FOR TORSION

CAST-END METHOD

At the inception of this project no satisfactory methods of gripping were known for the torsion fatigue testing of tempered valve-spring wire in the as-received condition. Failure of straight wire specimens invariably occurred at the grips where the phenomena of stress concentration, microscopic rubbing, oxide formation, and corrosion were all present. The difficulties may be illustrated by Swan, Sutton & Douglas' torsion fatigue tests on Swedish wire (11). Of 25 specimens tested only two failed away from the grips, and another two ran unbroken for ten million stress cycles.

For cold-drawn wires, the difficulties had been overcome by F. C. Lea (2) by the use of cast type-metal ends. Adhesion was obtained by first tinning the ends of the wire which was then gripped in a split steel mold and poured with type metal. Molds and specimens of this type are indicated in Fig. 11. The temperature reached by the central portion of the wire in the process was not above 100 C, and when such high temperatures were reached they were only of momentary duration.

Lea's method was taken as the starting point for the present work with tempered wire. The alloy used was described by Lea (2) as a white metal having a melting point as low as 107 C, and by Goodacre (3) as a type metal melting at 180 C. In the experiments reported in this paper, a matrix metal, a tin-lead solder, and a commercial monotype metal were tried first. The matrix metal contained 28.5 per cent lead, 14.5 per cent tin, 48 per cent bismuth, and 9 per cent antimony, and had a melting point of 105 C. The tin-lead solder had a melting point of approximately 180 C. The monotype metal analyzed 76 per cent lead, 8 per cent tin, and 16 per cent antimony, and had a melting point around 240 C.

The matrix alloy and the tin solder did not adhere to the wire in torsion fatigue trials, whereas the monotype metal always adhered, even for torsional stresses in the wire as high as 140,000 lb per sq in. Monotype metal is relatively inexpensive, and as it

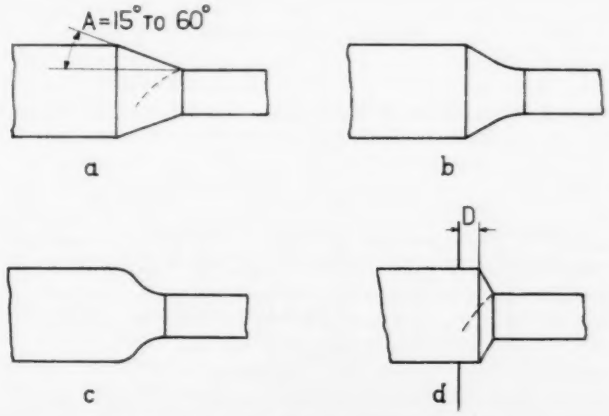

FIG. 12 SHAPE OF THE ENDS OF THE SPECIMENS USED IN TORSION FATIGUE TESTS

seemed to meet the initial requirements it was used in subsequent tests.

Specimens of 0.125-in. wire were prepared with cast monotype ends and tested in torsion fatigue. In all cases in the early experiments failure occurred at the inner end of the molded type-metal shank. To reduce stress concentration effects the ends were variously shaped as shown in Figs. 12*a*, 12*b*, and 12*c* and were gripped at varying values of *D* shown in Fig. 12*d*, but fractures were always at the junction with the white metal thus indicating that stress concentration was probably not the chief cause of failure. For small angles *A* and for large values of *D* shown in Figs. 12*a* and 12*d*, respectively, the white metal failed by cracking along a helix. In order to vary the hardness of the white metal, pouring temperatures were varied from 475 C to 300 C, and mold temperatures were reduced to as low as 5 C with no apparent effect on the position of wire fractures.

A few specimens were clamped directly in a split-copper bush

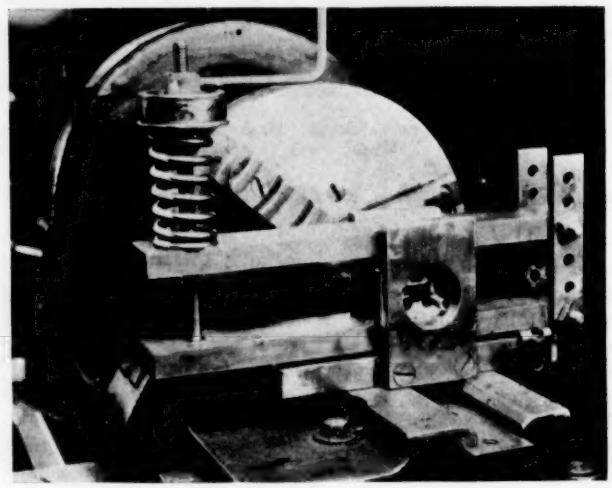

FIG. 16 DEVICE FOR ROLLING THE SURFACE OF THE WIRE. THE SPRING WAS CALIBRATED TO PRODUCE ACCURATE ROLLING PRESSURES

ing with a 0.009-in. layer of detail paper between the wire and bushing. These failed at the grips.

One specimen was clamped without paper in a split mild-steel bushing and failed at the grip.

Removal of the decarburized layer and polishing is known to greatly increase the fatigue strength of wire. When this was done and followed by tinning and casting on type-metal shanks, failure again, as with other methods, occurred at the grip.

Five specimens of 0.187-in. wire were prepared with cast monotype ends for testing in the rotating-beam machine, in the belief that conditions here would not be so drastic as for torsion and that bending fatigue experiments could be started. Although the different shapes of the ends of the specimens shown in Figs. 12*a*, 12*b*, 12*c*, and 12*d* were tried, failure always occurred at the grips. One bending specimen was not tinned, but cast directly on the wire which had been fluxed in zinc chloride. It failed at the grip, indicating that tinning was not an essential cause of failure.

The presence of a yellowish white oxide at the junction of wire with cast shank suggested a similarity in the gripping problem to that of the failure of axles at a press fit, where stress concentration

and corrosion fatigue due to the formation of oxides are present (8, 9, 10). In the experiments of Thum and Wunderlich remarkable increases of bending fatigue strength were obtained due to surface-rolling. This process was next tried and since it met with success it will be described in detail.

Surface-Rolling of Wire Specimens

The apparatus detailed in Fig. 13 and shown in Fig. 16 was assembled and used to roll the surface of wire specimens at the points where failure had previously been found to occur. The rollers were made of $^{7}/_{16}$-in. diameter hardened steel with the face crowned to $^{3}/_{32}$-in. radius. Roller dimensions were taken from the dissertation of O. J. Horger (9). A load of approximately 100 lb was used at the spring, giving roller loads of about 230 lb each. The approximately straight wire specimens were gripped in a lathe chuck and rotated at various speeds. The 0.225-in. wire was rotated at 25 rpm and the 0.187-in. wire at 35 rpm, giving a surface speed of 1.5 fpm. A feed of 0.0055 in. per revolution was used.

With the roller dimensions and loading as given, the maximum shear stress in a perfectly elastic solid calculated by the Herz theory for contact stresses was in the neighborhood of 500,000 lb per sq in. The yield point in shear of the tempered wire is from 120,000 to 140,000 lb per sq in. Consequently, this extremely high stress is not reached but plastic flow takes place to a depth depending upon the roller pressure. The slow rolling speed allows time for plastic flow to occur. As a result of rolling, the surface material is work-hardened, is made more dense, and is left with heavy compressive residual stresses, all of which probably contribute to its increased fatigue strength.

Two portions of the wire specimen, each about $^{5}/_{8}$ in. long, were rolled as shown in Fig. 14. The roller pressure was increased linearly from zero to a maximum in a length of $^{1}/_{16}$ in. to $^{1}/_{8}$ in. and similarly reduced to zero at the other end of the rolled portion. The tinning was not permitted to touch the natural surface of the wire in the center portion because of possible penetration and weakening (5). The cast end was kept clear of the end of tinned portion so that perfect adhesion was obtained. The beveled ends of the wire specimen were centered in female lathe centers for turning the type-metal ends to fit the chucks of the torsion machine. It was obviously not necessary for the wire to be straight with this method of gripping.

Before tinning, the ends of the wire were rubbed lightly with emery cloth to remove scale, and fluxed in zinc-chloride solution. They were tinned by dipping into molten 50/50 lead-tin solder at 325 C. The momentary temperature reached at a point in the wire just clear of the tinning did not in general exceed 75 C. This was measured by inserting a thermocouple in small holes drilled in pieces of $^{1}/_{8}$-in. and $^{1}/_{4}$-in. drill rod, and tinning these as for the wire specimens.

The monotype metal was poured at 325 C and the molds were usually at or slightly below room temperature. The split molds weighed 0.60 and 1.25 lb for the 0.187-in. and 0.225-in. wires, respectively. The metal cooled quickly and wire temperatures as measured by thermocouples did not exceed 75 C.

The combination of cast ends with surface rolling of the wire was successful for alternating torsion fatigue tests on as-received wire and on wire with the surface ground. Practically every specimen failed away from the gripping points. The method was not successful for shot-blasted wire, since the surface material of this wire is strengthened greatly by work-hardening. The method was successful for bending fatigue tests in a short-span rotating-beam machine on wire in the as-received, ground, shot-blasted, and shot-blasted-and-blued conditions.

To obtain torsion fatigue results for shot-blasted wire, a surface layer of approximately 0.0015 in. was removed from the two end portions of the specimens after which they were polished and rolled. Since the wire specimens were not perfectly straight it was necessary to rotate them in a lathe and clean them with emery cloth. All scratches had to be removed to eliminate the danger of the specimen breaking at the scratches. The few specimens prepared in this way did not fracture as desired, probably due to scratches from the emery, but the double strengthening due to removal of decarburized layer and to surface rolling should more than counterbalance the strengthening in the center portion of specimen due to shot-blasting. Further work with this method should yield results.

When the cast-end type of specimen was tested in a zero-to-maximum torsion-stress cycle, there was a continuous angular creep in the type-metal ends. The effect of this creep was to shift the stress range to a position with a lower mean stress value so that it was necessary to adjust the machines at frequent intervals in order to maintain the intended stress cycle. The cast-end method was consequently abandoned for zero-to-maximum stress cycles, although it is probable that an automatic method of maintaining the proper stress cycle can be worked out. This may be a desirable development as the cast-end method has the great advantage of reducing stress concentration to a minimum.

Split-Bushing Methods

For tests in a zero-to-maximum torsion-stress cycle, split bushings were used to grip the wire. In conjunction with the bushings surface rolling was always used to strengthen the wire in the critical region. Bushing materials experimented with were ordinary cold-rolled steel, hard-drawn copper, and a copper-lead alloy with about 25 per cent lead. Steel was used because of its high coefficient of friction, requiring lower gripping pressures, while copper-lead was used because of its successful application in the pulsating tensile tests of Shelton and Swanger (13). The friction coefficient of brass was too low for satisfactory gripping. In some cases the ends of bushings were faced square with no attempt at relieving stress concentration, while in other cases they were beveled in an attempt to reduce the pressure peak occurring at the ends. When set in the machine they were chucked sometimes flush at the ends, and sometimes protruding a short distance, which was believed to reduce the pressure peak due to gripping. In some cases a thickness of paper was used between the wire surface and the bushing bore. Rolling and subsequent gripping of the wire were done either directly on the natural surface or on a portion which was polished after being reduced about 0.004 in. in diameter to remove the decarburized layer.

The wire diameter was reduced either by grinding between centers which could only be done on samples specially selected for straightness, or more practically by hand in a lathe using strips of successively finer emery cloth. Bushings were drilled solid with a twist drill and sometimes finish-bored by a gun reamer with which it was attempted to bore them 0.0005 in. smaller than the neat-wire size. They were split into halves by a $^{1}/_{64}$-in. milling cutter, and in one case each half was slotted to provide greater flexibility in clamping around the surface of the wire.

Five specimens of 0.225 in. wire in the as-received condition were selected for straightness and ground between centers to 0.221 in. diameter using the tapered-end fittings shown in Fig. 15*a*. They were rolled and gripped by the methods of either Fig. 15*a* or Fig. 15*b*. Specimens Nos. 350 and 351, shown in Fig. 25, were gripped in the copper-lead bushing detailed in Fig. 15*b*. Both of these specimens fractured in the center as shown in Fig. 25. However, the fracture of specimen No. 350 was at a surface flaw as is evidenced from the stress-repetition or S-N curve in Fig. 18. Specimen No. 352 was gripped in a copper

bushing 1 in. long, as shown in Fig. 15*a*, and was run 10.1 million cycles of 0 to 97,000 lb per sq in. stress without breaking. Specimen No. 353 shown in Fig. 25 was gripped in a cold-rolled steel bushing 1 in. long and broke in the center portion. Specimen No. 354 similarly gripped in a steel bushing was removed unbroken after 4.4 million cycles. Very little galling of the wire surface was evidenced. Copper-lead bushings could not be used more than once because of plastic deformation. The method may be considered successful but somewhat elaborate.

In an effort to simplify the procedure, the reduction in diameter of the gripped portions of specimens was omitted. The natural surface of the wire, or 0.187 in. diameter in this case, was rolled as required, the scale was removed with fine emery paper, and the wire was gripped in split copper bushings. Although the wire had been straightened by hand bending none of the specimens were actually straight so that gripping in the torsion machine would introduce small static bending stresses which were neglected. Specimens Nos. 201 to 207 were prepared in the manner described and gripped in copper bushings having an end detail as shown in Fig. 15*c*. Specimens Nos. 201, 205, and 206 fractured clear of the grips while specimens Nos. 202, 203, and 204 broke at the grips. Specimen No. 207 ran 10.1 million cycles at 0 to 105,000 lb per sq in. stress. There was noticeable galling and probably penetration of the copper into the steel wire at points near the inner ends of the bushings where the pressure was greatest. Fatigue cracks started at such points. It was believed that the decarburized surface was particularly susceptible to this welding or seizing action and the next group of specimens Nos. 208 to 210, were prepared with the gripped portions reduced in a lathe to 0.183 in. by emery cloth previous to the surface-rolling operation. Fig. 15*c* indicates the tapered end of bushing and projection from the chuck as used for all three specimens. Specimen No. 208 was gripped in a steel bushing and broke at the grip. Specimens Nos. 209 and 210 were gripped in split copper bushings but were first wrapped with a 0.003-in. layer of a high-grade linen bond paper. The bushings had been bored to 0.185 in. diameter and therefore had to be forced onto the paper-covered specimen. Both specimens broke clear of the bushings. The paper was somewhat disintegrated at the inner ends of bushings, as is usual, due to small relative motion. There was also some fusing of copper to steel.

It is believed that with better distribution of gripping pressure most of the failures at the grips in these experiments might have been avoided. A good bond-paper filler will compensate for irregularities in the surface of the bushing bore, but it is also necessary that the gripping pressure be distributed radially around the wire surface rather than along two lines which are diametrically opposite to one another. To obtain this distribution, an undersized bushing bore was tried as mentioned, and in some cases a paper filler was placed between the outside of the bushing and the bored hole of the torsion-machine chucks. This had the effect of forcing-in the opposite edges of the bushing halves and thus improving the distribution of pressure.

Welding of the bushing material to the wire surface had troublesome consequences in the tests. Apart from providing points of weakness, it reduced the effective length of specimen between grips and thus, since the torsion machines are constant-strain machines, increased the range of stress applied to the specimen. The action was progressive and called for frequent strain adjustments to keep the stress range within reasonable limits. This effect was observed on the 0.187-in. wire gripped on the natural surface and when reduced to 0.183 in. by emery cloth and paper. It was also observed on the 0.225-in. wire ground between centers to a 0.221-in. diameter gripping seat when gripped in copper-lead bushings (specimen No. 351), but was not observed when gripped in steel or copper bushings (specimens Nos. 354 and 352). These

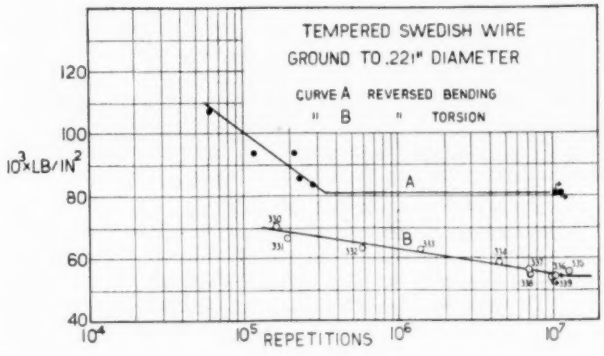

Fig. 19

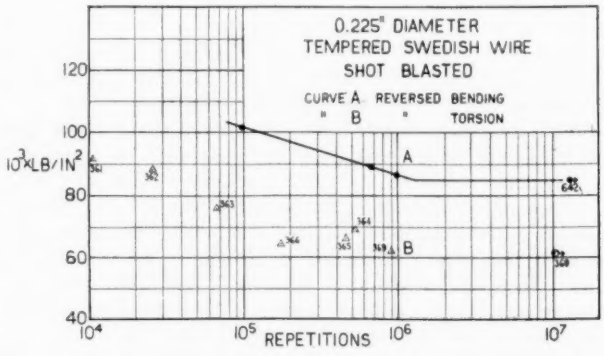

Fig. 20

TABLE 2 VARIATIONS IN STRESS RANGE IN SEVERAL OF THE TESTS

Specimen no.	Type grip	Variation in range
207	Copper bushing	Increase 6% in 2 million cycles
208	Steel bushing	Increase 3 to 5% in 0.2 million cycles
224	Monotype metal	± 7% in 3.6 million cycles
226	Monotype metal	Decrease 1.5% in 2.5 million cycles
364	Monotype metal	Decrease 8% in 0.5 million cycles
354	Steel bushing	Decrease 1% in 4.5 million cycles
351	Copper-lead metal	Increase 7.5% in 0.7 million cycles
352	Copper bushing	Decrease 4.5% in 2.2 million cycles
338	Copper bushing	Decrease 1.0% every 2.5 million cycles

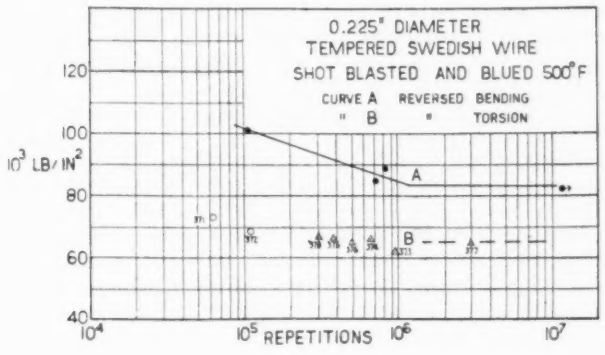

FIG. 21

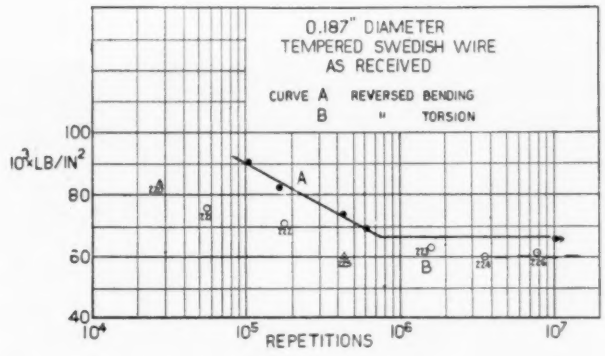

FIG. 22

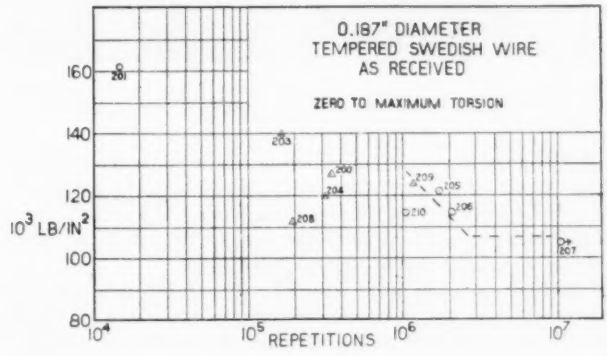

FIG. 23

latter results do not agree with Shelton and Swanger's (13) conclusion that copper-lead causes less galling of the surface than copper, and it may be, as mentioned previously, that the distribution of gripping pressure was the determining factor.

The stress range did not remain constant throughout the endurance test of any one specimen, although in some instances the variation was very small. In contrast with the phenomenon mentioned previously, some specimens gripped in split bushings showed a gradual reduction in stress range, probably due to a loosening of the wire at the inner ends of the bushings. The specimens with cast type-metal ends always showed a reduction in range which seemed to be due to relaxation under the gripping pressure, and consequent loosening in the chuck. This was corrected easily by tightening the gripping bolts. The effect was greatest at high stress ranges when specimens heated up considerably, but was quite small in tests near the fatigue limit. Regular attention and readjustment was thus necessary in all torsion tests to maintain stress ranges within satisfactory limits. The observed variations in stress range for some individual specimens are given in Table 2.

5—TEST PROCEDURE

The wire surface was examined by etching in a solution of equal amounts of concentrated hydrochloric acid and water maintained at 80 C. The wire was reduced in diameter in steps of about 0.0005 in. and examined at each stage until a reduction of about 0.004 in. had been made. The surface of all three sizes was exceptionally homogeneous and free from defects. With much deeper etching longitudinal streaks appeared which were probably not related to the original surface.

A seam about 0.001 in. deep, found in a photomicrograph of the 0.225-in. wire, shown in Fig. 9, could not be located in other sections and therefore probably did not extend a great distance in the wire.

Fractures were examined directly and at about 10 magnifications. In general, inclusions, if present at the point of origin of the fatigue crack, were too small to be seen, but their presence was often indicated by a slight distortion of the fractured surface at this region, as it is known that the value of stress and its direction in the region of a cavity are largely determined by the shape of the cavity. Some individual specimens which did not show up well in the fatigue tests showed failure to have begun at an inclusion or seam as, for example, specimens Nos. 350 and 221, shown in Figs. 25 and 27, respectively. A few cross-sections of failed specimens were polished and examined at 100 magnifications for cracks without success.

The clear length between grips of torsion specimens was determined by the maximum angular travel of the oscillating chuck, and the stress range desired for the individual specimen. Values of length L used in the tests were approximately as follows:

Wire diameter, in.	L
0.125	$^5/_8 \pm {}^1/_8$
0.187	$^3/_4 \pm {}^1/_8$
0.225	$^7/_8 \pm {}^1/_4$

Specimens were cut to a length of about $4^1/_2$ in. and prepared with either cast ends or split bushings as previously described.

In the early tests on 0.225 in. wire, it was used just as it came from the coil, having a slight natural curvature. In all later tests, for convenience, the wire was hand-straightened by being bent in opposition to this natural curvature. Residual stresses were no doubt present in both cases.

Care was taken not to scratch the wire in preparing specimens, as it was found that scratches were often, though not always, the points at which the deciding fatigue crack started.

Specimens were mounted in the testing machine which was started at approximately the desired stress range. By adjustment of the angular travel of the oscillating grip the desired stress range would be obtained in a few thousand stress cycles. Adjustments were made as required to maintain a fairly constant range.

In general, a point on the fatigue diagrams of Figs. 17 to 23 represent a stress cycle which did not vary more than ±5 per

cent. Error in reading torque was about 0.5 per cent, and the error in initial calibration is estimated at 0.5 per cent.

Torsion stresses were calculated by the formula

$$\text{Maximum shear stress} = \frac{5.1 \times (\text{maximum twisting moment})}{\text{Diameter}^3}$$

Bending stresses were calculated by the formula

$$\text{Maximum bending stress} = \frac{10.2 \times (\text{maximum bending moment})}{\text{Diameter}^3}$$

Because of its possible effect on the relative strength in torsion and bending fatigue, the presence of residual stress in the wire was verified experimentally. The method neglects any circumferential stress which may be present and, therefore, at best is only approximate. A flat surface about $^1/_{32}$ in. wide was ground on one side of a length of wire and the change in curvature of the wire noted. From the change in curvature and the calculated segmented area of the portion removed the longitudinal stress in the surface material can be found. A change of curvature in one direction indicates a tension stress, while a change in the opposite direction indicates a compression stress.

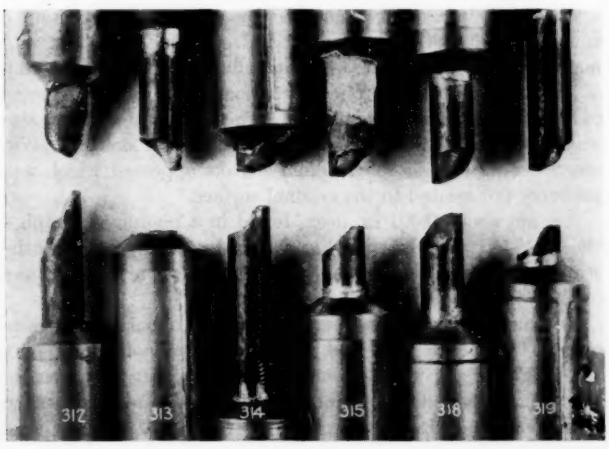

FIG. 24 TYPICAL FATIGUE FRACTURES OF 0.225-IN. WIRE TESTED IN ALTERNATING TORSION. WIRE USED IN AS-RECEIVED CONDITION

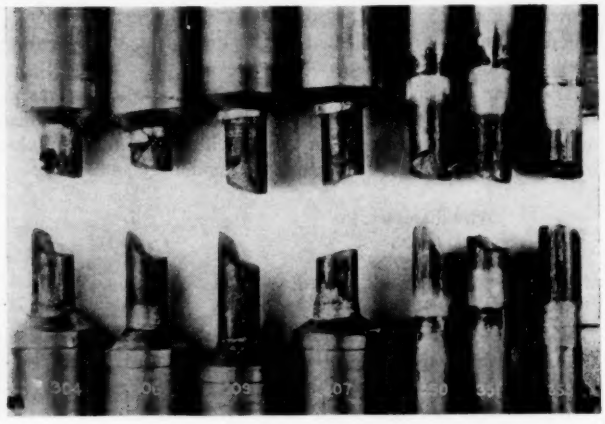

FIG. 25 TYPICAL FATIGUE FRACTURES OF 0.225-IN. WIRE TESTED IN ZERO-TO-MAXIMUM TORSION. WIRE USED IN AS-RECEIVED CONDITION

Measurements were made on straight pieces of wire in different conditions and on half-coils of wire specially prepared for the measurement of coiling stresses. Fig. 30 shows the device for measuring the coiling stresses with a half coil clamped in position and an ordinary micrometer arranged to measure deflections. Contact was determined by the use of ear phones and a battery circuit.

Where residual stress values are given, the possible error might easily be ±50 per cent although the figures given are averages of 2 to 4 separate determinations which usually agreed within ±25 per cent. Measurements of coiling stresses were made in a limited time and only relative values of stresses are available.

6—RESULTS OF TESTS

The results of tests on 0.225-in. and 0.187-in. wire are plotted as stress against the logarithm of the number of repetitions to failures on the S-N diagrams of Figs. 17 to 23. Fractures which occurred away from the ends are indicated by circles while specimens which did not fracture are indicated by a circle and an arrow. In some cases, since they provide useful information, fractures which occurred at or near the grips are included, and are indicated by triangles.

RESULTS OF TESTS ON 0.125-IN. WIRE AS RECEIVED

A complete series of tests was not made on 0.125-in. wire as received, but the results of tests on two specimens give some idea of the fatigue strength in a zero-to-maximum torsion stress cycle. One specimen without failure withstood 15 million repetitions of a stress cycle which at the beginning of the test was from zero to 125,000 lb per sq in., at 10 million zero to 107,000 lb per sq in., and at 15 million zero to 106,000 lb per sq in.

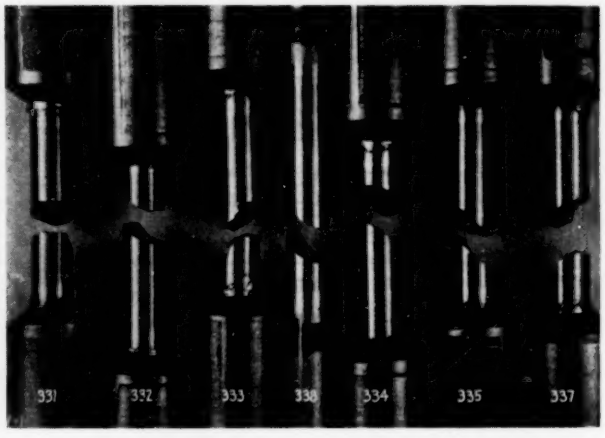

FIG. 26 TYPICAL FATIGUE FRACTURES OF 0.221-IN. CENTERLESS-GROUND WIRE TESTED IN ALTERNATING TORSION

Another specimen broke after 5.7 million repetitions of a stress cycle which at the beginning of test was from zero to 124,000 lb per sq in., at 0.26 million cycles it was from zero to 116,000 lb per sq in., and at the end of the test it was from zero to 113,000 lb per sq in.

From these two tests the zero-to-maximum torsion endurance limit for 0.125 in. wire as received may be estimated at something over 110,000 lb per sq in.

RESULTS OF TESTS ON 0.225-IN. WIRE AS RECEIVED

The bending fatigue results show little scatter, as seen from the curves in Fig. 17, and give a smooth curve, with the endurance limit at 67,000 lb per sq in. which is 33 per cent of the ultimate

strength of 204,000 lb per sq in. Reversed torsion tests show an endurance limit of 56,000 lb per sq in. which is 34 per cent of the ultimate torsional strength of 166,000 lb per sq in. Bending fractures shown in Fig. 29*a* were smooth and showed clean material. Torsion fractures also were all in homogeneous material, the crack starting at about 45 deg to the axis forming two roughly symmetrical fractured surfaces as shown in Fig. 24. Reversed torsion endurance limit is 0.84 times the reversed bending endurance limit.

Zero-to-maximum torsion tests showed an endurance limit of 100,000 lb per sq in. as observed from Fig. 18. Fractures of this specimen, shown in Fig. 25 were unsymmetrical and of a different type. The fatigue crack started at about 45 deg and curved around the specimen in circumferential and longitudinal directions. Specimen No. 350 gave a point well off the curve and the position of the surface flaw responsible for failure can be seen in Fig. 25. Fractures otherwise showed clean material.

Tests of 0.225-In. Wire Reduced to 0.221 In. in a Centerless Grinder

This series of tests was run to determine the effect of a surface-grinding treatment which might be commercially practicable. A single pass across a 60-grit wheel was used. The surface though smooth in appearance was considerably coarser than a surface polished with No. 1 emery paper. It was found that due to slight curvature of the wire before grinding, a variable thickness

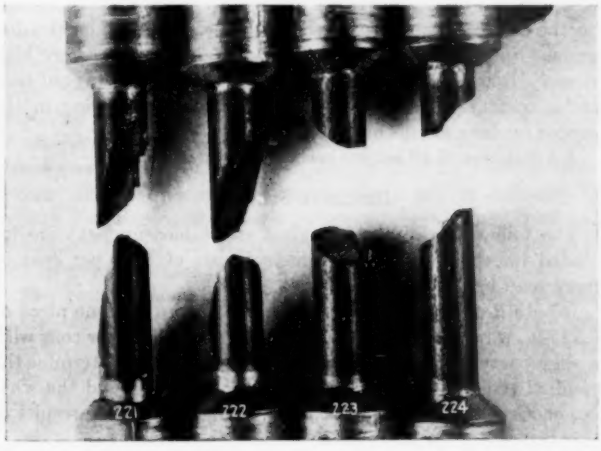

Fig. 27 Typical Fatigue Fractures of 0.187-In. Wire Tested in Alternating Torsion. Wire Used in As-Received Condition

of layer was removed. Only specimens which had "cleaned up" all over were tested.

Fatigue curves for this test are shown in Fig. 19. The bending endurance limit is 81,000 lb per sq in., an increase of 21 per cent over the value for wire as received, in spite of the fact that grinding marks are circumferential. Bending fractures of the specimens used in this test, shown in Fig. 29*b*, are seen to be slightly stepped and ragged, and are not as clean cut as for the as-received wire.

The endurance limit in reversed torsion from the curve in Fig. 19 is 54,000 lb per sq in., which is 4 per cent lower than the value for as-received wire and 0.67 times the reversed bending endurance limit of ground wire. Fractures occur at 4½, 6, and 13 million cycles, and the curve does not become horizontal until about 10 million cycles are reached.

The "delayed fractures" of French (34) and Jünger (35) are suggested by these results. French found that fractures occurred after 10 million cycles in nickel steels harder than about 45–50 Rockwell *C*, but not in steels with lower Rockwell values. Removal of the soft outer surface may leave a surface which is in the hardness range where delayed fractures occur, and the usual test to 10 million cycles is not sufficient. Also the grinding marks might provide stress concentrations and cause delayed fractures such as Jünger observed. These effects are not present in the bending fatigue curve, however.

An examination of the fractured torsion specimens showed that a cross-section of specimen No. 330 revealed no cracks or seams. The fractured surface was stepped and a crack extended at about 45 deg into the metal, suggesting the presence of an inclusion. Specimens Nos. 332, 333, 334, 335, and 337, Fig. 26, showed slight irregularities on the fractured surface at the region of crack formation which might have been flaws, whose effect was accentuated in some manner by the grinding.

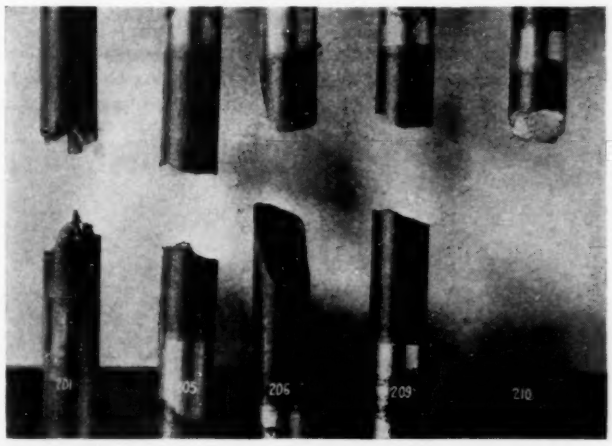

Fig. 28 Fatigue Fractures of 0.187-In. Wire Tested in Zero-to-Maximum Torsion. Wire Used in As-Received Condition

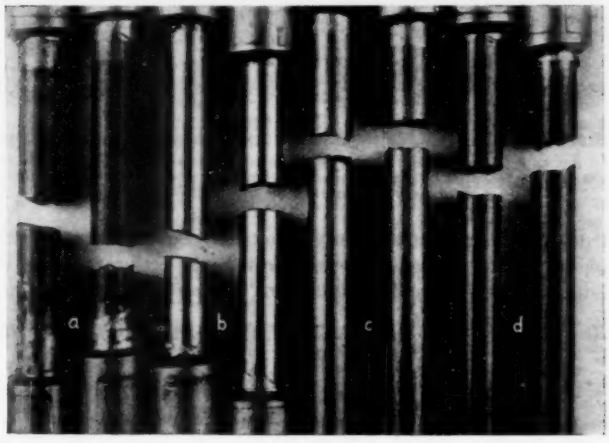

Fig. 29 Typical Bending Fatigue Fractures of 0.225-In. Wire. (*a*) As-Received Condition; (*b*) Ground to 0.221 In. Diameter; (*c*) Shot-Blasted Condition; (*d*) Shot-Blasted and Blued Condition

Results of Tests on 0.225-In. Shot-Blasted Wire

Wire in the as-received condition was shot-blasted in a standard revolving drum for 25 min with air at a pressure between 70–75 lb per sq in.

The reversed bending endurance limit as shown by the curve in Fig. 20 was 85,000 lb per sq in. which is 27 per cent higher than for wire as received. Bending fractures of the specimens are shown in Fig. 29*c*.

[a] Based upon 10 million stress reversals.
[b] Wire tested in as-received condition.
[c] Wire ground to size from 0.225 in. diameter with No. 60 grit.
[d] Wire shot-blasted before testing.
[e] Wire shot-blasted and blued before testing.

All torsion fractures occurred at or near the grips and these are shown on the diagram in Fig. 20 by triangles. One specimen ran 10 million cycles at 61,500 lb per sq in. without fracture. The

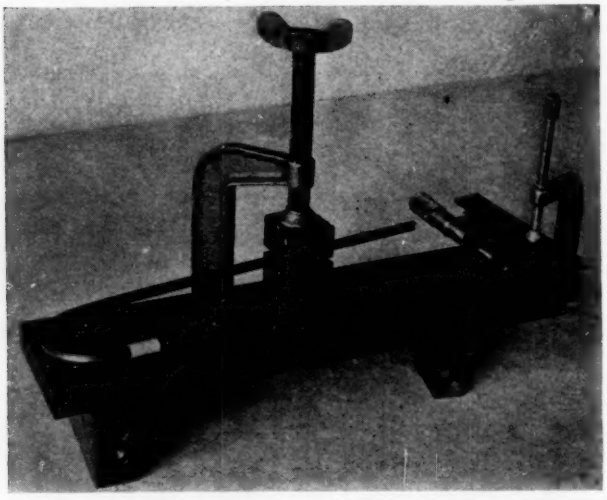

FIG. 30 DEVICE FOR MEASURING COILING STRESSES IN A HALF-COIL
(A flat spot is ground on the inner surface of the coil and the deflection of the arm is measured by a micrometer. Earphones and a battery circuit are used to record contact at the micrometer.)

true fatigue curve will lie above the triangular points in Fig. 20 representing fracture at the grips so that the endurance limit is estimated to be an unknown amount above 61,500 lb per sq in.

RESULTS OF TESTS ON 0.225-IN. SHOT-BLASTED-AND-BLUED WIRE

After shot-blasting the specimens were blued at 500 F for 30 minutes in a Homo furnace and cooled in the furnace.

The bending-endurance limit shown by the curve in Fig. 21 is 83,000 lb per sq in. which is about 24 per cent greater than for wire as received. Fractures were slightly irregular but clean, and are shown by the specimens in Fig. 29*d*.

Only two reversed-torsion specimens fractured clear of the grips although some of the other fractures started clear of the grips and extended to them. None of the specimens ran 10 million cycles without fracture, but the endurance limit is probably above 65,000 lb per sq in.

RESULTS OF TESTS ON 0.187-IN. WIRE AS RECEIVED

The bending fatigue limit for 0.187-in. wire as-received is shown on the curve in Fig. 22 to be 67,000 lb per sq in., which is about 32 per cent of the ultimate strength of 211,000 lb per sq in.

Seven points are shown for the reversed-torsion endurance curve, two of which represent failure at the grips. No specimen ran through 10 million cycles without failure, up to the time of making the diagram, but the endurance limit is very probably at 60,000 lb per sq in., which is 0.90 times the reversed bending endurance limit, and 37 per cent of the ultimate torsional strength.

Some torsion fractures of the 0.187-in. specimens are shown in Fig. 27. Specimen No. 221 failed at a longitudinal surface flaw or inclusion about 0.04 in. long. Two diagonal cracks are seen extending from the points of stress concentration at each end of the flaw.

The curve for zero-to-maximum torsion tests on 0.187 in. wire is shown in Fig. 23. One specimen was unbroken after 10 million reversals at 105,000 lb per sq in. A greater number of significant points was not obtained because of difficulties encountered with seizing of the copper-bushing to the wire thereby increasing the stress range in an erratic manner. The endurance limit is estimated at 107,000 lb per sq in. Specimen No. 210 failed clear of the grips but a radial crack about 0.03 in. long could be seen on the fractured surface, which explains the position on the diagram. Specimen No. 201 was accidentally run at a very high stress. Fracture started at many points forming a ragged cone and a conical hollow. There was considerable slipping in the copper bushing at this high stress.

A tabulation of all fatigue results is given in Table 3.

RESIDUAL STRESSES

The following results of residual stress measurement are included for their suggestive value. Errors of ±50 per cent or more may be present.

(*a*) *As Received.* One piece of 0.187-in. wire and one piece of 0.225-in. wire, just as they came off the 36-in. diameter coils with a slight permanent set or curvature, were used to determine the residual stress along four edges spaced 90 deg around the wire. No check measurements were made in this case. The results of this test are given in Table 4.

TABLE 4 LONGITUDINAL RESIDUAL STRESSES IN WIRE AS RECEIVED[a]

Diameter of wire, in.	0.187	0.225
Kind and location of stress:		
Inside edge of coil, tension	180,000	90,000
Outside edge of coil, compression	70,000	120,000
Flat side (1), tension	40,000	30,000
Flat side (2), tension	15,000	20,000

[a] All values in lb per sq in.

The results in Table 4 show very well that even coiling to 36 in. diameter leaves large tensile stresses at the inside of the coil and corresponding compression stresses at the outside. The averages of the values measured along the two flat sides are approximately 25,000 lb per sq in. in both cases, which is probably not sufficient to materially affect fatigue strength (29).

(*b*) *Ground 0.221-In. Diameter Wire.* Measurements on three samples of this wire were erratic and gave compressive longitudinal stresses from 0 to 8000 lb per sq in. The fact that an uneven thickness of layer was removed will explain the variation in stress measurements.

(*c*) *Shot-Blasted 0.225-In. Diameter Wire.* Measurements on three samples gave values of longitudinal compressive stress which were within ±12 per cent of 165,000 lb per sq in.

(*d*) *Shot-Blasted and Blued 0.225-In. Diameter Wire.* Three measurements gave values of longitudinal compression within ±14 per cent of 27,600 lb per sq in. The bluing treatment reduced shot-blasting stresses to one-sixth their value.

(*e*) *Measurements on Fatigue Specimens.* Bending specimen No. 611, made of 0.225-in. diameter as-received wire, after 10 million reversals at 67,000 lb per sq in., showed an average value of longitudinal tension stress, for four sides of the wire of 73,000 lb per sq in. No other specimens were available to check this result which would indicate that residual tension stresses from tempering do not disappear under fatigue loading, and may, therefore, have an effect on the fatigue strength.

Bending specimen No. 642 of shot-blasted wire had run 13 million reversals at 85,000 lb per sq in. The only two measurements obtained on this specimen were zero and 56,000 lb per sq in. longitudinal compressive stress. No other specimens were available for check measurements. It would appear that the heavy compressive stress due to shot-blasting does not remain under fatigue stressing and consequently tests to 20 or 30 million cycles might give lower fatigue values than those obtained.

(*f*) *Coiling Stresses.* After coiling as-received wire in a 2-in. diameter coil, heavy residual longitudinal tensile and compressive stresses were present on the inside and outside of the coil, respectively. Bluing reduced these stresses to about one-third their original value, but they were still appreciable in magnitude.

7—CONCLUSION

The zero-to-maximum torsion endurance limits of 110,000, 107,000, and 100,000 lb per sq in. for as-received wire are about 70 per cent higher than the values of 68,000 and 58,000 lb per sq in. estimated from the results of experiments on completed springs of similar material by F. P. Zimmerli (12). Residual tension stresses at the inside of the coils, even if they were shown to be present after the bluing treatments, would not be sufficient to explain such large differences in fatigue strengths, as Buehler and Buchholtz' results (29) show variations of only 15 or 20 per cent due to internal stress.

The results given in this paper may be considered as ideal values as it is possible to attain if no serious flaws are present. The twelve 0.225-in. specimens tested in zero-to-maximum torsion, the results of which are plotted in Fig. 18, represent a total length of not over 12 in. of wire actually submitted to the repeated stressing. In a single complete spring, possibly 40 in. of wire would be under test and if there were only one flaw in each spring such as that in specimen No. 350, indicated in Fig. 18, it is obvious that lower fatigue values would be obtained in the tests on complete springs. The only remedy for such a condition would be the elimination of all serious flaws in the material.

Comparison may also be made with Swan, Sutton, and Douglas torsion results (11) on straight specimens of 0.182-in. diameter tempered Swedish wire with natural surface. The present zero-to-maximum value of 110,000 lb per sq in. for 0.125 in. wire is about 70 per cent higher than the results of their tests which were made at a ratio of minimum-to-maximum stress of 1:4.

The consistently high values of torsion endurance limit obtained for three sizes of wire in the experiments reported in this paper might suggest the presence of some consistent error in the work. However, the tests were made on three machines which were separately calibrated statically; calibration factors agreed closely and test results for the same wire on different machines were consistent among themselves.

Although ratios of reversed-torsion fatigue strength and of zero-to-maximum torsion fatigue strength to reversed-bending fatigue strength have been obtained for 0.187 in. and 0.225 in. wires and given in Table 3, it has not been possible to correlate these ratios with the factors which largely determine them, such as the shape of inclusions and of surface flaws. The extent and relative effect on bending and torsion fatigue strengths of anisotropy due to the drawing process has not been investigated. The effect of residual stress, if present, on the ratio of bending and torsion fatigue strengths would appear to call for investigation. Until information is available in the directions indicated it is not apparent that the bending fatigue strength of a wire will be a certain measure of the torsion fatigue strength of that wire.

Acknowledgment

The tests reported in this paper were sponsored by the A.S.M.E. Special Research Committee on Mechanical Springs, and were carried out through the Engineering Research Department of the University of Michigan, Ann Arbor. Acknowledgment is here made to members of the subcommittee, in particular to F. P. Zimmerli, to Profs. A. E. White and E. L. Eriksen for assistance of various kind, and to Prof. S. Timoshenko for helpful criticism and suggestions. Full responsibility for results or statements, however, is taken by the author.

Evaluation of Effective Radiant Heating Surface and Application of the Stefan-Boltzman Law to Heat Absorption in Boiler Furnaces

By H. F. MULLIKIN,[1] NEW YORK, N. Y.

In the first section of this paper a method has been developed for converting well-known types of furnace heat-absorbing surfaces into an equivalent effective radiant heating surface. It concerns the evaluation of this effective radiant heating surface as controlled by (1) various spacings of waterwall tubes, (2) various kinds of blocks on the waterwall tubes, (3) various amounts of slag on the waterwall tubes or blocks, and (4) the emissivity of the waterwall surface exposed to the flame. The second section deals with the fraction of heat supplied to the furnace that is given up by the gases in the furnace which is solved most simply and practically by the use of the Stefan-Boltzman radiation law.

Results computed in this manner have been compared with results reported in a paper entitled, "An Experimental Investigation of Heat Absorption in Boiler Furnaces."[2] It is found that for large pulverized coal, and oil-fired and gas-fired furnaces, the assumption of an effective furnace emissivity of unity leads to results which are in substantial agreement with experimental data. For stoker-fired furnaces in general, the effective furnace emissivity appears to be less than unity.

1—EFFECTIVE RADIANT HEATING SURFACE

OF THE number of methods offered for the evaluation of effective radiant heating surface in steam-boiler furnaces, the most logical method appears to be that involving in part the work of Hottel.[3,4] Briefly this method is based on the fact that radiant-heat transmission is governed by the laws of absorption and reflection. Thus, Lambert's cosine law is applicable, that is, a rough or corrugated "black" surface will not receive any more radiant heat than a similar plane or flat surface. Although this principle has been contested by some investigators it is generally accepted.

In this work we are interested in the areas in so far as they effect the radiant-heat transfer. Therefore, we may adopt as a standard unit of area, a square foot of effective radiant heating surface (water- or steam-cooled surface) which absorbs a maximum amount of radiant heat. If our premises are based on the Stefan-Boltzman law this unit square foot of radiant heating surface must necessarily be defined as a square foot of plane surface, perfectly clean, having an emissivity of unity, and so cooled by water or steam that its temperature is not greater than that of the water or steam which is cooling it and absorbing heat.

Radiation to this unit surface from a black body or unity emissive surface at various temperatures will be as shown in Fig. 1 which was derived from the Stefan-Boltzman law. This curve does not change appreciably for temperatures of the absorbing radiant heating surface varying from 0 to 1000 F abs. Hence, the standard unit square foot of effective radiant heating surface may be further defined as that square foot of surface which would absorb an amount of heat as indicated by Fig. 1 when receiving radiation from a black-body source at the given temperature.

Using this latter definition, any area having less radiant-heat absorption per square foot may be converted into an equivalent smaller area having the defined unit radiant-heat absorption per square foot by the use of multiplying terms which take into account the divergence of the conditions of the actual surface from those of the theoretically defined surface.

In practice, radiant-heat surfaces differ from the defined unit surface in that they are formed of metal tubes, often spaced at intervals, separated by refractory, and perhaps are covered by steel, cast-iron, or refractory-faced blocks. Various amounts of slag will form on the surfaces thus causing them to be less effective in absorbing heat. In addition the surfaces will have an emissivity less than unity.

If A is the projected overall waterwall area under these latter conditions and A_{rhs} is the effective radiant heating surface as defined, then

$$A_{rhs} = AF_AF_CF_SF_E \quad [1]$$

where F_A is an area factor, F_C is an average conductivity factor, F_S is a slag factor, and F_E is an emissivity factor.

The area factor F_A is used to reduce overall surface to an equivalent effective radiant surface, assuming the surfaces clean and of perfect heat conductivity. The average conductivity factor F_C is used to take into account the fact that for refractory-

Contributed by the Special Research Committee on Absorption of Radiant Heat in Boiler Furnaces for presentation at the Annual Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS to be held in New York, N. Y., December 2 to 6, 1935.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until January 10, 1936, for publication at a later date.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

faced blocks the heat absorbed by the waterwall is less than for blocks consisting of a material of perfect heat conductivity. That is, if a refractory face on a 1-sq ft block diminishes the heat transfer one-half, this surface is equivalent to 0.5 sq ft of defined effective radiant heating surface. It can be shown that this F_C-factor varies with furnace temperature. In this paper, however, a mean value for the average furnace temperature has been assumed. The value will be sufficiently correct for the

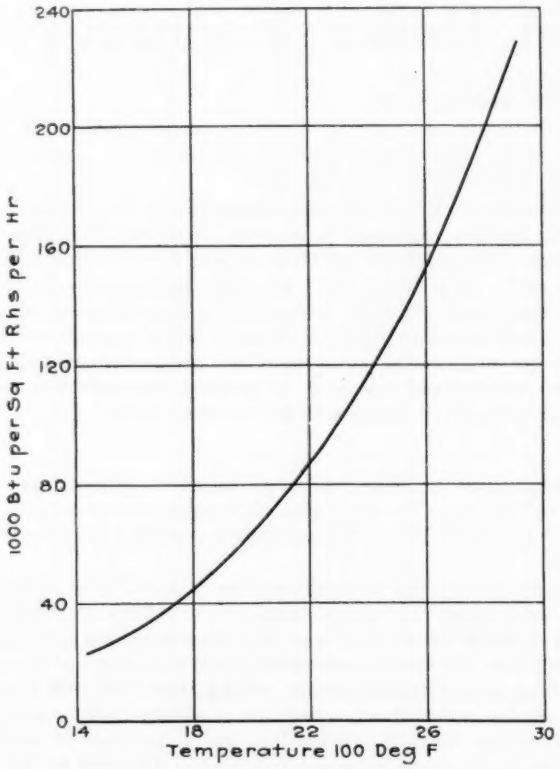

FIG. 1 RADIATION BASED ON THE STEFAN-BOLTZMAN LAW. EMISSIVITY = 1

present until more data becomes available. The slag factor F_S is similar to F_C, but is dependent for its value on the thickness of slag present. The emissivity factor F_E is used to take into account the fact that the emissivity of the surface is less than unity.

Thus, effective radiant heating surfaces are computed on a basis of radiant-heat-absorbing ability, and all furnace waterwalls, no matter what their construction, may be reduced to a number of defined unit effective radiant heating square feet of surface by suitable selection of correction factors.

AREA FACTOR F_A

The selection of these factors must be based upon existing data. Values of F_A may be mathematically calculated for all shapes and constructions of waterwalls. Fig. 2 shows curves taken from Hottel[3] for various bare-tube arrangements. Ordinarily curve 2, Fig. 2, is the only curve of those given that is used to determine F_A in boiler furnaces. The curves hold without significant error for all values of the dimension T for one row of tubes from zero to infinity.

The foregoing is applicable to completely bare tubes. Occasionally it is necessary to obtain F_A-values for bare tubes half recessed in refractory. It is necessary to solve for this separately using the method of Hottel as given in Fig. 4 of his first paper,[3] which will not be dealt with here. However, it is readily possible to draw up a curve similar to Fig. 2 for this special case.

Fin tubes may be handled in the same way when recessed in refractory and when the fins do not overlap or touch each other as is sometimes the case. Here the edges of the fins are to be considered as the heat-absorbing surface extremities. If these fin tubes are located at a distance from a refractory wall, Fig. 2 would be used. The heat-transfer coefficient of the metal of the fins is assumed to be sufficiently great so that the fins absorb as much heat per unit of exposed area as the tube wall does. This assumption is open to question but is adopted in view of the lack of data indicating otherwise. On this basis a fin tube has an effective diameter equal to the distance between the extreme edges of the fins. Where the tubes or fins touch each other, F_A must equal unity as L/D in Fig. 2 will equal unity.

For reasons similar to those stated for the fins of fin tubes, bolted-on or shrunk-on metal blocks with either plain or refractory faces have been assumed to have an effective area equal to the area of the face of the block. Where the blocks are adjacent to each other, F_A is equal to unity. The reduction in heat transfer caused by the joint between the block and the tube is taken into account in the F_C-factor.

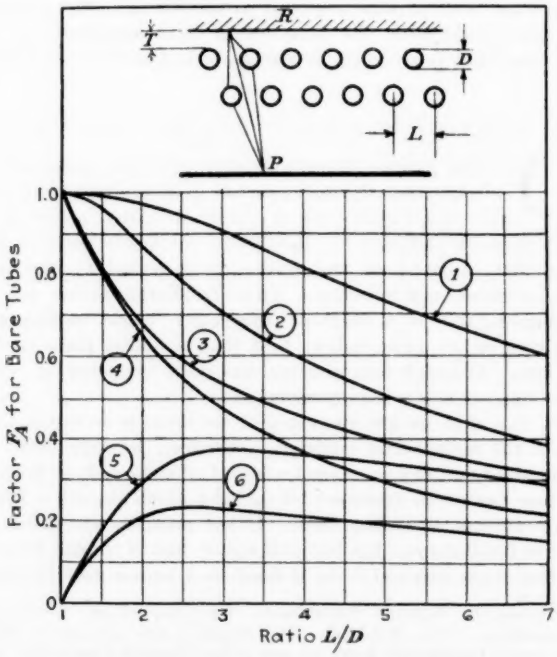

FIG. 2 VALUES OF THE F_A-FACTOR FOR BARE TUBES. THESE VALUES HOLD FOR ALL VALUES OF T WITHOUT APPRECIABLE ERROR

(Curve 1—total to two rows when two are present. Curve 2—total to one row when only one is present. Curve 3—total to first row when two are present. Curve 4—direct to first row. Curve 5—total to second row when two are present. Curve 6—direct to second row. R denotes refractory. P denotes radiating plane. When two rows are present they are spaced so that the tubes form equilateral triangles. The tubes are considered to be perfect absorbers. The curves give the fraction (F_A) of total plane incident radiation absorbed either by the total tube, including reradiation, or by the tube directly, excluding reradiation by the refractory. For ordinary boiler-furnace calculations curve 2 only is used.)

The factor F_A is most simply defined as that factor by which it is necessary to multiply projected overall clean waterwall surface (including perfect conducting tubes and exposed refractory between the tubes) in order to obtain the effective exposed radiant surface. This effective surface is not appreciably different from the projected tube surface except where there are reradiating refractory walls in back of the waterwall tubes.

Conductivity Factor F_C

The conductivity factor F_C is introduced to take care of the heat resistivity of the wall. This factor is necessary because, although exposed areas of a bare metal block and a refractory-faced metal block may be equal, i.e., F_A is identical, these areas will absorb different amounts of heat by radiation from the furnace. Therefore, F_C is a ratio between the actual heat conducted and the maximum amount of heat that could be conducted, other conditions remaining constant.

E. G. Bailey[5] has given some figures indicating that the comparative heat-transfer rates of type-*BAG* refractory-faced blocks and type-*C* bare-faced blocks are 50,000 and 70,000 Btu per sq ft per hr. Thus F_C would be equal to 50,000/70,000 or 0.71. Other published material[6] and experimental data which cannot be included here would indicate that this value of the F_C-factor is somewhat high. After careful consideration of the meager data available the values of F_C in Table 1 were adopted.

TABLE 1 CONDUCTIVITY FACTORS

Type of surface	F_C
Bare tubes	1.00
Fin tubes	1.00
Bare-faced metal blocks on tubes	0.70
Refractory-faced metal blocks on tubes, type-*BAG*	0.35

Theoretically, F_C varies with furnace temperature but this correction is omitted as the present knowledge of the effect of refractory on waterwalls is so scanty as to render small corrections unimportant. There is urgent need of laboratory experiments to establish the F_C-values more correctly than the approximations given in this paper.

Slag Factor F_S

The slag factor F_S is introduced to take care of the reduced heat absorption of waterwalls due to accumulated slag. It is similar to the conductivity factor in its variation with furnace temperature, but in view of the meager data this correction seems superfluous. When the boiler furnace is first operated, F_S is equal to unity, it being assumed that the surfaces are uncoated with slag. During the course of time slag will build up on the waterwall surface until a certain average equilibrium thickness is reached. Therefore, it is possible to compute by the use of F_S the difference in heat-absorbing capacity of a boiler furnace when initially started and when operated under known conditions of wall cleanness.

The literature is almost devoid of data on this phase of the subject. Some information was obtained from two boiler tests[7] run under the direction of the A.S.M.E. Radiation Committee. In a stoker-fired boiler, in which the waterwall tubes comprise a separate screen boiler, records were available to show the amount by which the proportional evaporation of the screen boiler had been reduced from five days after initial operation up to 18 months after initial operation. While reliable records over such a period of time were not available for a pulverized-fuel-fired boiler having a similar separate screen boiler, a separate test was run on this boiler for which the slag was completely cleaned off of the side-wall tubes and the tubes wire-brushed to assure cleanness. Fig. 3 has been plotted from the results and is used to determine this slag factor. The derivation of these curves and the special case where bare tubes are located entirely in front of refractory are discussed in the Appendix to this paper.

[5] "Some Factors in Furnace Design for High Capacity," by E. G. Bailey, Trans. A.S.M.E., vol. 49–50, 1927–1928, paper FSP-50-78, p. 253.

[6] "Water-Cooled Furnaces for Underfeed Stokers," by O. De Lorenzi, *Combustion*, vol. 3 (new notation), May, 1932, p. 15.

Emissivity Factor F_E

There are very few data upon which the value of the emissivity factor F_E may be based for conditions as they exist within furnaces. This factor, as used by some investigators, was not

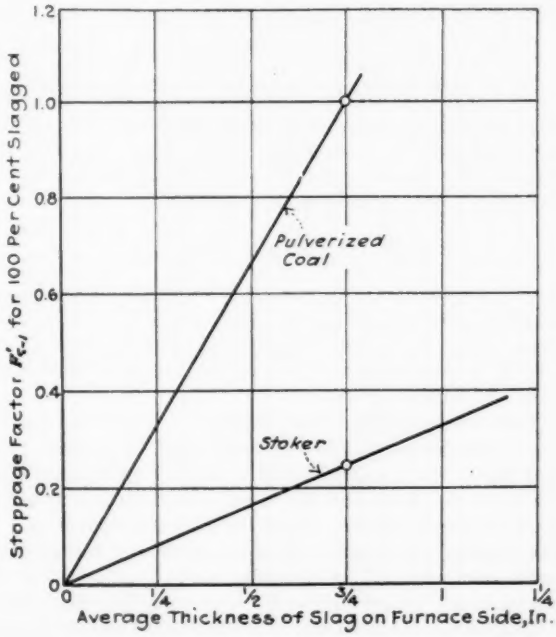

Fig. 3 Determinations of Slag Factor F_S
(For tubes half embedded in refractory, fin tubes, or waterwall block tubes, $F_S = (1 - xF'_{S-1})$ where x = fraction of the front of the tube that is slagged.)

clearly differentiated from the F_A-, F_C-, and F_S-factors, hence their data cannot be used. Wohlenberg has used a value of 0.95. There is every reason to believe that this factor is not far from unity.

Furnace Exit

Any radiant-heat ray from the furnace toward the exposed bottom boiler tubes at the furnace exit must strike tube surface, hence F_A will be unity. When these tubes are of the ordinary bare type, F_C is unity. The factor F_S may also be taken as unity when the tubes are relatively free of slag. Under these conditions the effective radiant heating surface A_{rhs} of the furnace exit will be equal to the product of the width and length of the tube bank.

In the special case of the double-ended boiler, it is obvious that the above will not hold. In this case it is suggested that the apex be considered nonexistent, that is, the area of the furnace exit be taken as the product of the length of the bottom side of the triangle of which the boiler tubes form two sides, and the width of the tube bank. The furnace volume used is then computed only up to this furnace exit.

Total Refractory Surface in the Furnace

Having obtained the effective radiant heating surface A_{rhs} by use of Equation [1], there will be an equivalent summation of areas A_{ref} defined by

$$A_{ref} = A - A_{rhs} \quad [2]$$

The area A_{ref} is not refractory surface in the ordinary sense, no effective radiant heating surface; but rather one which may be considered to be the surface equivalent of a summation of non-absorbing particles of refractory located among the waterwall tubes.

Here a new concept is offered. For calculation of the total exposed refractory surface in the furnace in order to determine the fraction cold, it would appear reasonable to add this refractory area to the pure refractory occurring in the furnace as such. Thus, the total refractory area in a furnace will be the sum of the areas of any purely refractory walls plus the value $(A - A_{rhs})$.

The Stefan-Boltzman Law and Furnace Emissivity

It is known that radiation from an absolutely "black" body follows the Stefan-Boltzman law as shown in Fig. 1 which is comparatively simple and, for a hot surface completely surrounded by a cold surface, is expressed by

$$R = ECS[(T_1/100)^4 - (T_2/100)^4] \quad [3]$$

where R = radiation, Btu per hr; C = black-body constant, 0.1723 Btu per sq ft per hr per (deg F abs)^4; S = area of hot surface, sq ft; E = effective emissivity, 1.00 for both surfaces black; T_1 = temperature of hot surface, F abs; T_2 = temperature of cold surface, F abs.

A furnace approximates these conditions only if the mass of hot gases or flames acts like a black body. To exactly what extent this is true is problematical. Small or microscopic black particles in the flame and the effect of reradiating refractory walls will cause the effective emissivity E to approach unity.

For purposes of simplification of the problem of furnace-heat-transfer calculation, T_1 of Equation [3] is taken equal to the furnace-exit gas temperature rather than a possibly higher mean radiating furnace temperature. Mathematically speaking, this is simply stating that the radiation of a body at a given temperature and given emissivity may be equal to that of the same body at a lower temperature and higher emissivity. Therefore, it is believed that the emissivity based on furnace-exit temperature may not be far from unity.

TABLE 2 EMISSIVITY DATA

Station no.	Location	Avg flame emissivity[a]	Remarks
1	Grate	1.00	250,000 lb per hr rating
1	Furnace	0.75	250,000 lb per hr rating
2	Middle furnace	1.00	Same at all loads
2	Top of furnace	0.80	Same at all loads
7	Middle furnace	1.00	Same at all loads
8	Middle furnace	0.68	Increases with load
10	Middle furnace	0.72	Same at all loads

[a] Calculated.

TABLE 3 CALCULATED EMISSIVITY OF PULVERIZED ILLINOIS COAL BURNED IN SPECIAL EXPERIMENTAL FURNACE

Distance from burner, ft	3.5	7.5	11.5
Emissivity, 10-ft flame depth	0.96	0.85	0.83
Emissivity, 20-ft flame depth	1.00	0.98	0.97

In regard to this particular matter the experimental data is not conclusive. Table 2 gives some results of calculation based on radiation pyrometer data taken in the course of the A.S.M.E. Radiation-Committee investigation.[2]

Table 3 contains some data given by Sherman.[7] Koessler[8]

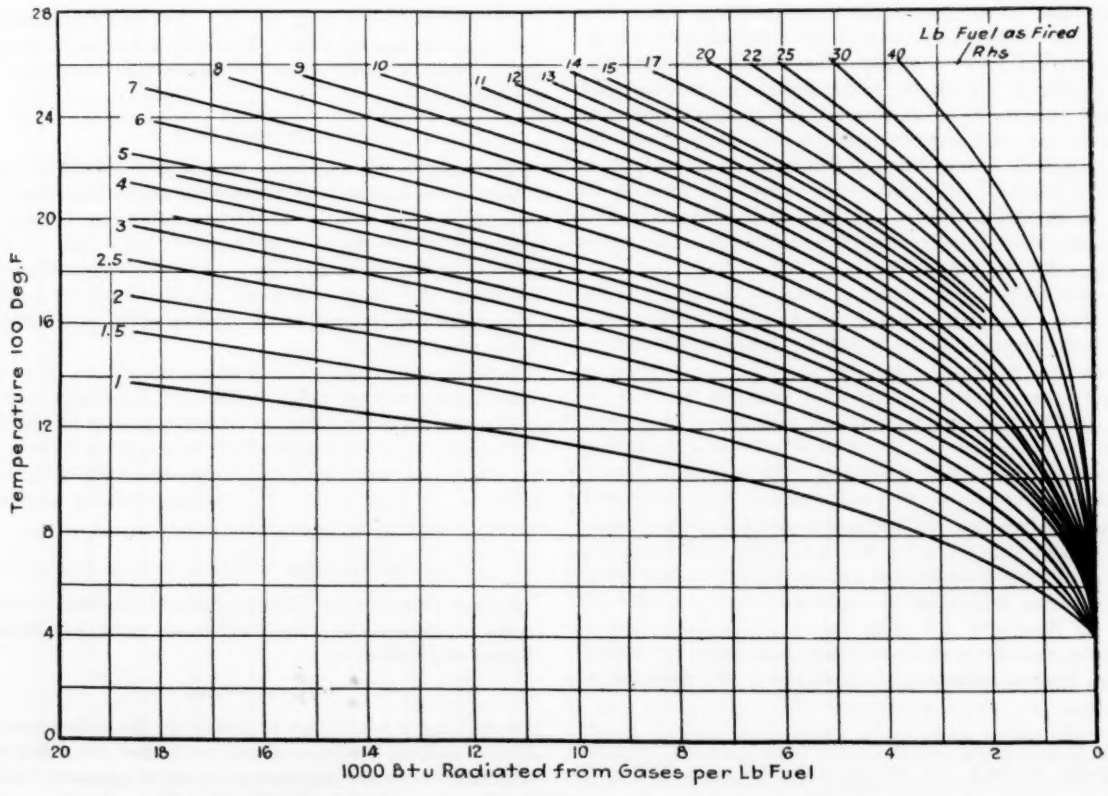

FIG. 4 HEAT RADIATED FROM GASES PER LB OF FUEL BURNED BASED ON THE STEFAN-BOLTZMAN LAW
(Lb fuel burned equals lb fuel as fired if consumption is assumed to be complete.)

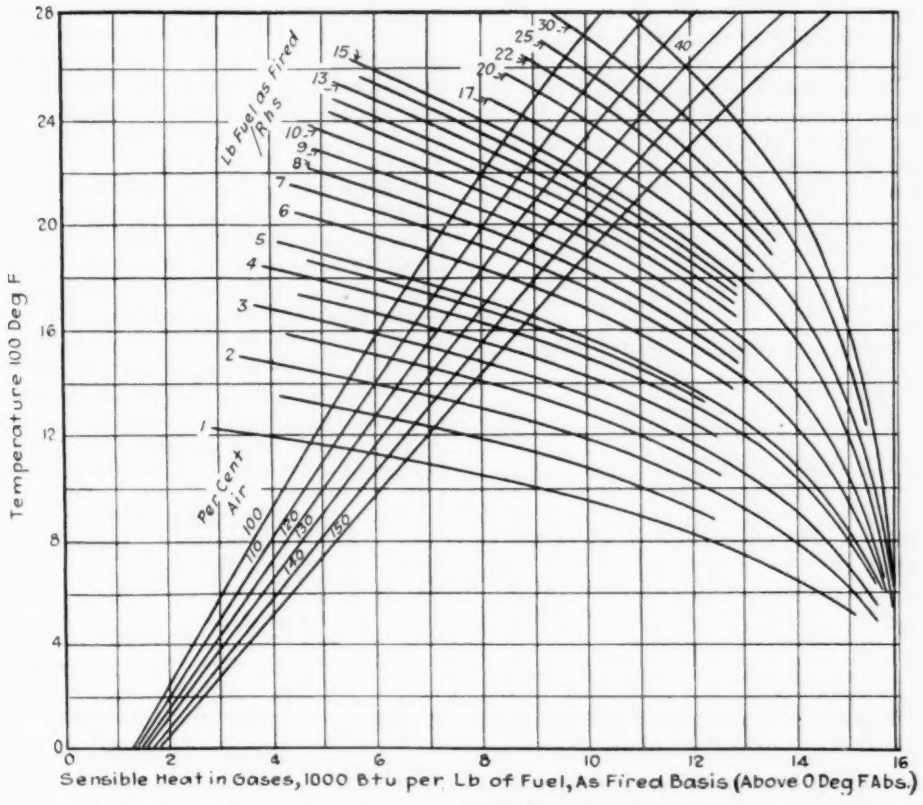

FIG. 6 CALCULATION OF μ_L BY MEANS OF THE METHOD ADVANCED IN THIS PAPER
(Example for test No. 1 on boiler No. 1 given in the A.S.M.E. Radiation-Committee report.[2])

has also given considerable data on several different types of furnace in which the values of emissivity very often reach unity. It is not possible to give his data here.

2—APPLICATION OF THE STEFAN-BOLTZMAN LAW TO FURNACE-HEAT-TRANSFER CALCULATIONS

Utilizing the preceding information, a method was developed for the solution of the problem of furnace radiation on the basis that each square foot of effective radiant heating surface will absorb heat according to the Stefan-Boltzman law using an emissivity of unity, and that the furnace-exit temperature may be used as the mean radiating furnace temperature.

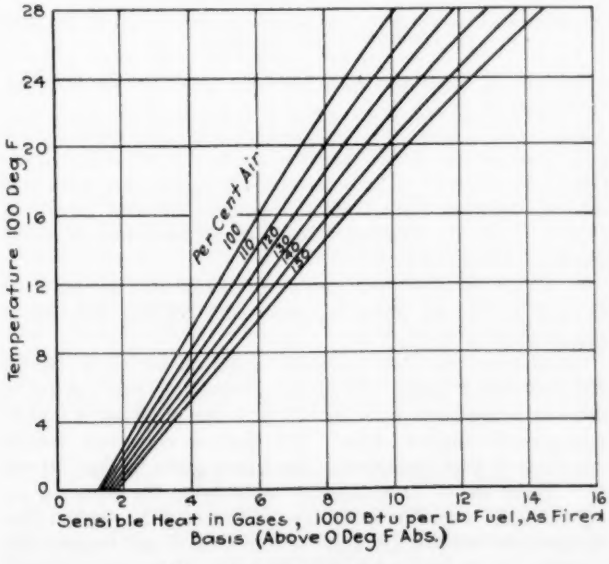

FIG. 5 HEAT-CAPACITY CURVES

Fundamentally, the relation between the radiation to the furnace walls, furnace temperature, and heat in the gases leaving the furnace, is based upon a furnace heat balance which may be expressed by

$$Q_U + Q_A = Q_R + (Q_{GF} - Q_G) \quad [4]$$

or

$$Q_U + Q_A + Q_G - Q_{GF} = Q_R \quad [5]$$

where Q_A = heat of preheated air, Q_G = heat of gases at 80 F, Q_{GF} = heat of gases at furnace temperature, Q_R = heat radiated, Q_U = low heat value of fuel. To make use of Equation [5], the effective radiant heating surface in the furnace must be determined according to the principles given in Part 1 of this paper.

It will be observed that the principal differences between the proposed method and older schemes of applying the Stefan-Boltzman law to furnace-heat-transfer calculations lie in the manner of evaluating effective radiant heating surfaces and in the use of an emissivity of unity. A third difference lies in the practical method of graphical calculation now to be explained.

In Fig. 1 furnace temperature is plotted against heat received by radiation per square foot of effective radiant heating surface. It is desirable to introduce the combustion rate expressed as pounds of fuel burned per square foot of effective radiant heating surface. Now

$$\frac{\text{(Heat radiated per hr/rhs)}}{\text{(Lb fuel burned per hr/rhs)}} = \frac{\text{heat radiated}}{\text{lb of fuel burned}} \quad [6]$$

By use of Fig. 1, Equation [6] and various values of pounds of fuel burned per square foot of effective radiant heating surface, the curves of Fig. 4 may be obtained. Since the effective radiant heating surfaces will absorb only a given amount of heat at any furnace temperature, this merely states that if the combustion rate is doubled only half as much heat can be absorbed per pound of fuel supplied. This will hold only if the furnace temperature remains the same. Actually the smaller quantity

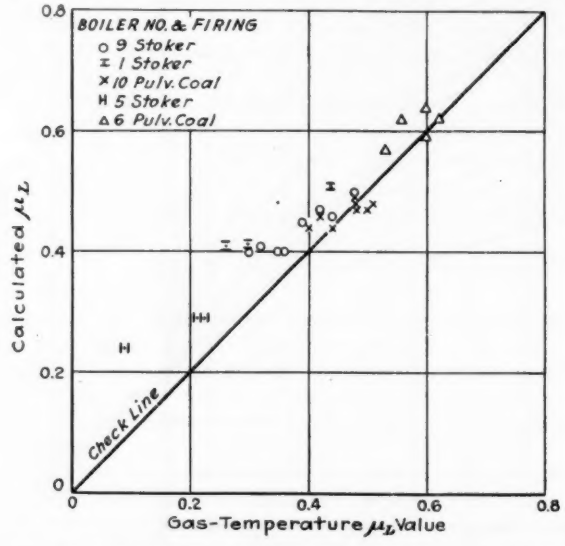

FIG. 7 COMPARISON BETWEEN RESULTS OBTAINED BY THE METHOD ADVANCED IN THIS PAPER AND THOSE OBTAINED FROM EXPERIMENTAL DATA

(Experimental data and boiler numbers are those given in the A.S.M.E. Radiation-Committee report.[2])

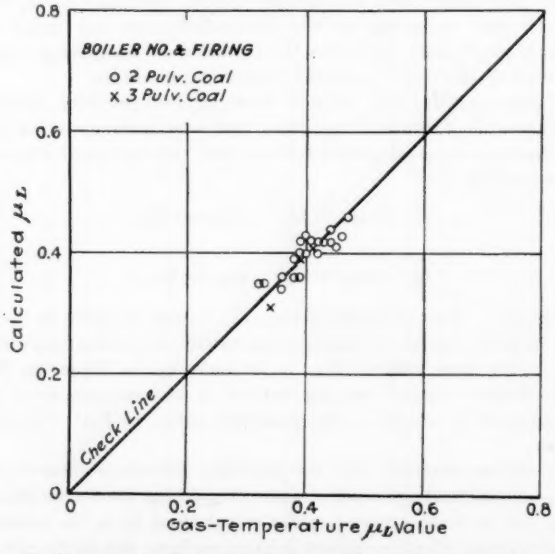

FIG. 8 COMPARISON BETWEEN RESULTS OBTAINED BY THE METHOD ADVANCED IN THIS PAPER AND THOSE OBTAINED FROM EXPERIMENTAL DATA

(Experimental data and boiler numbers are those given in the A.S.M.E. Radiation-Committee report.[2])

of heat absorbed by radiation causes the furnace temperature to rise and hence more heat will be radiated until a balance is reached.

To use Fig. 4 in calculations the procedure is as follows: Using a sensible-heat curve for the flue gases of the particular fuel, such as Fig. 5, the furnace temperature is found on both Figs. 4 and 5 such that the effective or low heat value per pound of wet fuel, plus the heat of preheat in the air, plus the heat in the gases of combustion at 80 F, all being the heat input per pound of wet fuel, minus the heat in the gases at the furnace temperature from Fig. 5, is equal to the heat radiated per pound of wet fuel in Fig. 4.

In order to eliminate the time involved in a trial-and-error solution, Fig. 4 should be drawn on tracing paper. It can then be superimposed on Fig. 5 as shown in Fig. 6, the origin on the heat-radiated curve being placed on the heat-capacity-curve base line at a value equal to the total heat input (using low heating value) to the furnace per pound of fuel as fired. At the intersection of the curve for per cent supplied air in the furnace and the curve for pounds of fuel per square foot of effective radiant heating surface, the furnace temperature, the heat in the gases at the furnace temperature, and the heat radiated may be obtained simultaneously. The value μ_L is then a ratio of the heat radiated to the heat input per pound of wet fuel, the

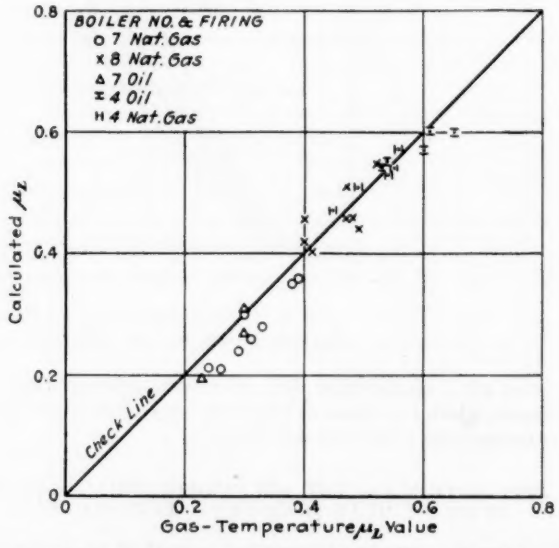

FIG. 9 COMPARISON BETWEEN RESULTS OBTAINED BY THE METHOD ADVANCED IN THIS PAPER AND THOSE OBTAINED FROM EXPERIMENTAL DATA

(Experimental data and boiler numbers are those given in the A.S.M.E. Radiation-Committee report.[2])

subscript $(\ )_L$ denoting that μ has been based on the low heat of the fuel.

Values of μ_L using this method have been computed for the tests given on ten boiler furnaces in the A.S.M.E. Radiation-Committee report.[2] These computed μ_L-values are compared with gas-temperature μ_L-values determined in that report[2] in Figs. 7, 8, and 9. The boiler numbers correspond to the boiler numbers of the report.[2]

It will be observed that results are satisfactory, for all types of fuels and firing, excepting the results for the stoker-fired furnaces which are high.

An attempt was made to derive empirical correction factors K_X that would modify the results obtained by this method in order to bring them more in line with the observed A.S.M.E. Radiation-Committee data.[2] The derived correction factors appear to be best embodied in the curves given in Figs. 10 and 11. These are to be applied by multiplying the obtained μ_L-values by the correction factor K_X. The modified μ_L-values thus obtained are compared in Figs. 12 and 13 with gas temperature μ_L-values given in the A.S.M.E. Radiation-Committee report.[2]

It will be seen that the modified results represent the data rather closely considering the simple correction used. The multiplying correction factor is unity for oil and gas firing except for all-refractory furnaces, in which case the mean furnace temperature is probably somewhat higher than the furnace-exit temperature due to the lack of waterwall surfaces available for absorbing heat in the lower portion of the flame. For this same reason the correction factor for pulverized coal approaches unity for furnaces in which the waterwall surface is not a large fraction of the total surface. The correction factor for stoker firing depends upon fraction cold in very much the same manner as has been shown by Wohlenberg in his method.

The new method given is not difficult. The greatest amount of time required in obtaining solutions by its use will be used in plotting a heat-capacity curve and in computing the effective

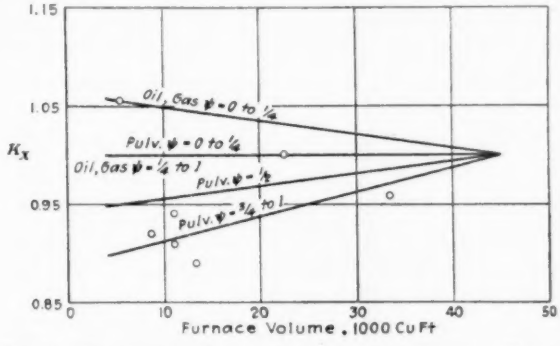

FIG. 10 CORRECTION FACTOR K_X FOR μ_L — SUSPENSION FIRING
(Fraction cold ψ = effective radiant heating surface/total furnace surface less grate area.)

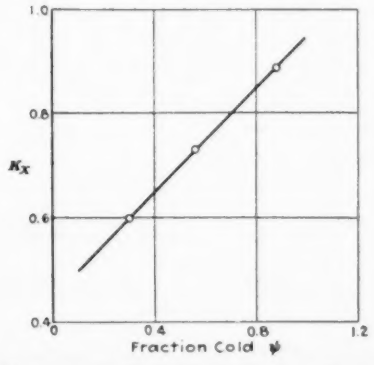

FIG. 11 CORRECTION FACTOR K_X FOR μ_L — STOKER FIRING
(Fraction cold ψ = effective radiant heating surface/total furnace surface less grate area.)

radiant heating surface. For extended use the former may be simplified by plotting heat-capacity curves for typical commercial fuels, which can also be used for boiler-design purposes. In routine work, a heat-capacity curve corresponding to the nearest fuel analysis may be used for calculations. There has been considerable agitation for a more rational method for evaluating effective radiant heating surface and it is possible that a method on the order of that which is given in this paper may be used in the future by boiler manufacturers to rate their product.

COMPARISON WITH THE BROIDO AND ORROK METHODS

It can be shown that the Broido and Orrok methods are derivable from the preceding method of calculation. Using the Stefan-Boltzman law curve of Fig. 1 and a heat-capacity curve as in Fig. 5, other types of curves may be plotted. One type is shown in Fig. 14. This curve was obtained by assuming a furnace temperature from which the heat radiated per square foot of effective furnace surface was found in Fig. 1 and the value of μ_L for a particular per cent air and heat input to the furnace per pound of fuel was found from Fig. 5. Dividing the heat radiated by μ_L gives the heat liberated per square foot of radiant heating surface for the particular conditions. This was

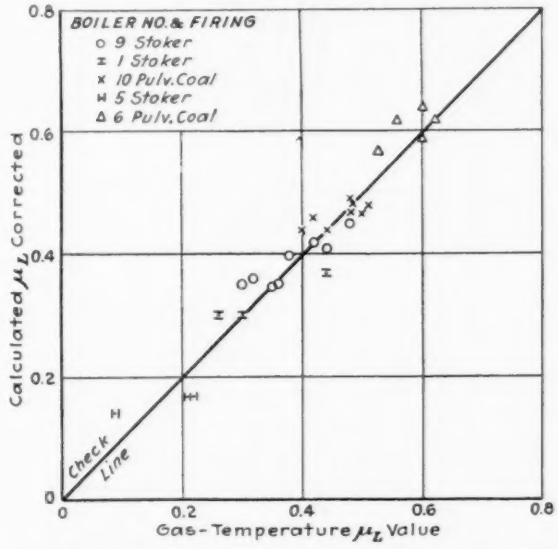

FIG. 12 COMPARISON BETWEEN CORRECTED RESULTS OBTAINED BY THE METHOD ADVANCED IN THIS PAPER AND THOSE OBTAINED FROM EXPERIMENTAL DATA
(Experimental data and boiler numbers are those given in the A.S.M.E. Radiation-Committee report.[2])

done for a number of values of furnace temperature and the results were plotted as in Fig. 14. Thus, this curve might have been used to determine μ_L according to the new method derived. However, it was not used because it is not as flexible as the curves previously given which were plotted on a slightly different basis.

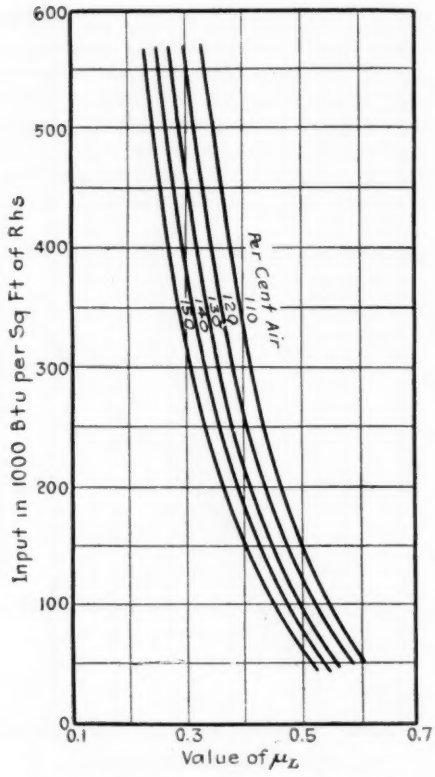

FIG. 14 SPECIAL TYPE OF μ_L CHART

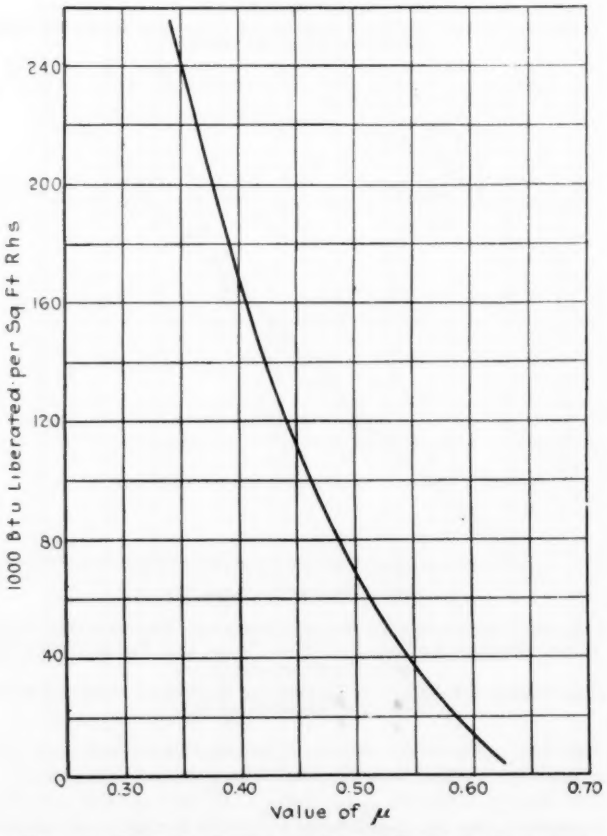

FIG. 15 BROIDO'S CURVE OF BOILER-FURNACE RADIATION

An interesting fact is revealed by this type of curve. If it is compared with Fig. 15, which is a plot of the Broido curve, it will be seen that the Broido curve might be derived from the curves in Fig. 14 assuming a certain relation between the per cent of theoretical air for combustion and the rate of driving. A similar comparison for Fig. 16, which is a plot of the Orrok equation, shows that the Orrok equation might be similarly derived by assuming a given heat value input per pound of fuel.

Therefore, we might conclude that the Broido curve should be accurate for a furnace having a certain excess-air characteristic for various boiler loads and the Orrok equation is applicable to a fuel having a given heat value.

ACCURACY OF THE PROPOSED METHOD

To the engineer who frequently has used empirical formulas for the calculation of furnace-heat transfer, the present attack based on the Stefan-Boltzman law may appear as a rational attack in that the empirical corrections, considering the diversity

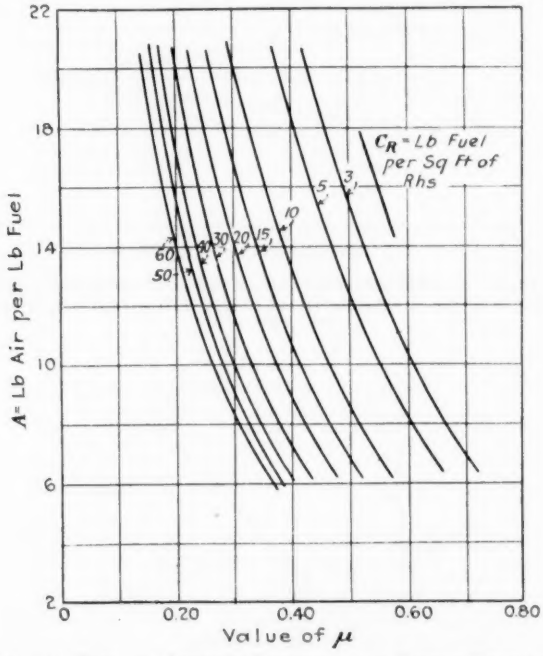

FIG. 16 PLOT OF ORROK'S EQUATION FOR BOILER-FURNACE RADIATION

in types of fuels and firing arrangements, are not great. From the strictly theoretical viewpoint of the physicist it will appear to a large extent empirical. Whether the method be considered to be based upon a firm theoretical foundation or upon an empirical basis it is submitted as being in agreement with such experimental data as is available, as having sufficient simplicity for use in practical calculations, and as showing clearly from the graphical standpoint the influence of various operating factors on the result desired. It is probable that the method will give an average furnace-exit temperature within 75 F. It should be noted however that the data by means of which the method advanced in this paper has been checked were taken almost entirely from large furnaces. Therefore, application to small furnaces must be made with caution.

STUDY OF THE EFFECT OF COMBUSTION CONDITIONS OF SUSPENSION FIRING ON FURNACE-OUTLET TEMPERATURE

A special study was made in order to determine the effect of fixed furnace characteristics such as fraction cold, furnace

volume, and furnace length, as well as such operating conditions as per cent air, temperature of preheated air, and energy-release rate. Using the method developed in this paper, the furnace-outlet temperature was computed for various arrangements

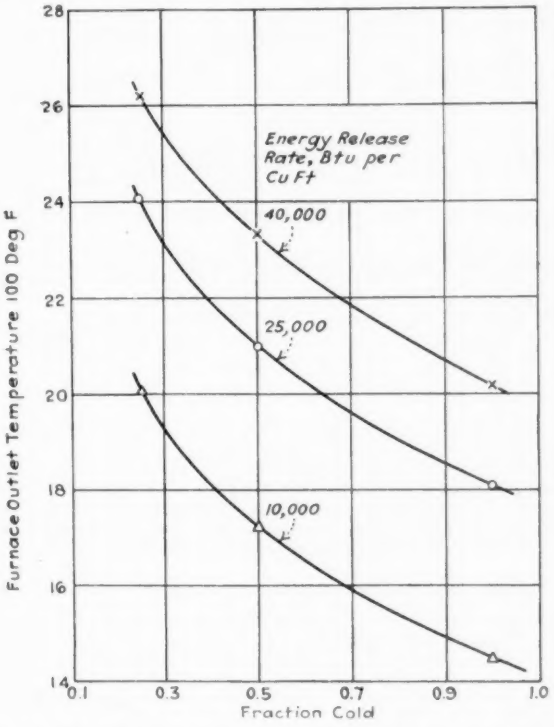

FIG. 17 EFFECT OF VARIATION OF FRACTION COLD ON FURNACE-OUTLET TEMPERATURE AT VARIOUS VALUES OF ENERGY-RELEASE RATE

(Air = 120 per cent, air temperature = 80 F, furnace volume = 8000 cu ft, and furnace length = 20 ft.)

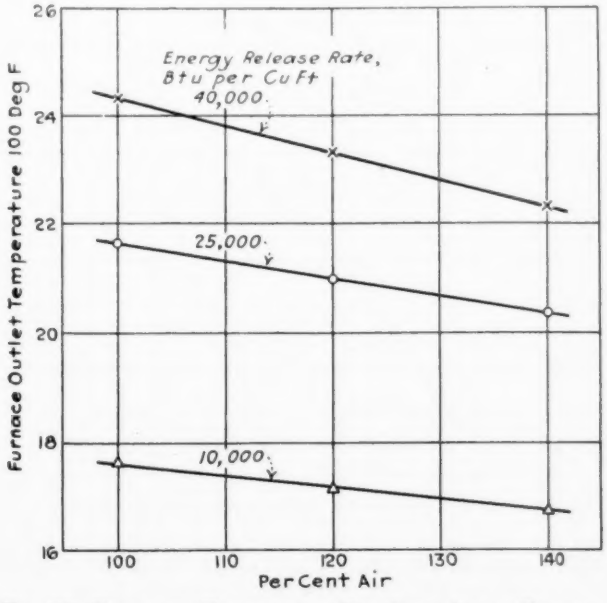

FIG. 18 EFFECT OF VARIATION OF PER CENT AIR ON FURNACE-OUTLET TEMPERATURE AT VARIOUS VALUES OF ENERGY-RELEASE RATE

4	Energy-release rate	Increase
5	Furnace volume	Increase
6	Furnace length	Decrease

furnace-outlet temperatures calculated by the method developed, except that the K_x correction factors were not applied. Therefore, the results, as far as the indication of absolute values is concerned, are slightly inaccurate, although the trends are correct.

Part of the results are presented in Figs. 17 to 26. From the shape of the curves, it is possible to draw certain general conclusions which are summarized in Table 5. These results agree

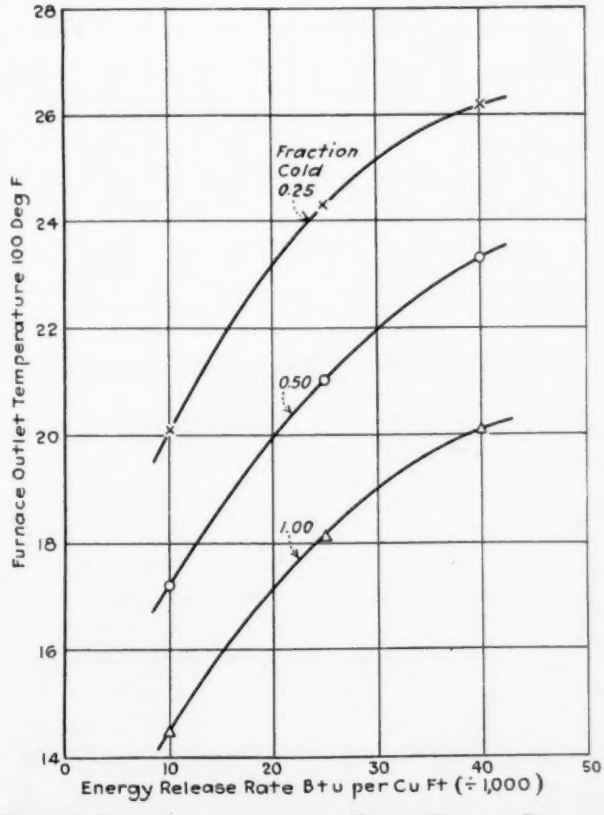

FIG. 25 EFFECT OF VARIATION OF ENERGY-RELEASE RATE ON FURNACE-OUTLET TEMPERATURE AT VARIOUS VALUES OF FRACTION COLD

(Air = 120 per cent, air temperature = 80 F, furnace volume = 8000 cu ft, furnace length = 20 ft.)

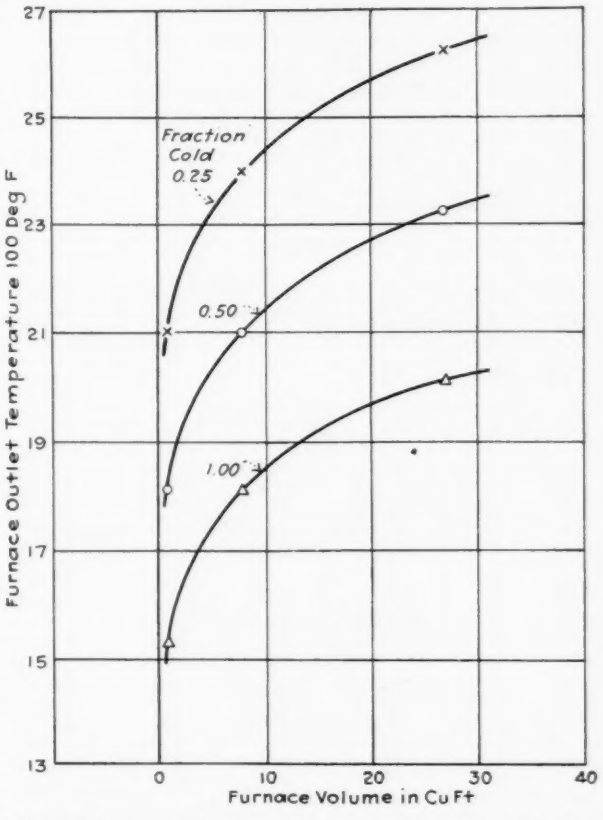

FIG. 26 EFFECT OF VARIATION OF FURNACE VOLUME ON FURNACE-OUTLET TEMPERATURE AT VARIOUS VALUES OF FRACTION COLD

(Air = 120 per cent, air temperature = 80 F, energy-release rate = 25,000 Btu per cu ft, furnace length = 10, 20, and 30 ft.)

with those which would be expected from qualitative theoretical considerations.

Appendix

CALCULATION OF SLAG FACTORS FOR TUBES BY USE OF EXPERIMENTAL DATA

From the A.S.M.E. Radiation-Committee report,[2] the test of boiler No. 1, which is a stoker-fired unit, makes available data on a separate screen or waterwall boiler composed of sidewall tubes and a slag screen at the furnace exit. Data for the evaporation of the screen boiler, compared to the total evaporation, for clean tubes and for slag-covered tubes after 18 months' operation, are given in Table 6. The average per cent of slag on the furnace effective radiant-heating-surface area of 2027 sq ft of this boiler has been computed to be 55 per cent. In addition there are 394 sq ft of radiant heating surface at the furnace exit. It is assumed that the furnace-exit surfaces evaporate the same quantity of steam after long operation as

TABLE 6 EVAPORATION OF SCREEN BOILER NO. 1[a]

Total boiler evap, 1000 per hr	Screen-boiler evap, 1000 lb per hr: Clean tubes	Slagged tubes	Evap ratio, slagged to clean tubes
120	67	58	0.865
140	75	67	0.895
180	93	84	0.903
200	102	92	0.900
240	120	108	0.900
260	129	114	0.885
300	147	124	0.845

[a] Data taken from a test of boiler No. 1 as given in the A.S.M.E. Radiation-Committee report.[2]

they did at initial operation, that is, they do not accumulate slag, the slag being accumulated only on the side waterwalls. From this an equation may be set up in which x = the slag factor and E = the original screen-boiler evaporation. Then, for initial operation

$$394 + 2027 = f(E) \quad [7]$$

and for slagged operation

$$394 + 2027x = 0.9f(E) \quad [8]$$

The value of 0.9 was taken as the approximate average reduction in evaporation of the screen boiler from Table 6. Solving the equation, $x = 0.88$. Thus, although the screen boiler evaporates

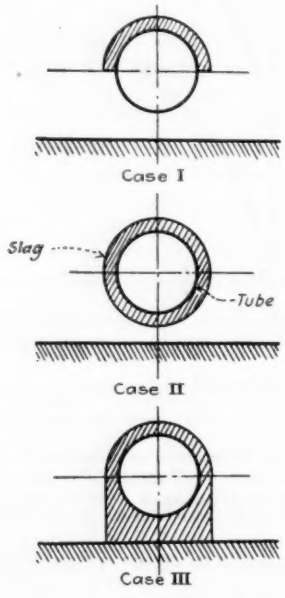

FIG. 27 DETERMINATION OF F_S-FACTOR FOR VARIOUS CONDITIONS

0.90 of its initial evaporation, because of the constant evaporation of the furnace-exit surface the screen waterwalls only evaporate 0.88 of their initial evaporation. If the wall is 55 per cent slagged with slag estimated $^3/_4$ in. thick, it has a stoppage factor of 1.00 — 0.88 = 0.12. A wall 100 per cent slagged would have a factor of 0.12 (100/55) = 0.22. This value has been plotted as F'_{S-1} in Fig. 3. It is realized that the above solution is not correct inasmuch as it does not take into account convection at the furnace exit. More involved calculations would not appear to be justified by the data.

The second boiler from which tests are available in the A.S.M.E. Radiation-Committee report[2] is a pulverized-fuel-fired boiler with a bottom screen and side waterwalls on separate circulation. Here the effect of slagged waterwall tubes was obtained by comparing the evaporation of the screen or radiant boiler when slagged and when the side-wall tubes had been

TABLE 7 EVAPORATION OF SCREEN BOILER NO. 2[a]

Total boiler evap, 1000 lb per hr	Screen boiler evap, 1000 lb per hr — Clean side of wall tubes	Screen boiler evap, 1000 lb per hr — Slagged side of wall tubes	Evap ratio, slagged to clean tubes
150	72	64	0.890
200	91	82.5	0.906
250	107	98	0.906
280	114	103.5	0.908

[a] Data taken from a test of boiler No. 2 as given in the A.S.M.E. Radiation-Committee report.[2]

cleaned of slag and wire-brushed. Results are summarized in Table 7.

Boiler No. 2 is different from the stoker-fired boiler No. 1 in that the horizontal tubes of the screen boiler were not appreciably slagged and were therefore not cleaned. Their evaporation should remain constant.

It is estimated that in boiler No. 2 there were 340 sq ft of side-wall surface 30 per cent slagged with $^3/_4$-in. thick slag. The horizontal bottom-screen tubes and the furnace exit together comprise 1083 sq ft of effective radiant heating surface. From Table 7, the heat transfer of the boiler was reduced 90.5 per cent because of the slag. For clean operation using the same method as for Equations [7] and [8]

$$1083 - 340 = f(E) \quad [9]$$

and for slagged operation

$$1083 - 340x = 0.905f(E) \quad [10]$$

from which $x = 0.60$.

Since this was for tubes 30 per cent slagged, tubes 100 per cent slagged would have a stoppage factor of (1.00–0.60) (100/30) = 1.33 which of course is impossible as 1.00 would be the highest value. Due to lack of data the factor has been taken as equal to 1.0 and is plotted as F'_{S-1} in Fig. 3.

CALCULATION OF SLAG FACTORS FOR SINGLE ROW OF TUBES IN FRONT OF REFRACTORY

The estimated per cent of slag is usually given as a percentage of the surface of the waterwall tubes on the furnace side. On this account a distinction must be made between tubes placed with the rear half imbedded in refractory and tubes placed en-

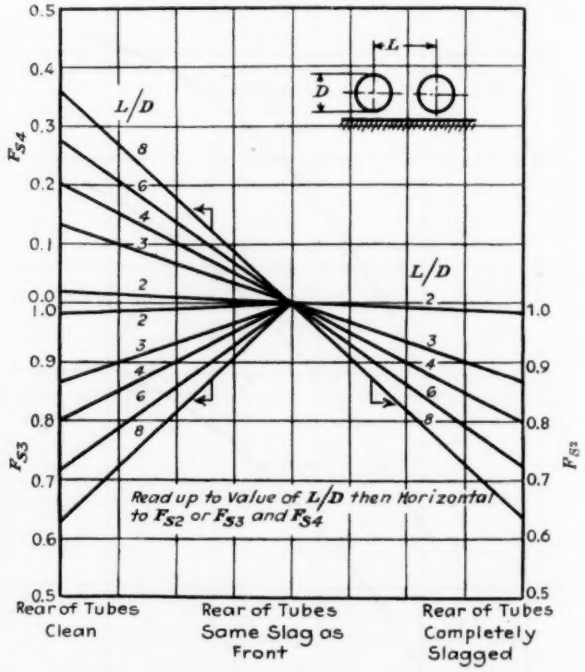

FIG. 28 CALCULATION OF SLAG FACTORS FOR TUBES IN FRONT OF REFRACTORY

tirely in front of refractory. The first of these will be taken as the standard condition. The second case will necessarily be calculated somewhat differently, but will be related to the first case. The second case may be divided into three additional

divisions. The first is when the front of the tube is slagged and the rear of the tube is clean. The second is when the whole circumference of the tube is uniformly slagged. The third occurs when the front is slagged and the rear is completely slagged up. These cases are illustrated in Fig. 27.

TABLE 8 TABULATION OF RESULTS FROM HOTTEL'S CURVES

L/D	2	3	4	6	8
Heat direct to furnace side	0.66	0.47	0.37	0.25	0.08
Total heat to one tube	0.68	0.54	0.45	0.35	0.18
Diff. = heat to rear of tube	0.02	0.07	0.09	0.10	0.10
Fraction to front of tube	0.97	0.87	0.80	0.72	0.64
Fraction to rear of tube	0.03	0.13	0.20	0.28	0.36

It is necessary to set up a proportion between the amount of heat received by the front of the tube and the amount of heat received by the back of the tube. This has been done by the use of Hottel's curves of Fig. 2. The results are tabulated in Table 8.

Let F_S = the true slag factor, F'_{S-1} = the stoppage factor = (1.00 — slag factor), and x = the estimated fraction of front of tube slagged.

Consider the specific case where $L/D = 6$. Using Table 8 for the values of the heat to the front and the rear of the tubes and Fig. 3 for F'_{S-1} values, then for case 1

$$F_S = 0.28 - 0.72(1.00 - xF'_{S-1}) \quad [11]$$

and for case 2

$$F_S = 1.00 - xF'_{S-1} \quad [12]$$

and for case 3

$$F_S = 0.72(1.00 - xF'_{S-1}) \quad [13]$$

This last case assumes that no heat is transferred to the back of the tube when it is completely slagged.

By letting $0.28 = F_{S4}$ and $0.72 = F_{S3}$ in case 1 and $0.72 = F_{S2}$ in case 3 a curve may be plotted to show the relation for various values of L/D as in Fig. 28. Equations [11], [12], and [13] then become

$$F_S = F_{S2}(1 - xF'_{S-1}) \text{ or } F_{S4} + F_{S3}(1 - xF'_{S-1}) \quad [14]$$

which is the relation desired to define slag factors for tubes in front of refractory. The values for insertion in Equation [14] are obtained from Figs. 3 and 28.

Review of Methods of Computing Heat Absorption in Boiler Furnaces

By W. J. WOHLENBERG,[1] NEW HAVEN, CONN., and H. F. MULLIKIN,[2] NEW YORK, N. Y.

This paper contains results obtained by each of a number of methods of computing heat absorption in boiler furnaces. These are compared with the results reported by the A.S.M.E. Committee on Absorption of Radiant Heat in Boiler Furnaces.[3] Particular emphasis has been placed on the Broido, Orrok, and Wohlenberg methods. It is shown that the influence of various conditions as found by experiment are in substantial agreement with results expected from a theoretical consideration of the problem and those arrived at by certain well-known methods now in use.

Introduction

THE purpose of this paper is to endeavor to check, by such experimental data as may be available, the various formulas and methods for the calculation of boiler-furnace heat transfer as have been advanced by various investigators. It is not proposed to discuss either the derivation or the methods themselves to any extent as the original articles may be readily inspected.

These methods have never been checked quantitatively, with the exception of a few limited calculations on individual furnaces, principally because of the lack of experimental data which could be used for that purpose.

The report of the A.S.M.E. Committee on Radiation in Boiler Furnaces entitled "An Experimental Investigation of Heat Absorption in Boiler Furnaces,"[3] and hereafter referred to in this paper as the Radiation-Committee Report, furnished such data based on various sizes and types of furnaces fired in different manners. This report also has a bibliography which contains the titles and locations of the different papers describing the various methods of calculation to be utilized in this paper, as well as a short discussion of each.[4]

The form in which the original investigators have stated their results has in some cases required revision in order to enable comparisons to be made in a reasonable amount of time, such revision generally consisting of putting formulas in chart form. These revisions are described, in the first part of this paper, after which the calculations made on the basis of the experimental data are considered.

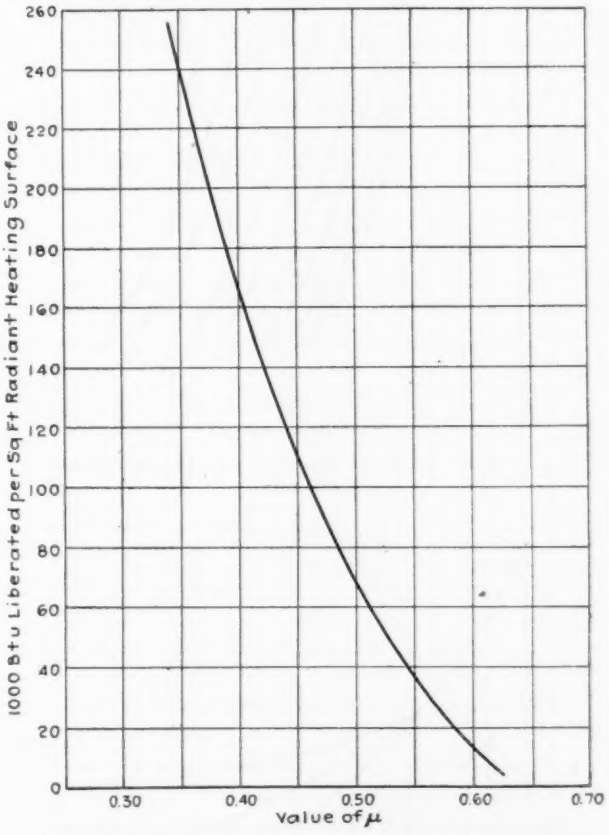

FIG. 1 BROIDO'S CURVE OF BOILER-FURNACE RADIATION

Five methods of calculation have been investigated. These are (*a*) actual measurement (7, 12, 22);[4] (*b*) Broido method (7); (*c*) Orrok formula (20); (*d*) Wohlenberg method (1, 2, 3, 4, 5); and (*e*) Stefan-Boltzman law method. Method (*e*), for reasons stated later, is not included in the present paper.

Broido Method

Broido (7) has given a curve which represents the first important contribution to the subject. This curve, given in Fig. 1,

[1] Professor of Mechanical Engineering, Sheffield Scientific School, Yale University. Mem. A.S.M.E. Professor Wohlenberg received the degree of B.Sc. in mechanical engineering from the University of Nebraska in 1910, and the degree of M.S. from the University of Illinois in 1916. From 1910 to 1918 he served in the engineering department of the Westinghouse Machine Company as Research Fellow at the University of Illinois, and on the engineering faculties of the Universities of Oklahoma and Montana. He has been a member of the engineering faculty of Yale University, and engaged in consulting work in the field of power and steam generation, since 1918. He is the author of numerous papers dealing with power generation and in particular with radiation in furnaces.

[2] Research Fellow, Superheater Company-Yale University Fellowship. Jun. Member A.S.M.E. Dr. Mullikin is a graduate of Baltimore Polytechnic Institute and Johns Hopkins University, and the recipient of graduate degrees, including Ph.D. from Yale. He spent a year in the test department on boiler development at the General Electric Company.

Contributed by the Special Research Committee on Absorption of Radiant Heat in Boiler Furnaces for presentation at the Annual Meeting, December 2 to 6, 1935, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until January 10, 1936, for publication at a later date.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[4] Numbers in parentheses correspond to similarly numbered references given in the bibliography of the A.S.M.E. Radiation-Committee report "Experimental Investigation of Heat Absorption in Boiler Furnaces."[3]

shows the relation between μ and heat input to the furnace per square foot of exposed projected radiant surface, where μ is defined as the ratio of heat given up from the furnace gases by radiation to the heat input to the furnace.

Orrok Formula

Orrok has given the following empirical formula derived from Hudson (39)

$$\mu = \frac{1}{1 + (A\sqrt{C_R/27})} \quad \ldots\ldots\ldots\ldots [1]$$

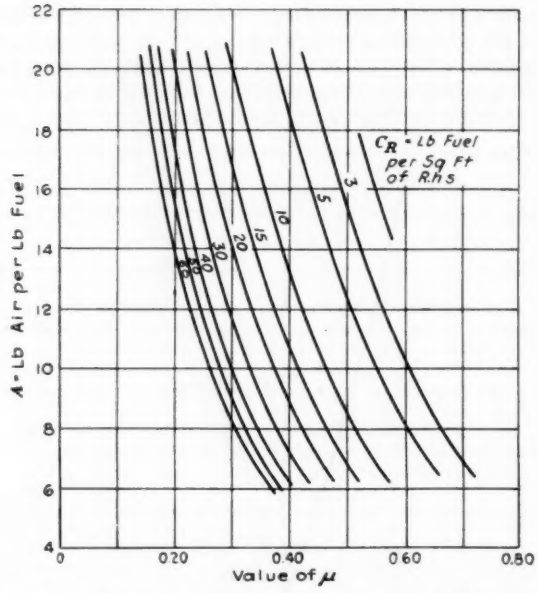

Fig. 2 Plot of Orrok's Equation for Boiler-Furnace Radiation

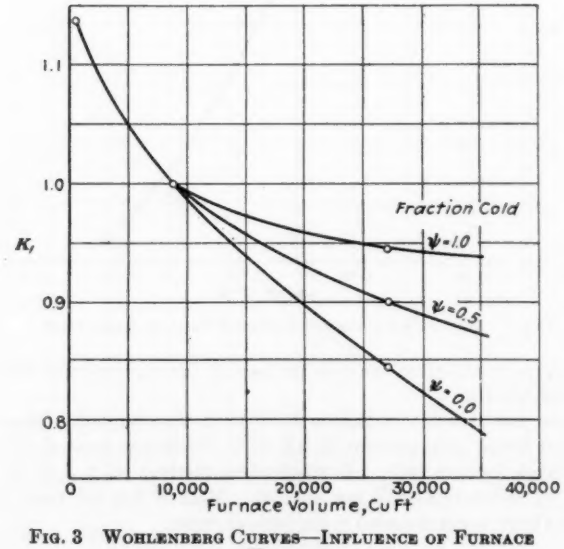

Fig. 3 Wohlenberg Curves—Influence of Furnace Volume

$\left(\psi = \frac{\text{effective radiant heating surface}}{\text{total furnace surface less grate}}\right)$

where μ = the fraction of liberated energy given up by gases in the furnace, A = lb of air per lb of fuel, and C_R = lb of fuel per sq ft of projected radiant heating surface. Fig. 2 shows Equation [1] plotted in the form of a series of curves for ready use. The Wilson, Lobo, and Hottel modification (45) is apparently not valid for the furnaces of steam boilers.

TABLE 1 CONDITIONS OF BASE SOLUTION FOR WOHLENBERG CURVES

1	Furnace volume	8,000 cu ft
2	Release rate	25,000 Btu per cu ft for pulverized-coal firing 40,000 Btu per cu ft for stoker firing
3	Excess air	120 per cent for pulverized-coal firing 140 per cent for stoker firing
4	Fraction cold[a]	unity
5	Coal	Illinois bituminous
6	Fineness	75 per cent through 200 mesh

[a] Fraction cold is defined as the effective exposed radiant heating surface in the furnace divided by the total exposed furnace surface (exclusive of the grate in stoker firing).

Wohlenberg Method

This is an extensive theoretical attack based upon the use of various physical constants rather than an empirical solution as given in the two previous methods. The method is quite complex in that it attempts to evaluate, as far as possible, all the factors that enter into furnace design, in contrast to the simplicity of the empirical attacks which depend upon one or two variables. In applying this method use is made of a furnace heat balance and values of μ for various given conditions of furnace volume, energy-release rate, etc., which are given in several of the papers previously presented on this method.

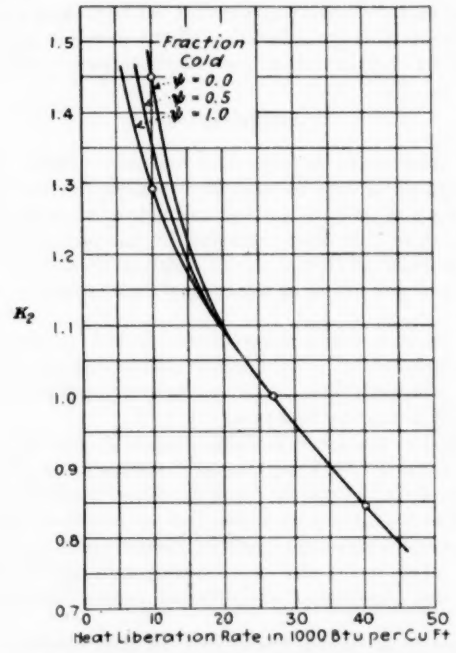

Fig. 4 Wohlenberg Curves—Influence of Liberation Rate. Liberation Rate Based on High Heat Value of Fuel + Air Heat

$\left(\psi = \frac{\text{effective radiant heating surface}}{\text{total furnace surface less grate}}\right)$

It is possible, by use of this material to arrive at results by interpolation. For convenience in calculation, however, these data, together with some additional information, have been graphically restated in the present article in such a form as to enable a more rapid solution of the problem.

After trying several schemes of presentation it was decided to take as a base, the results for a furnace whose physical operating conditions were about in the middle of the range of physical characteristics selected for solution in the original papers. These conditions are given in Table 1.

Since the original publication of the Wohlenberg method,

better physical data have become available, especially in regard to the Stefan-Boltzman and gas-radiation coefficients. Thus, a Stefan-Boltzman coefficient of $\alpha = 0.1723$ Btu per sq ft per hr per (deg F abs)[4] (6), and the radiation values of Schmidt[5] are to be preferred.

The values of μ for the base furnace are henceforth designated as the F-factors. Under conditions of the base furnace defined in Table 1, the F-factors (μ-values) may be calculated using the

TABLE 2 VALUE OF F-FACTOR

Firing method	Method of calculation—With old coef	Method of calculation—With new coef	Coef ratio new/old
Pulverized	0.418	0.452	1.08
Stoker	0.258	0.311	1.20

old coefficients as given in the original papers (1, 2, 3, 4, 5) and also using the new coefficients mentioned in this paper. A comparison of results is shown in Table 2. It will be noted that the

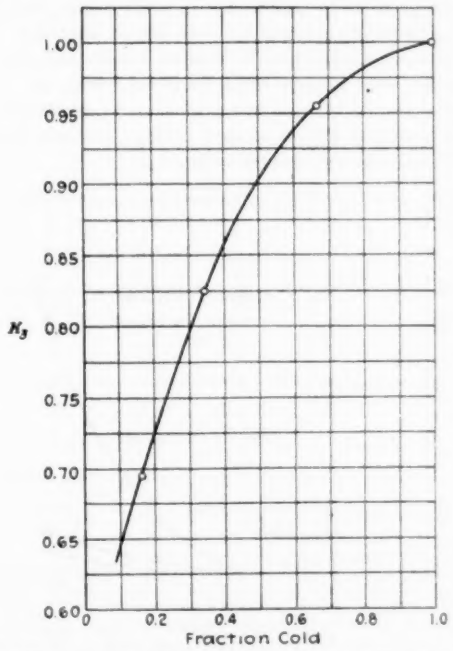

FIG. 5 WOHLENBERG CURVES—INFLUENCE OF FRACTION COLD

$$\left(\text{Fraction cold} = \frac{\text{effective radiant heating surface}}{\text{total furnace surface less grate}}.\right)$$

values of the new coefficients are as much as 20 per cent greater than the old coefficients. The old values are valuable as a basis of comparison but the new F-factors should be used in computations.

Returning for the moment to the data tabulated by Wohlenberg and Lindseth (2) for pulverized coal, each of the factors of Table 1 was varied separately and the resultant ratios of the μ-values, termed K-factors, were plotted as shown in Figs. 3 to 7, inclusive. In order to obtain results within the desired degree of error, it was necessary to modify the curves somewhat as may be noted in the figures. The method of introducing this modification was determined by trial and error.

Using the curves obtained for the pulverized-coal furnace, a ratio was obtained, as shown in Figs. 8 and 9, between the results for pulverized-coal firing and for stoker firing.

The effect of preheated air was next noted in Fig. 10, where C is an additive increase in the value of μ.

[5] "Messung der Gessamtstrahlung des Wasserdampfes bei Temperaturen bis 1000 deg C," by E. Schmidt, *Foschung auf dem Gebiete des Ingenieurwesens*, vol. 3, 1932, p. 57.

Using some calculations made by the 1931 graduate power class at Yale University, the curve of Fig. 11 showing the effects of variation of particle size has been computed.

The curves give multiplying or additive correction factors to apply to the F-factor (μ-value) for the base or standard furnace. The procedure may be embodied in the equation

$$\mu = F\,K_1K_2K_3K_4K_5K_6K_7K_8 + C \qquad [2]$$

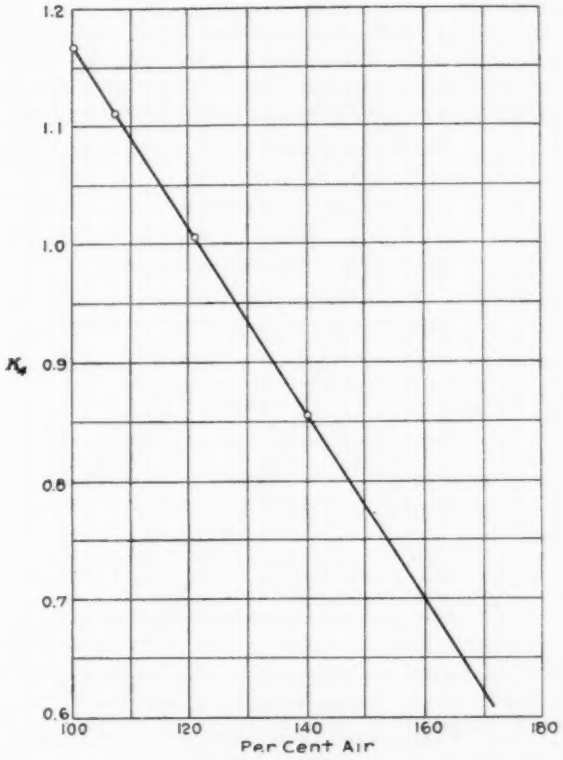

FIG. 6 WOHLENBERG CURVES—INFLUENCE OF EXCESS AIR

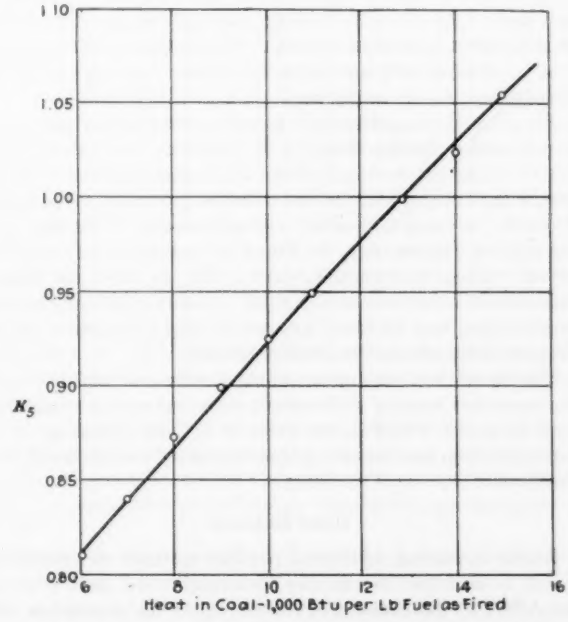

FIG. 7 WOHLENBERG CURVES—INFLUENCE OF FUEL HEAT VALUE

where $F = 0.452$ for pulverized-fuel firing and 0.311 for stoker firing. The K- and C-values are obtained from Figs. 3 to 11, inclusive, for the given conditions.

Thus, these figures give a series of correction curves for pulverized-coal and stoker furnaces which serve to determine μ for any condition of: (*a*) furnace volume, (*b*) heat-liberation rate, (*c*) amount of water-cooled surface in the furnace, (*d*) per cent air used for combustion, (*e*) heat value of fuel, (*f*) temperature of preheated air, and (*g*) coal fineness through 200 mesh.

One of the present authors has made a sample calculation (7), given in Table 3, for the value of μ for a gas-fired furnace as compared with pulverized-coal-fired and stoker-fired furnaces.

It will be seen that, according to the Wohlenberg method, μ

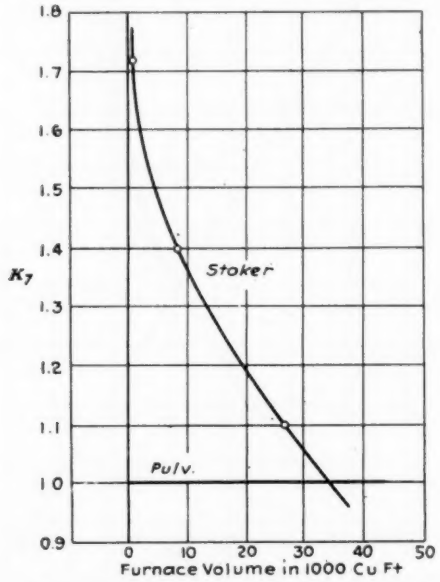

FIG. 8 WOHLENBERG CURVES—ADDITIONAL INFLUENCE OF FURNACE VOLUME

is much less for gas firing than for either stoker or pulverized-coal firing. As will be later shown, the experimental data at hand would seem to indicate otherwise. This results in the conclusion that the Wohlenberg method in its present form and as applied does not hold for gas or oil firing.

Equation [2] thus developed may be solved for any pulverized-coal or stoker furnace within 2 or 3 minutes, the only work involved being the selection of the appropriate K- and C-factors from Figs. 3 to 11, inclusive, and a simple slide-rule multiplication. From the value of μ obtained, the temperature of the flue gases leaving the furnace may be found by means of heat-capacity curves. These heat-capacity curves, Fig. 12, show the relation between the sensible heat of a given quantity of gas and its temperature and may be found by conventional combustion calculations using the ultimate analysis of the fuel.

The curves just developed will check values obtained by using the somewhat lengthy Wohlenberg equations within a maximum error of about ± 0.03 in the value of μ. An advantage of the curves given in this manner is that they show clearly the effect of variation of any one of the factors.

HEAT RELEASE

Before discussing additional possible methods of calculation, it will be desirable to examine the experimental data given by the A.S.M.E. Radiation-Committee report[3] in connection with the Broido, Orrok, and Wohlenberg methods. In making such an examination, it is necessary to consider two quantities which

TABLE 3 COMPARISON OF μ FOR DIFFERENT FIRING METHODS AS COMPUTED BY THE WOHLENBERG METHOD

Firing method	Air, per cent	Furnace temp, F	μ
Pulv. coal	120	2230	0.40
Stoker	120	2386	0.36
Gas	120	2720	0.25

enter into the combustion process, namely, heat released in the furnace and the radiant heating surface in the furnace. There has been considerable diversity in the method of calculating these items in the literature.

In regard to the heat liberated in the furnace, some of the attacks on the problem have used an energy-release rate based on the calorific or high heat value of the fuel plus any sensible heat in the combustion air due to preheating.

From a theoretical point of view this is not thoroughly logical in that the latent heat required to vaporize the moisture due to hydrogen and water in the fuel is invaluable for raising the temperature of the gases or for radiation. In other words, instead of the high heat value, the low heat value should be used as in European practice, even though it may be somewhat indeterminate.

Thus, as far as furnace radiation is concerned, the low or net heat value should be used in calculations to determine the heat released per cubic foot of furnace volume, the heat released per pound of fuel supplied, and the value of μ.

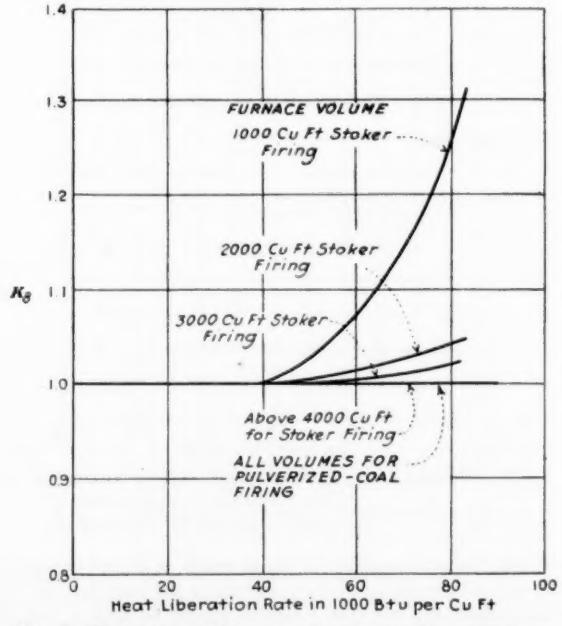

FIG. 9 WOHLENBERG CURVES—ADDITIONAL INFLUENCE OF LIBERATION RATE. LIBERATION RATE BASED ON HIGH HEAT VALUE OF FUEL + AIR HEAT

Various investigators have used the high or low heat value of the fuel rather indiscriminately. The Wohlenberg method made use of the high value and the Orrok method has made use of the low value although Orrok has compared his μ-values directly with values given in the Wohlenberg papers, thereby introducing confusion. Broido's procedure is not clear. The A.S.M.E. Radiation-Committee Report[3] gives experimental values of μ computed on both the high- and low-heat-value basis.

The heat supplied per pound of fuel fired should take into account incomplete combustion in any form.

In order to relate the various furnace-heat-transfer methods to each other, they have been reduced to a determination of μ, from which the furnace-exit temperature may be found through the use of heat-capacity curves. This μ in the case of the Wohlenberg

method has been based on the high heat value of the fuel, denoted as μ_H, hence the comparison with the experimental data will be made on this basis. The Orrok and Broido methods will be compared by a μ based on the low heat value of the fuel, denoted as μ_L. The μ values calculated in either manner do not differ greatly, the maximum differences occurring, of course, for natural-gas firing.

Since the degree of completion of combustion in the various

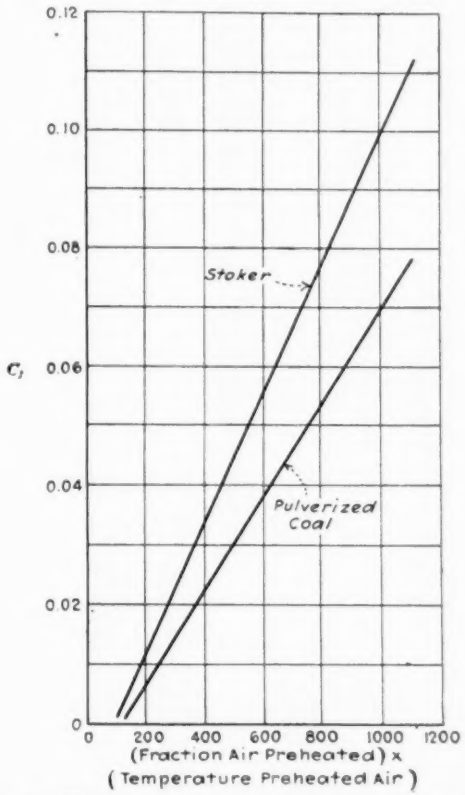

FIG. 10 WOHLENBERG CURVES—INFLUENCE OF PREHEAT

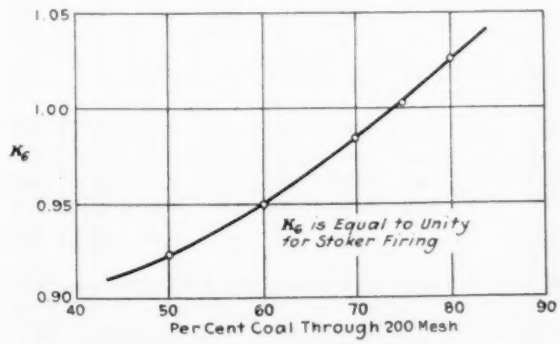

FIG. 11 WOHLENBERG CURVES—INFLUENCE OF PULVERIZATION FINENESS

furnaces listed in the A.S.M.E. Radiation-Committee report[3] is not accurately known, it has seemed advisable to compare μ-values, computed by the various methods, on the basis of complete combustion. The gas-temperature μ-values of the report[3] were likewise computed on this basis and therefore the error in making this comparison should not be large.

EFFECTIVE FURNACE RADIANT HEATING SURFACE

The radiant heating surfaces in the furnace are those portions of the waterwalls and lower surface of the tubes of the boiler proper which "see" the gases in the furnace. Considerable difference of opinion exists on the exact method of evaluating this surface, due to different arrangements of bare tubes in front of refractory, bare tubes recessed in refractory, fin tubes, cast-iron or steel block covered tubes, and refractory-faced block-covered tubes.

For bare tubes the projected surface, that is, the diameter

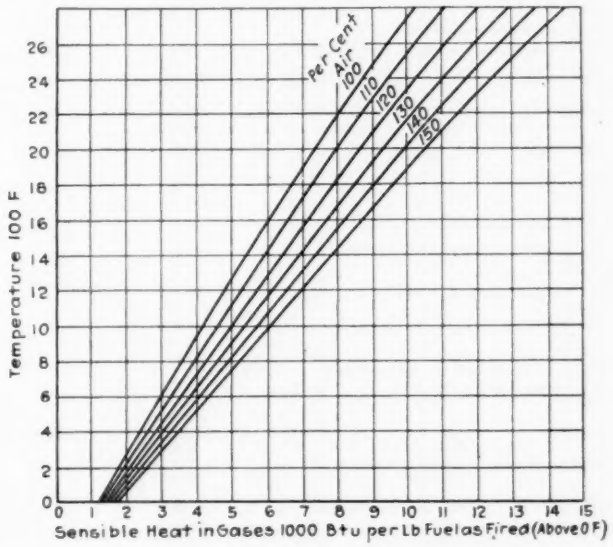

FIG. 12 HEAT-CAPACITY CURVES FOR BITUMINOUS COAL USING GOODENOUGH SPECIFIC HEATS

times the length is often taken. Many use the surface based on half the circumference, the surface based on the whole circumference, and other possible combinations. In comparing or using any method, the manner of measuring the surface must be noted.

Obviously, the effective radiant heating surface should have a value independent of any method that may be used for the calculation of heat absorption. It is usually thought of as the equivalent plane surface which absorbs the same amount of heat as the cold surface or waterwall under consideration.

Most of the methods have given the procedure for the calculation of heat absorption, that is, the μ-value, without stating how to reduce the furnace walls actually found in practice to this plane-surface base.

In order to establish the values of the effective furnace radiant heating surfaces of the different boilers tested, usually denoted by rhs, it was necessary to decide upon a procedure which would be applicable to all types of furnace surfaces such as bare block, refractory-faced block, bare tube, and fin tube. This meant that certain assumptions had to be made, based upon such scanty information as could be discovered concerning the relative heat-absorbing capacities of such surfaces as refractory-faced blocks and fin tubes.

It is appreciated that a procedure so selected may not be acceptable to the proposers of the various formulas and methods, on the ground that they either recommend other procedures or had other procedures in mind when presenting their method.

However, the impracticability of calculating different effective radiant heating surfaces for each of the various furnaces is obvious and the results given in this paper must be accepted with this in mind.

For the purpose of this paper, the radiant heating surface has

[c] Data for boilers 11, 12, and 13 are taken from the literature.
NOTE: F_E taken equal to 1.00.

been computed on the basis given in an article by one of the present authors.[6]

This procedure makes use of the formula

$$A_{rhs} = A\,F_A F_C F_S F_E \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

where A_{rhs} = equivalent effective plane radiant heating surface; A = the total overall plane area of the wall in question, regardless of the tube spacing, whether bare or block covered, etc.; F_A = an area factor to reduce overall surface to equivalent effective radiant heating surface, assuming all surfaces clean and of perfect conductivity; F_C = a conductivity factor to take into account the heat conductivity of various types of block-covered walls; F_S = a slag factor to account for reduction in heat transfer caused by slag coatings; and F_E = an emissivity factor.

The value of the factors for use in Equation [3] under various conditions are given by H. F. Mullikin[6] and not repeated here.

[6] "Evaluation of Effective Radiant Heating Surface and Application of the Stefan-Boltzman Law to Heat Absorption in Boiler Furnaces," by H. F. Mullikin, Trans. A.S.M.E., vol. 57, 1935, RP-57-2.

[a] Effective furnace radiant heating surface.

Equation [3] has been used, as shown in Table 4, to determine the effective radiant heating surface of the boilers enumerated in the A.S.M.E. Radiation-Committee report.[3] It was deemed best to take F_E equal to unity at the time the calculations were made although a value of 0.95 would perhaps have been preferable.

Data taken from the literature for three additional boiler tests is also included.

Check of Experimental Data by Waterwall Evaporation

Ordinarily the check of experimental data by waterwall evaporation is accomplished by segregation of a part of the furnace waterwalls or, as in the case of the first three units tested in the A.S.M.E. Radiation-Committee report,[3] by constructing the waterwalls so as to have their own feed and steam drum, thus acting as a separate steam-generating unit. Some of the boilers of the Ford Motor Company at Fordson, Mich., are also constructed in this manner. There are several difficulties encountered in the use of this method.

In the first place, results will depend upon the estimated relative heat-absorption rates at different kinds of surfaces. These rates are needed to determine the values of the effective radiant heating surfaces. Two such values are involved. The first is the total effective radiant heating surface in the furnace and the second is that part of the surface for which the absorption was measured. The ratio of the first surface to the second is a factor used in the calculation.

In the second place, certain boilers, as in the case of the first unit of the A.S.M.E. Radiation-Committee report,[3] are constructed so that the furnace-exit slag screen is part of the waterwall boiler. Under these conditions some heat will be transferred by convection through this slag screen into this waterwall boiler.

It is difficult to allow for this heat transfer. In addition, some radiant heat will pass between these slag-screen tubes, be absorbed by the boiler tubes proper and not be measured. In the calculation given in the present paper, these last two quantities of heat have been assumed equal, a very rough approximation.

TABLE 6 DETERMINATION OF μ_L BY HEAT ABSORPTION OF PART OF FURNACE WALLS

1	3		5	39	40	41

Item 43	Fig. 1 using item 42
Item 44	calculated using item 20
Item 45	item 42/item 25
Item 46	Fig. 2 using items 44 and 45
Item 47	Equation [2] and Figs. 3 to 11, inclusive.

[a] Items previous to item 39 will be found in Table 3 of the report "An Experimental Investigation of Heat Absorption in Boiler Furnaces."[3]
[b] Effective furnace radiant heating surface.

The plane of the furnace exit (side of boiler tubes adjacent to furnace) is always an effective exposed furnace surface which cannot be segregated for radiant-heat measurement without inducing the problem of convection-heat transfer.

With this in mind, calculations have been made for six boiler furnaces for which test data are available to show the heat absorbed by a portion of the furnace surfaces. Three of these units are boilers Nos. 1, 2, and 3 of the A.S.M.E. Radiation-Committee report[3] for which the computations are given as items 39, 40 and 41 of Table 5 and indicated in Table 7. Table 5 is, in effect, a continuation of Table 3 of the A.S.M.E. Radiation-Committee report.[3] Tests were also available from the literature on boilers for which the construction data of the furnaces are given in Table 4. In this table, boiler No. 11 is a unit at Cahokia Station, St. Louis, Mo. (27); boiler No. 12 is a special test boiler at the Tekniska Hogskolan, Stockholm, Sweden (15, 16); and boiler No. 13 is a Fordson, Mich., unit (10, 19). The μ-determinations, based on segregated furnace-wall surfaces for boilers Nos. 11, 12, and 13 are given in Table 6. The full calculations

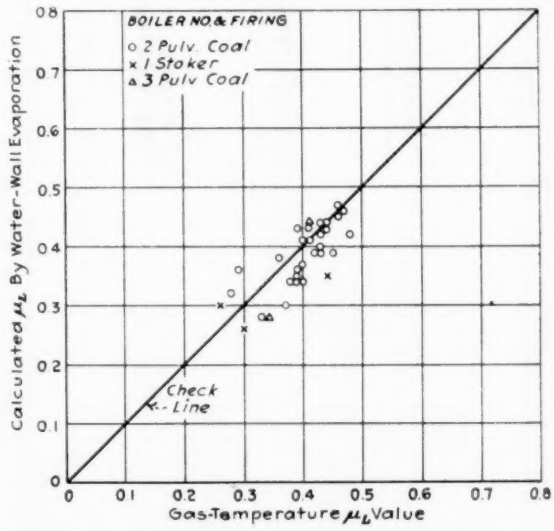

FIG. 13 COMPARISON OF RESULTS BY MEASUREMENT OF WATERWALL EVAPORATION

have been omitted to save space. The μ-values calculated in this manner for boilers Nos. 11, 12, and 13 are compared in Fig. 13 with the values as determined by furnace-exit temperature in the A.S.M.E. Radiation-Committee report[3] for boilers Nos. 1, 2, and 3. Reliable μ-values were not available for the units taken from the literature. The results check approximately. The μ-values, calculated by means of the waterwall-boiler evaporation, are seen to vary somewhat with the flame length, as effected by changes in the primary and tertiary air pressures. Long flames produce a greater heat absorption in the screen boiler than short flames. This causes a variation in the resulting μ-determination.

The gas-temperature μ-values do not exhibit as much variation. It is evident that the increased heat transfer of the surfaces of the waterwall boiler in the case of the long flame would have to be compensated for by decreased heat absorption in the furnace-exit surfaces in order that the gas-temperature μ-values might remain nearly constant.

The foregoing appears logical since long flames occupy more of the bottom portion of the furnace, thus causing increased radiation to the bottom tubes and decreased radiation to the top of the furnace. They also cause considerable convection-heat transfer to the bottom screen-boiler tubes.

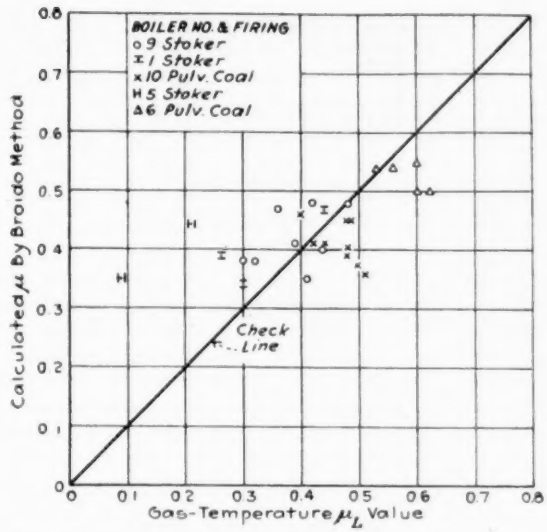

FIG. 14 COMPARISON OF RESULTS BY BROIDO METHOD FOR BOILERS NOS. 1, 5, 6, 9, AND 10[3]

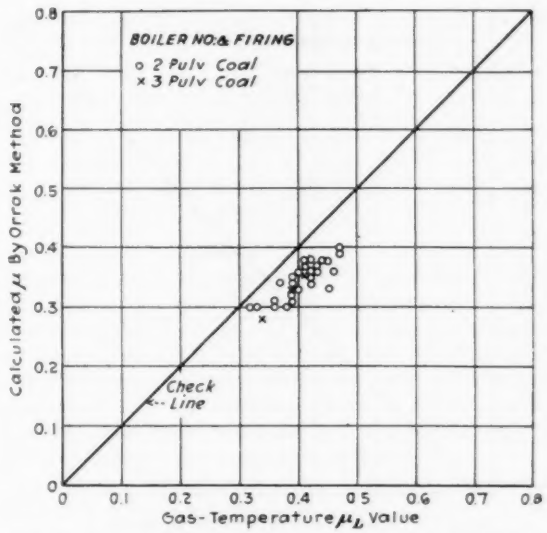

FIG. 15 COMPARISON OF RESULTS BY BROIDO METHOD FOR BOILERS NOS. 2 AND 3[3]

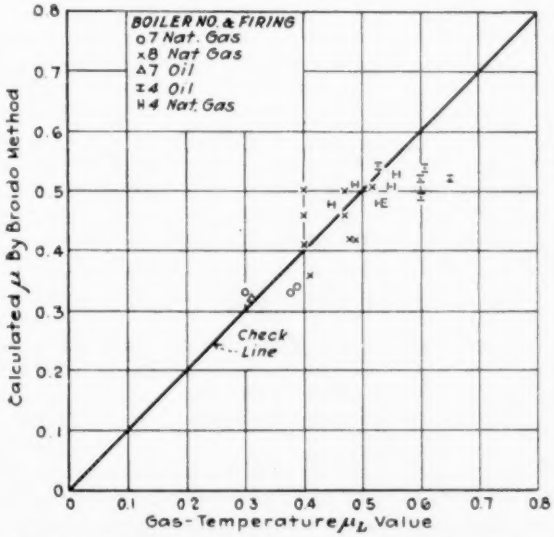

FIG. 16 COMPARISON OF RESULTS BY BROIDO METHOD FOR BOILERS NOS. 4, 7, AND 8[3]

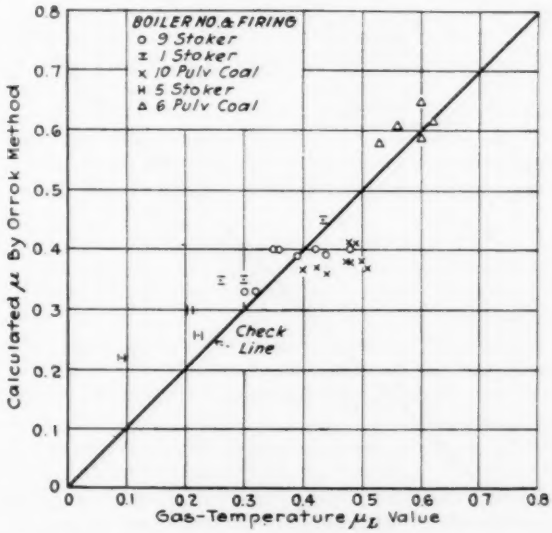

FIG. 17 COMPARISON OF RESULTS BY ORROK METHOD FOR BOILERS NOS. 1, 5, 6, 9 AND 10[3]

It is interesting to note that the values of μ check as closely as they do, but since the method employing the evaporation of the waterwall boiler is limited to special cases, and the gas-temperature μ-values determined by the method of furnace heat balance are more accurate, those determined by the evaporation method appear to be of no particular importance.

CHECK OF BROIDO, ORROK, AND WOHLENBERG METHODS

In Table 5 are given calculations for the tests on the units for which data is given in the A.S.M.E. Radiation-Committee report.[3] Item 43 in the table gives the μ-values obtained by the Broido method, item 46 the μ-values obtained by the Orrok method, and item 47 the μ-values obtained by the Wohlenberg method.

The results obtained by these three methods are compared in Figs. 14 to 21, inclusive, to the gas-temperature μ-values as given by A.S.M.E. Radiation-Committee report.[3] The line marked "check line" in these figures shows where the points lie if the two values check each other. The boiler numbers given in the various charts and tables correspond with those of the A.S.M.E. Radiation-Committee report.[3]

It should be again emphasized that in any usage of the Wohlenberg, Broido, or Orrok formulas, the results are dependent on the method of calculating the effective furnace radiant heating surface and that the surface calculated in a manner different from that used in this paper would yield different results.

It will be noted that the Broido determinations are surprisingly close considering the fact that only a single curve is used in the method.

The Orrok results are fairly representative except for the natural-gas tests for which the formula yields rather high values. The Orrok formula was probably not intended for natural-gas fuels. Further comment on these findings does not seem necessary, as the relative value of the methods, for the units for which tests are available, is quite apparent from the curves.

In view of the foregoing results it appears on the surface as though the values for gas radiation given by Schack (59) and used in the Wohlenberg method are somewhat low.

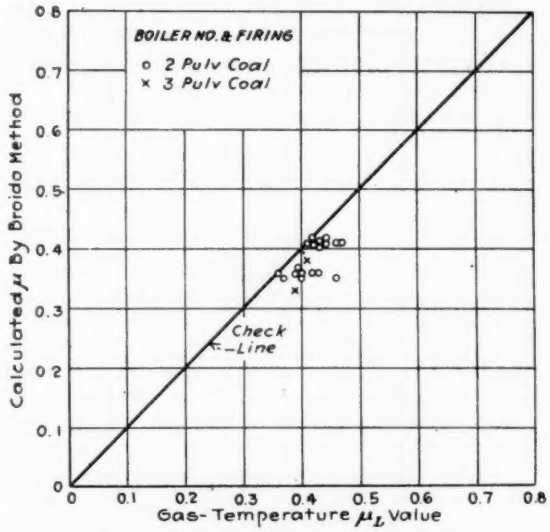

FIG. 18 COMPARISON OF RESULTS BY ORROK METHOD FOR BOILERS NOS. 2 AND 3[3]

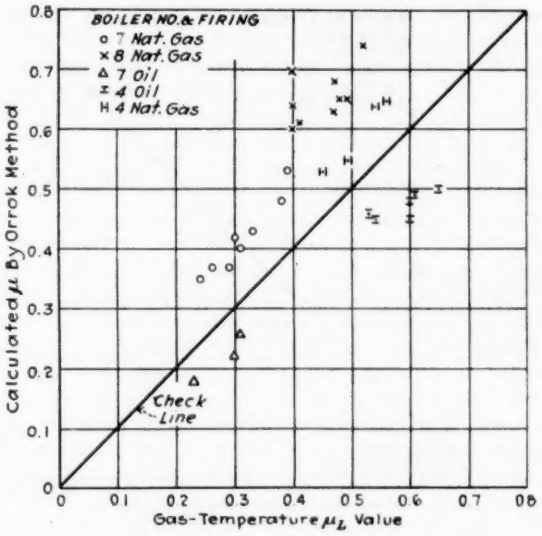

FIG. 19 COMPARISON OF RESULTS BY ORROK METHOD FOR BOILERS NOS. 4, 7, AND 8[3]

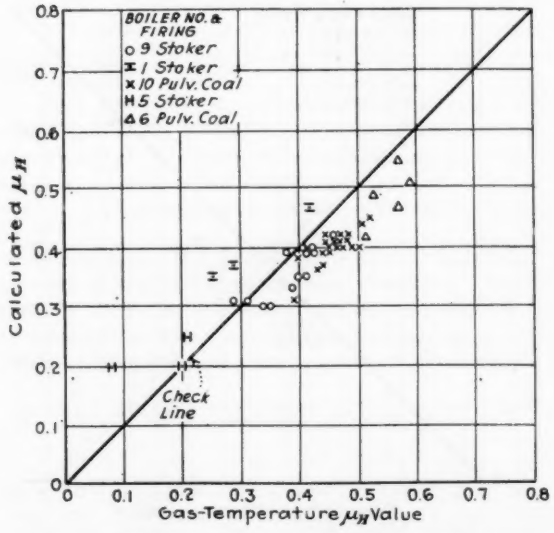

FIG. 20 CHECK OF WOHLENBERG METHOD FOR BOILERS NOS. 1, 5, 6, 9, AND 10[3], USING THE NEW COEFFICIENTS (*F*-FACTORS)

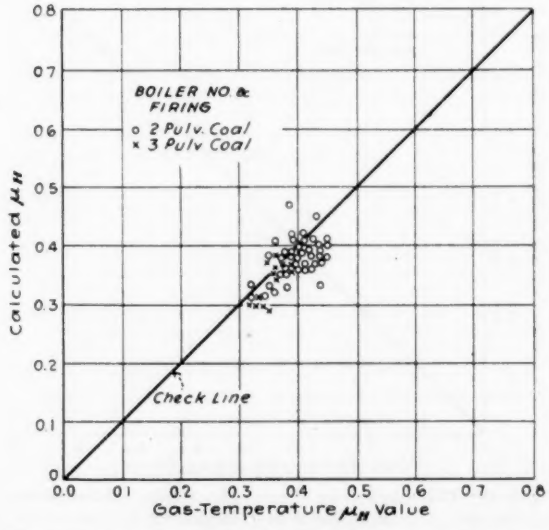

FIG. 21 CHECK OF WOHLENBERG METHOD FOR BOILERS NOS. 2 AND 3[3], USING THE NEW COEFFICIENTS (*F*-FACTORS)

This apparent discrepancy may, however, be due to the fundamental assumption of the Wohlenberg method that the furnace-exit-gas temperature is also equal to the mean radiating furnace temperature.

The so-called straight Stefan-Boltzman law method has had so many different values given for the constants therein contained, and is in such a crude form as ordinarily used, that no determinations have been made by this method for presentation in this report. While the Stefan-Boltzman law is used in the Wohlenberg derivation, it is only one of the factors used to obtain a solution, and therefore the method is not classified under the foregoing heading. An attack using the Stefan-Boltzman law is included in a paper by one of the present authors.[6]

An Experimental Investigation of Heat Absorption in Boiler Furnaces

By W. J. WOHLENBERG,[1] NEW HAVEN, CONN., H. F. MULLIKIN,[2] NEW YORK, N. Y., W. H. ARMACOST,[1] NEW YORK, N. Y., AND C. W. GORDON,[2] CHICAGO, ILL.

This paper is a report of the A.S.M.E. Committee on Absorption of Radiant Heat in Boiler Furnaces and includes test data obtained on ten boilers in different power plants in the United States. It involves stoker-fired, pulverized-fuel, and oil- and gas-fired units with various combinations of refractory and water-cooled furnaces. The data include furnace-exit gas temperatures as measured by means of the high-velocity thermocouple. These temperatures are used to determine the fraction of heat input to the furnace that was absorbed in its walls.

AT THE time the committee[4] submitting this report was formed it was suggested that radiation tests on large commercial boiler furnaces be made to supplement work of a more fundamental nature which was being conducted by various agencies. As a result a fellowship, sponsored by the Superheater Company, was established under the joint direction of Professor Wohlenberg of Yale University and Messrs. R. M. Gates, R. M. Osterman, and C. W. Gordon to study the problem and make such tests as might be necessary to put the subject on a more practical basis. H. F. Mullikin was appointed research fellow under this arrangement and had charge of the tests.[5] These tests were made on ten boilers in different power plants in the United States and involve stoker, pulverized-fuel, oil, and gas firing with various combinations of refractory and water-cooled furnaces.

Before describing these tests in detail, it seems advisable to discuss briefly the more important papers which have appeared on the subject. It is not proposed to outline in detail the previous material printed on this subject but merely to refer to the works of past authors.

Since the general adoption of the waterwall furnace for large steam-generating units beginning about 1924, many articles have been written offering various methods of obtaining a solution to the furnace heat-transfer problem. The majority of these have been technical, and are based on physical constants and laws, and on observed general conditions in furnaces. Several have been based on empirical test data.

The principal objection to any type of solution based on theory is that it is difficult to take into account a large number of design variables such as type of fuel; fineness of fuel; location and type of burners; location, type and surface of waterwalls and exposed boiler tubes; volume and shape of furnace; combustion characteristics of different fuels or of the same fuel under slightly different conditions; and such operating factors as slag on surfaces, flame length, draft, flame impingement, flame volume, excess air, method of air supply, and temperature of air.

Because of the difficulties involved in making heat-transfer tests, very few of them have been made, and it is upon the data from this insufficient number of tests that most empirical methods for solving heat-transfer problems are based. Therefore, it is questionable as to what extent these results can be applied. The empirical formulas generally neglect most of the factors and depend only upon one or two of the principal variables. Very few of the methods have not been checked by any one other than the original investigator.

With these facts in mind, attention is called in the bibliography to some of the more notable attacks on the problem. The list is not claimed to be complete but it is believed that most of the methods yielding fairly reasonable quantitative results are included.

In 1925 Broido (7)[6] presented a paper giving an excellent general discussion of the problem with a single curve to summarize several tests. Wohlenberg and various associates have presented numerous papers (1, 2, 3, 4, 5) containing an attack on the problem from a fundamental theoretical basis. Modified forms of this method, some of which are better adapted to practical application, are given by Haslam and Hottel (13, 60), and Münzinger (21, 41, 55). Even so, it is difficult to evaluate certain practical conditions in the process of solution. Orrok (20) has presented a formula empirically derived from Hudson (39). Wilson, Lobo, and Hottel (45) have adapted the Orrok equation in oil-still design. In most of these methods the Stefan-Boltzman law has been adapted.

Others making use of the Stefan-Boltzman law are: Schack (6, 59), Roszak and Veron (23), Gerbel (40), Ritchie (42), Forssblad (9), Seibert (48), and Müller (46). Rosin and Fehling (47) have developed theoretical equations to give maximum furnace heat liberation rates. DeBaufre (17) has reported tests on several units and has used a furnace heat balance to correlate his results. Kuhn (14) and Friedrich (54) have reported tests similar to those of DeBaufre.

A large number of tests have been run on boiler furnaces in which one or more tubes were isolated and the actual heat absorbed was measured by water circulated through the tubes. Results have in most cases been reported, but no attempt was made to derive an equation or formula therefrom. A number of these tests have been reported by Broido and Orrok (7). Others may be found in some of the N.E.L.A. serials (27, 28, 29, 33), transactions of various societies (10, 25, 34, 36, 37) and other sources (19, 26). A number were reported in papers by Artsay (12) and Ramzin (22).

Bailey (24) has developed a method of measuring heat absorption in furnaces having waterwalls covered with refractory facings. Schack has suggested the use of the radiation pyrometer for such measurements (6, 13). Koessler has used the thermopile (32). Croft and Schmarje (56) have used an absorption calorimeter to measure incident radiation to the walls of a furnace.

In Sweden, Lindmark and his associates have reported results (15, 16, 43) of tests involving the use of oil and pulverized fuel in an experimental furnace. In this country Sherman has published (51, 52, 53) considerable material on an experimental installation burning pulverized coal and gas. Brown advanced an empirical curve (8) which Marshall has discussed (44). Bottomley has presented a paper (49) based on data reported by Orrok.

Sherman has reported data on furnaces (31) taken during the course of an investigation on refractories. Artsay has presented two papers (11, 12) giving an analysis based on hydraulic similitude. Data on gas radiation have been reported by numerous investigators who will not be mentioned here.

Methods for Determining Radiant-Heat Absorption

Consideration of the previously described articles and papers reveals that five principal methods have been used in attempts to determine radiant-heat absorption in boiler furnaces. They are (*a*) determination of the actual evaporation in one or more tubes exposed to radiant heat, (*b*) use of physical methods such as the thermopile or radiation calorimeter, (*c*) the establishment of a temperature gradient through conducting material (only applicable to refractory-faced blocks), (*d*) a determination of the furnace temperature and subtraction of the heat leaving the furnace in the gases from the heat input to the furnace, and (*e*) the use of known physical data such as the Stefan-Boltzman law, and values of gas radiation.

The first four of these methods are empirical whereas the last is primarily a theoretical attack. Obviously the ideal procedure would be to develop first an attack which would give theoretical formulas to cover all cases and conditions, and then second to determine with the aid of data supplied from tests, the values of constants which appear in the theoretical formulas.

Unfortunately, the data given in the literature for each individual test usually are so meager that it is impossible to coordinate data from various sources in order to show the effect of such dimensions as furnace volume, and radiant heating surface. Thus, the committee submitting this report decided to conduct tests on a number of existing furnaces in order to obtain data which could be used as a reference for checking theoretical or empirical formulas.

The first of the four previously mentioned practical methods for determining radiant-heat absorption (segregating portions of the waterwall) is not ordinarily feasible in the case of the usual boiler furnace because of the expense and time involved. There are perhaps half a dozen boiler installations in the United States where the waterwall circulation is in some manner separated entirely from the boiler proper. Tests on three of these installations are given in this paper. Another notable example is the boiler installation at the Ford Motor Co., Fordson, Michigan, (10, 19), in which the side-wall tubes constitute an entirely separate boiler. Even here the top tubes of the furnace and the lower

boiler-tube row belong to the boiler proper and hence their heat absorption cannot be experimentally determined in this manner.

During the preliminary work on tests conducted by the committee, attempts were made to use a radiation calorimeter or "thermaprobe" as it has been termed. It was made of a flat-faced hollow steel block through which water was circulated. The heat absorbed by the circulating water was found by measuring its weight per unit of time, and its initial and final temperature. This method was discarded as being unsatisfactory. The objections are: (1) Limitation as to number and location of openings which may be made in the furnace walls, (2) difficulty in controlling the water flow at a constant value, (3) difficulty of operating more than one thermaprobe at the same time, (4) lag in responsivity during time intervals in which furnace conditions change, (5) difficulty in obtaining the same amount of slag on the thermaprobe that existed on the furnace tubes, or of allowing for it by correction and (6) possibility of considerable error due to peculiar local conditions.

[a] North side of boiler.
[b] South side of boiler.

The third method for determining radiant-heat absorption given by Bailey (24), is not applicable to bare-tube or fin-tube construction.

It appeared that the fourth method, which involves measuring the furnace-outlet gas temperature and setting up a furnace heat balance along the lines suggested by Kuhn (14) and DeBaufre (17), furnishes the most feasible method for determining heat transfer in boiler furnaces. The difference between the test procedures given by Kuhn and DeBaufre lay in the method of measuring gas temperatures. Kuhn used a high-velocity thermocouple, which is at present generally conceded to be the most accurate method of temperature measurement. DeBaufre, it is understood, used ordinary bare thermocouples.

TEST APPARATUS

The high-velocity thermocouple used in making the tests discussed in this report is shown in Fig. 11. The instrument consists of a water-cooled brass tube which can be inserted into the gas stream, the usual distance being 92 in. minus the wall thickness. The gases are aspirated past the hot junction of the thermocouple at a very high velocity by means of the air ejector. This increases the heat transfer from the gas to the thermocouple, thereby causing the thermocouple to read close to the true gas temperature. A more complete theory and description has been given elsewhere (18).

For some of the tests a radiation pyrometer was available which was used to take readings, where possible, for use according to Schack's (6) or Koessler's (32) method. These readings were later discarded, as early experiments showed that only indefinable mean results could be obtained by use of the radiation pyrometer. However, they did show that under certain conditions the emissivity of the furnaces, as indicated by a comparison of the high-velocity thermocouple and radiation-pyrometer determinations, may approach close to the value of unity.

DESCRIPTION OF THE BOILERS USED IN THE TESTS

In choosing boilers for test purposes, the committee endeavored to select representative boilers of various types burning various fuels in different manners. The following boilers were selected for testing:

1 Semivertical underfeed stoker-fired boiler, Fig. 1, with waterwalls on all four sides and 24,600 sq ft of heating surface.

2 Double-ended pulverized-coal-fired boiler, Fig. 2, with waterwalls on two sides, a slag screen on the bottom, and 27,548 sq ft of heating surface.

3 Double-ended pulverized-coal-fired boiler, Fig. 3, with a slag screen on the bottom and 27,548 sq ft of heating surface.

4 Semivertical combination gas- and oil-fired boiler, Fig. 4, with water walls on four sides and 10,830 sq ft of heating surface.

5 Horizontal cross-drum boiler, Fig. 5, with waterwalls on two sides, 15,000 sq ft of heating surface, and equipped with a chain-grate stoker.

6 Horizontal cross-drum boiler, Fig. 6, water cooled on four sides and the bottom. This boiler has 10,760 sq ft of heating surface and burns pulverized fuel.

7 Horizontal cross-drum combination gas- and oil-fired boiler, Fig. 7, with a refractory furnace and 15,150 sq ft of heating surface.

8 Horizontal cross-drum gas-fired boiler, Fig. 8, with waterwalls on four sides and 15,930 sq ft of heating surface.

9 Horizontal cross-drum boiler, Fig. 9, with waterwalls on four sides and 22,900 sq ft of heating surface. This boiler is equipped with an underfeed stoker.

10 Double-ended boiler, Fig. 10, with waterwalls on all sides and 60,706 sq ft of heating surface. This unit burns pulverized fuel.

Thus, data in this report include those from tests on three stoker-fired boilers, three gas-fired boilers, two oil-fired boilers, and four pulverized-coal-fired boilers.

A detailed description of these boilers is given in Table 1. This table also includes the various carefully measured exposed radiant surfaces, as well as construction and firing data. A considerable amount of data are given in order to furnish complete information concerning the tests, as it is not known exactly what factors influence the results obtained.

The surface areas given in Table 1 are overall values measured on the particular furnace walls taken as planes. The proximate analyses given are usually based on the fuel used during the tests. It was not always possible to take an ultimate analysis, and therefore, in some cases the values for the ultimate analyses are for the average station fuel rather than the specific values for the coal used during the tests. An estimate of the slag on the actual waterwall surfaces has been made. It was impossible to judge flame volumes to any degree of accuracy.

Preliminary Tests

Since the temperature measured at the furnace outlet (denoted by *M* in the figures) was the most important determination of the tests it is advisable to note some of the preliminary work.

During the tests on the first unit, Fig. 1, it was decided to measure temperatures by high-velocity thermocouples on one side of the boiler at points *A*, *M*, *N*, and *C*, and on the other side of the boiler at point *C*. Some of the data obtained at these points on the boiler shown in Fig. 1 are given in Table 2.

The temperature differences at *C* between the two sides of the boiler are less than 50 F at low loads and less than 20 F at high loads. The high-velocity thermocouples could be inserted up to a maximum distance of 7 ft into the boiler pass. Since this boiler, Fig. 1, is 24 ft wide, this left a space of 12 ft in the middle (less in the other boilers) which could not be reached by the high-velocity thermocouples. However, it was noted early and confirmed repeatedly that the gas temperature within reach of the tip of the high-velocity thermocouple showed no discernible temperature gradient to within 20 in. of the wall. On this account it is believed that the temperatures in the middle of the furnace width are not appreciably higher than at a point 6 or 7 ft from the wall.

Moreover, the furnace-gas temperatures are subject to minute-to-minute variations in the neighborhood of 100 F in most of the boilers tested, especially in the stoker-fired units.

Thus, it would seem that one reading on one side of the furnace width, while not as desirable as an average of temperatures taken across the pass and weighted according to mass flow, is nevertheless, over a period of time quite indicative of the average furnace-exit temperature within the accuracy of the other factors governing the tests.

The maximum error caused by this procedure of measuring temperatures will obtain at low loads where stratification of gas is more apt to occur. At high loads the gases will fill the furnace more uniformly and will promote temperature conditions which are more nearly uniform. Likewise, the furnace temperatures will be higher and since radiation is roughly proportional to the fourth power of the temperature, this radiation will also tend to equalize gas temperatures in various parts of the furnace cavity. This last statement is confirmed by the data of Table 2 where it will be seen that the temperatures at *A*, *N*, and *M* are in close agreement at the high load. Possibly it might be considered that high-load tests yield more accurate results than tests at lower loads.

It is possible that the temperature gradient frequently observed across boiler passes in the neighborhood of the superheater is more pronounced than in the hotter zones. This is due to unequal convection-heat absorption and the fact that radiation is insufficient to permit temperature equalization.

Description of Tests and Test Data

The boilers tested are shown in Figs. 1 to 10, inclusive, and are numbered from 1 to 10, respectively, in the tables. The furnace-exit temperature is taken at the point *M* as shown in the figures. This point was, whenever possible, chosen so as to be in the main gas stream approximately 1 ft underneath the boiler tubes at the furnace exit and about 6 ft toward the center of the furnace, measured from the inside furnace wall. Measurements were taken on one side of the furnace. The steam flows were measured

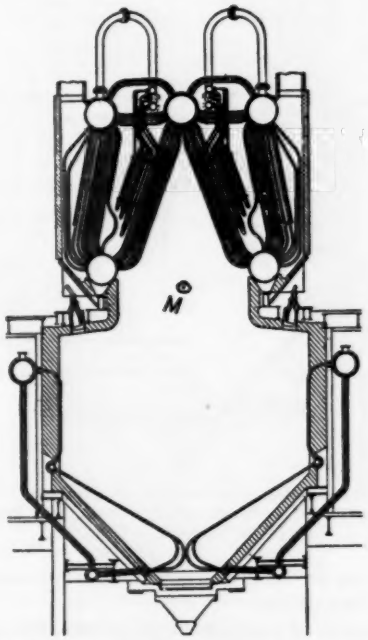

Fig. 2 Double-Ended Pulverized-Coal-Fired Boiler With Separate Waterwall-Boiler Circulation and Two Side Walls of Furnace Water Cooled

by flowmeters which were usually "water-columned" before the tests. The flowmeter readings are believed to be within 5 per cent of the true values, which is within the accuracy desired. Flowmeter corrections due to pressure and temperature were not made as they were small. The boiler-outlet temperatures were averages determined by a number of bare thermocouples or by calibrated recorders. Steam pressures were obtained by checked station gages. Feedwater and steam temperatures were obtained by thermometers or thermocouples.

Various auxiliary data which may be of interest were also included. The gas analysis is an average for samples taken across the top of the first pass or at the boiler outlet as noted in item 16 of Table 3.

The thermoelements of the high-velocity thermocouples were calibrated before a number of the tests and were always found to be within 10 F of their original calibration. The gas temperatures within the furnace, within the reach of the end of a high-velocity thermocouple located at any opening, were nearly always found to be constant at all points up to within about 2 ft of the

inside wall of the furnace for any of the tests, neglecting momentary total furnace-temperature variations of as much as 100 F.

A number of the readings of the high-velocity thermocouple were taken in various portions of the furnace and in the boiler passes but, as this paper is confined to the calculation of furnace radiation, they have not been included.

The furnace-temperature readings are usually averages of separate readings taken 10 minutes apart, the high-velocity thermocouple being removed between readings to avoid slagging difficulties. Duration of tests varied from 30 minutes to $3^1/_2$

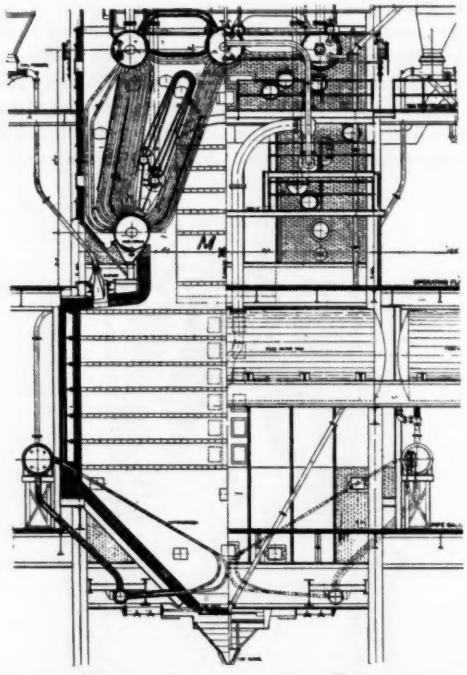

FIG. 3 DOUBLE-ENDED PULVERIZED-COAL-FIRED BOILER WITH SEPARATE WATERWALL-BOILER CIRCULATION AND WATER COOLING ONLY ON BOTTOM OF FURNACE

hours according to conditions governing boiler operation at the individual power plants.

The percentage of moisture in the steam entering the superheater was measured in almost all of the tests and was found to be less than 0.5 per cent.

The data of a number of specific tests are given in Table 3 in some detail. Due to space limitations a large number of the less important tests are not included.

The first boiler which was tested is fired by an underfeed stoker and has a separate screen or waterwall boiler. The greater portion of the front wall is covered with refractory block. The other walls are covered with bare-faced blocks in the lower part and bare tubes in the upper part of the furnace.

The furnace water-walls, constituting the screen boiler, have a separate drum, the steam from this drum mixing with the steam from the boiler proper before entering the convection superheater.

Flames passing up into the boiler as far as the superheater indicated somewhat delayed combustion. An attempt was made to take gas analyses at points in the furnace in order to estimate the amount of this delayed combustion. Results obtained were extremely erratic, carbon monoxide in the middle of the furnace ranging anywhere from zero to 10 per cent. An analysis for hydrogen was not made. After numerous trials this gas sampling was given up as being too difficult for practical accomplishment because the time required to obtain representative samples would be longer than the boiler could be held at the given condition. This matter of delayed combustion was found to be characteristic of stoker-fired furnaces. No such extreme condition was evident in the furnaces fired by fuel in suspension.

Due to the difficulty encountered in the testing, tests were run only at high, medium, and low loads, the actual time of the tests being but a few minutes although sufficient time was allowed between tests to obtain fairly steady conditions.

The second boiler tested, although fired by pulverized coal, was similar to the first in that the bottom screen and side-wall tubes constituted an entirely separate boiler as may be seen by reference to Fig. 2. In this type of firing, the fuel is conveyed from the burners by a small amount of primary air. Secondary air is drawn in through ports in the side wall adjacent to the burners, located in this case, among the side-wall tubes. In order to assure a sufficiently long flame at the higher combustion rates, a small amount of preheated forced-draft air is introduced under

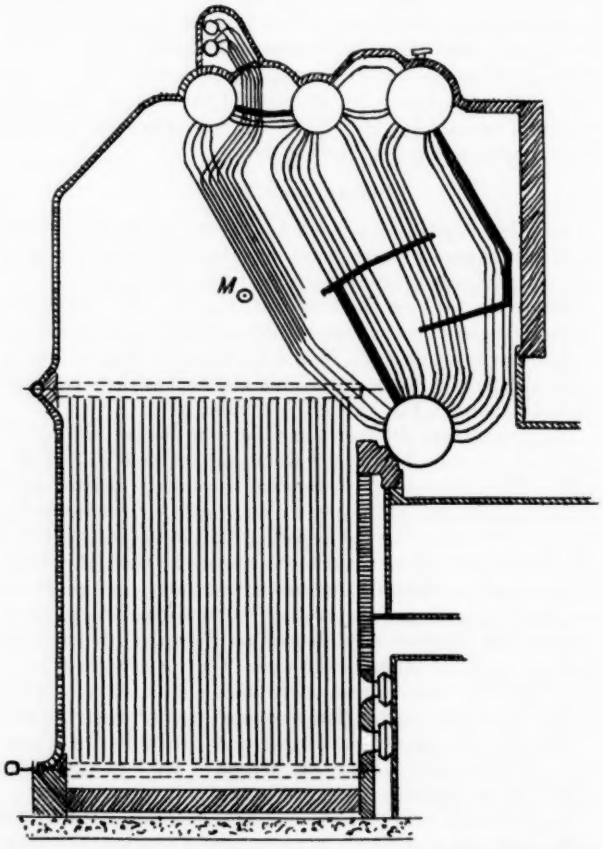

FIG. 4 ALL WATER COOLED COMBINATION GAS- AND OIL-FIRED BOILER

pressure at the burners. Because of this, the length of the flame is a function of both the primary and forced-draft air pressures.

Due to the operating and control conditions on this boiler it was feasible to make more extensive tests than were made on the first boiler. On this account each test was repeated for three excess-air values in order to determine the resulting effect.

Included in the first group of tests are results for three loads at three flame lengths and three excess-air values each, thus making a total of 27 tests. These tests were run half an hour apart, two readings being taken for each test. Gas analyses were also taken in the furnace during these tests. Although no carbon monoxide could be found, the gas-analysis results were so varied

that they were discarded and reliance was again placed on boiler-outlet gas-analysis values.

It should be noted that the terms "short flame," "normal flame," and "long flame" are only relative and do not have exactly the same magnitude for different tests.

As some of the results obtained in this first group of tests did not agree, it was thought that perhaps the duration of the tests was too short. It was then decided to run a second series of tests during which readings were taken every 10 or 15 minutes for a test period of 3 hours.

Comparison of the data obtained from this series of tests with the test data from boiler No. 1, showed that, in spite of the additional length of the tests, the results were not much better, and therefore the data have been omitted. The reason for this is probably the fact that the increased accuracy of the readings due to the longer time of the tests, is more than balanced by changed furnace conditions. Hence no more long-time tests were attempted on this boiler.

During the previous tests the side-wall tubes were covered with a certain amount of slag, the 2-in. space between the tubes and

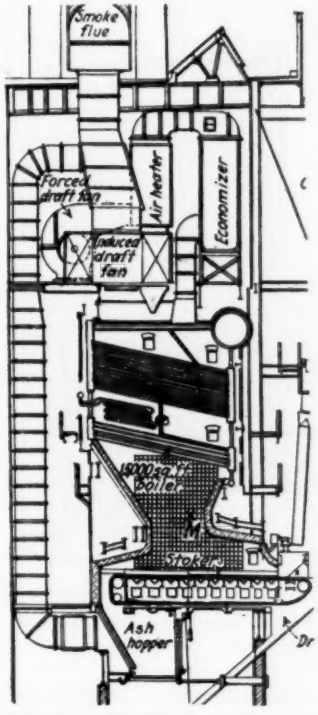

FIG. 5 BOILER COOLED ON TWO SIDES OF FURNACE AND FIRED BY CHAIN-GRATE STOKER

the wall being completely filled with slag. In order to ascertain the effect of this slag on the screen-boiler evaporation, the boiler was taken off the line, the slag removed, and the tubes wire-brushed. Tests 2–8*C*, 2–14*C*, and 2–23*C*, were made under these new conditions.

The third boiler tested, Fig. 3, is exactly similar to boiler No. 2 except that there are no side-wall tubes and the superheater and baffling, with which we are not concerned, are slightly different. Comments applying to the boiler No. 2 apply also to boiler No. 3. Fewer tests were run on this boiler. From among the first group of tests, 3–8, 3–6, and 3–13 are given for three steam ratings.

As was done in the case of boiler No. 2, a second series of tests was run using longer test periods. The results were susceptible to the same conclusion as was arrived at in the case of the boiler No. 2, and are likewise omitted.

The fourth boiler tested was the oil- and gas-fired unit shown in Fig. 4. Oil was the fuel ordinarily used, natural gas being used as a stand-by fuel. The gases within the furnace were almost transparent. Due to operating conditions, a high load could not be carried on this boiler. Tests were made at three loads with two excess-air values each, for both oil- and gas-firing, except that test 4–12, which would have been with a high per cent air, was omitted. Duration of tests was approximately 1 hour.

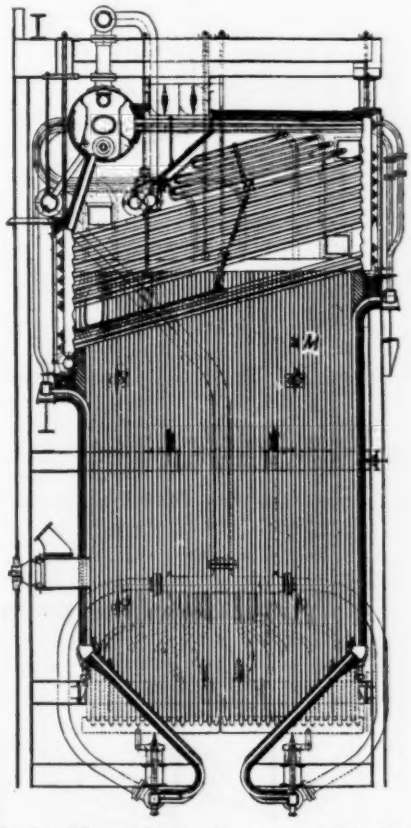

FIG. 6 ALL-WATER-COOLED PULVERIZED-COAL UNIT

The fifth boiler tested, shown in Fig. 5, was fired by a chain-grate stoker having two overhung combustion arches. The tests on this boiler were not as satisfactory as on the other boilers. Delayed combustion was again evident. Combustion was uneven on the grate and excess air was high. Instead of measuring the furnace-exit temperature just under the boiler tubes it was necessary to measure this temperature in the middle of the furnace as no other opening was available or could be made. It was not possible to vary the excess air, hence only three short tests were made at three boiler evaporations. These tests should not be considered as reliable as the other tests.

The sixth boiler tested, shown in Fig. 6, was an almost completely water-cooled furnace, burning pulverized coal and fired by two turbulent burners in the front wall. Due to temporary difficulty with the induced-draft fan, a high load could not be carried on the boiler. Similarly, a high excess-air medium load could not be carried. Hence, but five tests were run; three at different excess-air values at low load and two at different excess-air values at medium load. Duration of tests was from 1 to 2 hours.

The seventh boiler tested was the refractory-furnace gas- and oil-fired boiler shown in Fig. 7. Tests were made at three loads, when burning natural gas, operating with three excess-air values

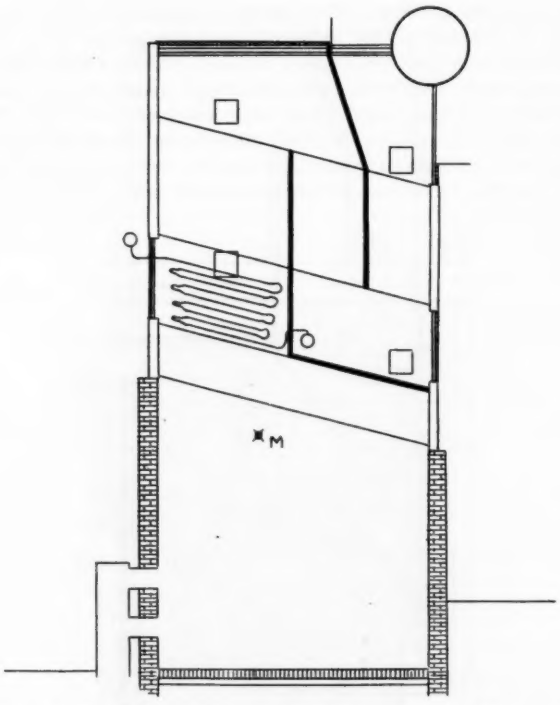

FIG. 7 COMBINATION GAS- AND OIL-FIRED BOILER WITH ALL-REFRACTORY FURNACE

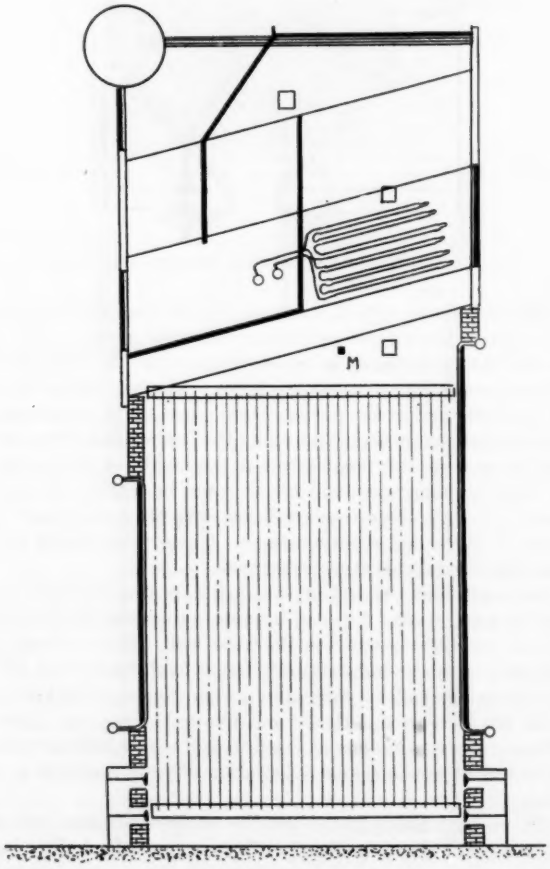

FIG. 8 GAS-FIRED BOILER WITH FURNACE COOLED ON FOUR SIDES

at each load except for the higher load where one test was omitted. Duration of tests was approximately half an hour with considerable time between tests.

The tests using oil (7–10, 7–11, and 7–12) were made at three boiler loads and were of limited duration because of the desire not to use oil, inasmuch as it was only an emergency or stand-by fuel. The furnace gases were transparent at all ratings.

The eighth boiler tested was the water-cooled natural-gas-fired boiler shown in Fig. 8. There was no provision for oil firing. Due to trouble in the turbine room, it was difficult to put high evaporative loads on this boiler. Tests 8–1 to 8–5 were run with low and medium loads and various air values. Tests 8–10, 8–11 and 8–12 were run at a medium boiler evaporation with different feedwater temperatures. Test 8–13 represents the one high-load test that was run. The furnace gases were perfectly transparent at all ratings. Each test required about 1 hour.

The ninth boiler was the underfeed-stoker-fired boiler with bare-tube waterwalls shown in Fig. 9. Tests 9–6 and 9–7 show

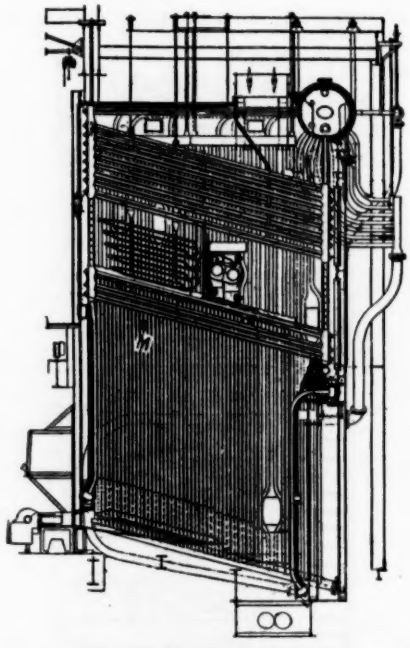

FIG. 9 UNDERFEED-STOKER-FIRED UNIT WITH ALL WATER-COOLED FURNACE

the effect of varying the feedwater temperature while holding the boiler at a constant output. Tests 9–6 and 9–7 were made on the boiler just before it was taken off the line for repairs. The tubes were dirty and the grates burned. Tests 9–14 to 9–19 were made after the grates had been reconditioned, the boiler having been in operation two days in order to obtain representative conditions. These tests were made at three evaporative ratings with two values of excess air each and each test lasted one-half hour.

The tenth boiler test was made on the large double-ended pulverized-coal-fired boiler shown in Fig. 10. This was the only boiler furnace in which any attempt was made to keep the side waterwall tubes clean during normal operation. The tubes were dusted twice daily by means of a compressed-air lance through four openings in each side wall, thus tending to retard slag formation on a portion of the waterwall surface.

Tests 10–12, 10–13, and 10–14 were run at three boiler loads with a low feedwater temperature. The feedwater temperature was increased and tests 10–15 to 10–20 followed at three loads with various excess-air values at each load. Each of these tests

were of 15-minutes duration. The data of a series of longer tests lasting perhaps three hours were discarded as being inconsistent, undoubtedly because boiler conditions change from day to day.

Discussion of the Tests

Several important points may be noted by examining the data obtained. Unless all of the tests are run in one day it is difficult to reconcile the data taken on two different days because of varying furnace conditions which are not a function of the operation of the boiler control instruments. In regard to future tests, it is believed that the influence of excess air has been amply demonstrated. Also, except for extremely accurate work, the importance of flame length in regard to furnace-exit temperature appears to be insufficient to warrant extended tests to show its effect.

As the object of these tests was to determine actual results which might be checked against theoretical calculations and existing formulas, it was advisable to determine values of the ratio of heat absorbed by radiation to the heat input to the furnace. These calculations are included in Table 3. The method of making the calculation is outlined in Table 4.

In calculations it is necessary to distinguish between the amount of excess air in the furnace and the amount at the boiler outlet. Using data obtained from a considerable number of tests, an average value of 7 per cent air leakage between the top of the first pass and the boiler outlet has been assumed. For calculation purposes the percentage of air at the top of the first pass has been assumed to be the same as that in the furnace. The percentages of air used as given in items 20 or 21 in Table 3, were obtained from calculated CO_2 curves for the fuels in question.

In order to determine the heat in the gases at the boiler outlet and at the furnace exit it was necessary to plot heat-capacity curves for the different fuels burned. A sample curve is given in Fig. 12. These curves are based on the values for the specific heat of gases recommended by Goodenough (58). Eastman's specific heats (57) are perhaps to be preferred and would result in an increase of about 2 per cent in the sensible heats. This difference in sensible-heat values affects the μ-values less than 2 per cent.

The initial temperature of the air, as well as the temperature at which the fuel is assumed to enter the furnace, has been taken as 80 F. The calculations are made as if the fuel entered the furnace at this temperature, the heat derived from combustion plus any preheat in the air being used to raise the products of combustion from 80 F to the actual furnace temperature. The sensible heat in the gases at any temperature therefore contains, not only any heat added by combustion, but also the heat in the gases at 80 F, i.e., the heat-capacity curves are based upon 0 F abs.

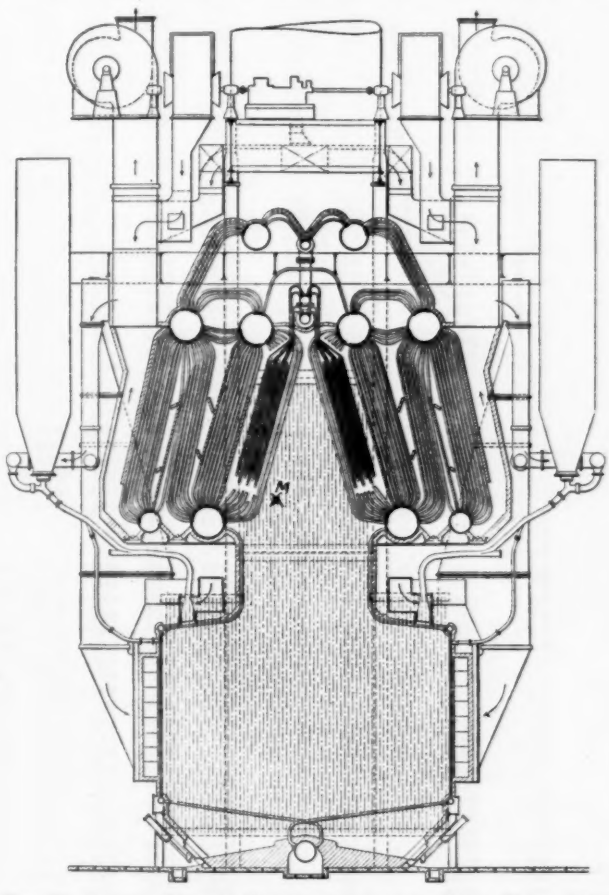

Fig. 10 Large Double-Ended Pulverized-Fuel Unit With Waterwalls on All Sides of Furnace

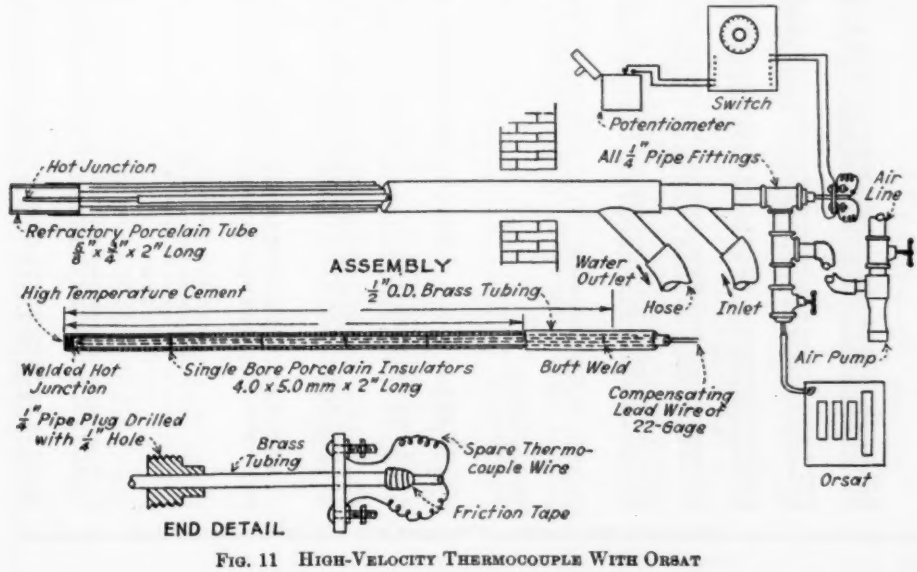

Fig. 11 High-Velocity Thermocouple With Orsat

The heat in the preheated air and the latent-heat losses have been calculated by conventional methods. The moisture is from (*a*) moisture in the air, (*b*) moisture in the coal, and (*c*) moisture resulting from the combustion of hydrogen and hydrocarbons in the fuel. The first does not occasion a latent-heat loss. The latter two require heat from the coal to vaporize the moisture.

It is to be noted that the energy as heat taken from the combustion heat to evaporate hydrogen and moisture into water vapor does not appear as British thermal units in the gases in the heat-capacity curves. Since the

[a] Equipped with underfeed stoker. [b] Burns pulverized coal. [c] Equipped to fire oil or gas. [d] Equipped with chain-grate stoker. [e] Burns natural gas.

TEMPERATURES AND CALCULATED μ-VALUES

22	23	24	25	26	27	28	29	30	31	32	33	34	35	36	37	38
Sensible heat in furnace gases at boiler outlet, 1000 Btu per lb wf	Sensible heat in gases at 80 F, 1000 Btu per lb wf	Heat in preheated air, 1000 Btu per lb wf	(High heat fuel + air heat), 1000 Btu per lb wf	(High heat fuel + air heat + latent heat), 1000 Btu per lb wf	(High heat fuel + air heat + gas heat at 80 F − latent heat), 1000 Btu per lb wf	Combustible + boiler radiation loss, %	Heat loss in dry gases at boiler outlet, 1000 Btu per lb wf	Summation of losses	Boiler efficiency based on furnace input	Heat added by boiler to total steam, 10^6 Btu per hr	Heat input to furnace, 10^6 Btu per hr	Heat in gases at furnace temp, 1000 Btu per lb wf	Heat to furnace surface, 1000 Btu per lb wf	Gas temp μ based on + [(high heat fuel) (air heat)]	Gas temp μ based on + [(low heat fuel) (air heat)]	Furnace heat input per unit volume, 1000 Btu per cu ft

TABLE 5 ASSUMED RADIATION LOSSES

Boiler surface, sq ft	Per cent loss
2,500 to 7,500	3.00
7,500 to 12,500	2.00
12,500 to 20,000	1.50
20,000 to 50,000	1.25
Over 50,000	1.00

heat is lost in so far as any heat transfer is concerned, unless the dewpoint of the gases is reached, it must be subtracted from the high heat value of the fuel.

It was impossible to conduct a weighed-fuel and water test on the boilers, thus necessitating the use of the heat-balance method (38) for the calculation of boiler efficiency. Results should be sufficiently close for the purposes of this report. The carbon, hydrogen, hydrocarbon, and overall boiler radiation loss have been combined and estimated in item 28 of Table 3.

The radiation loss through the furnace walls in per cent of the furnace heat input was taken as in Table 5.

The other losses were, judging by some experimental data (30), estimated as about 1 per cent for oil- and gas-fired boilers. For coal firing, these losses were estimated at values ranging from 2 per cent at normal ratings to 6 per cent at the higher ratings, these values being based on available data.

The calculations made in Table 3 to obtain the heat input to the furnace are evident. Using the heat-capacity curves in order to determine the heat in the gases at the furnace exit, the difference between this value and the heat of combustion plus the heat in the gases at 80 F plus the heat in the preheated air, will be the heat radiated or convected to the furnace surfaces. Complete combustion is assumed for this calculation. The ratio of the heat radiated to the heat input is readily calculated, and is termed the gas-temperature μ-value.

It will be seen that the heat in the preheated air used for combustion has been assumed to act exactly as if it were part of the calorific value of the fuel. This assumption is open to question in view of the possibility of chemiluminescence but no data exist to form a more exact conclusion. Any error from this source cannot be large.

There are two possible methods of computing the gas-temperature μ-value. In item 36 it is given as a ratio of the heat given up from the furnace gases to the calorific heat of the fuel plus sensible heat in air supplied from combustion.

Since the energy as heat required to evaporate the moisture resulting from hydrogen and moisture in the fuel is not available for radiation or to increase the sensible heat of the gases, a second determination of μ as a ratio of the heat given up from the furnace gases to the low heat value of the fuel plus any air preheat has been given as item 37.

In the cases where the boilers tested have separate waterwall circulation and drums, it is possible to estimate the heat absorbed in the furnace by use of a proportion between the total exposed effective radiant heating surface in the screen boiler and that part of the waterwall boiler on separate circulation.

This has not been done in this report since it involves an estimation of the relative heat-absorbing abilities of various kinds of waterwall surfaces which, in the present state of our knowledge of this subject, is to some extent dependent on individual opinion.

It should be noted that in calculating the gas-temperature μ-values, it was necessary to determine the boiler efficiency by the heat-balance method. This involves some element of personal judgment and it is realized that others would perhaps obtain different values for the boiler efficiency, thus getting slightly different μ-values. However, the differences should not be large and it has been deemed advisable to calculate and give these μ-values so as to present the data more effectively.

The data which are included will also serve, it is believed, as a criterion for checking results obtained by the various methods of calculation advanced by different investigators.

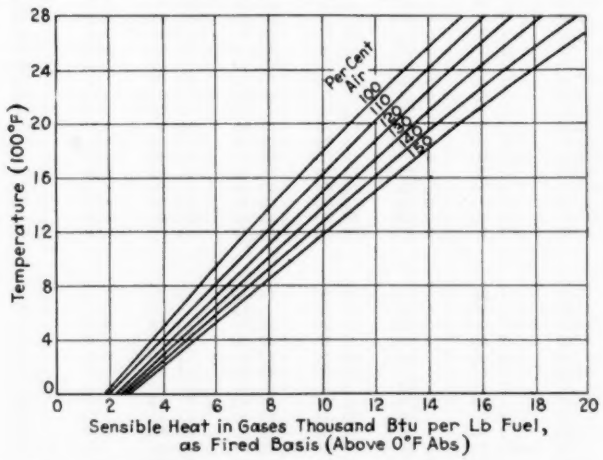

FIG. 12 TYPICAL HEAT-CAPACITY CURVES FOR NATURAL GAS (Goodenough specific heats used.)

With this in view the values of μ as computed from gas-temperature data have been included in Table 3, as stated previously. It is felt that the results included in a report by the committee should not be carried beyond this point because major assumptions would be involved about which there is no general agreement.

However, an investigation has been conducted in which the results of each of several well-known methods of arriving at μ-values are compared to the gas-temperature values of μ included in this report. This information is presented in the two papers, immediately preceding this paper, RP-57-2 and RP-57-3.

A study of the method of taking the experimental data included in this report will reveal the probable magnitude of any errors involved. The readings of the high-velocity thermocouples, by far the most important determination, are believed to indicate the true gas temperature within 50 F.

Furthermore, inspection of the data (of which a considerable amount is not given in this paper) will show that even under identical conditions of boiler-operating control, the furnace temperature may vary as much as 100 F from day to day. Theoretically, it would be possible to determine the cause of this variation which is probably due to such factors as irregular coal feeding, shifting combustion conditions, and different amounts of slag on the walls. Practically, the causes are indeterminate, hence, it would seem that a method yielding the greatest accuracy desirable should give results, in regard to the furnace temperature, of about ±50 F.

It is appreciated that many faults may be found with the

results. However, it is believed that a contribution has been made which will help in advancing the subject but which will require much more work, both practical and theoretical, before it can be said that it is on a thoroughly sound basis.

In the literature, the increasing tendency to measure furnace-exit-gas temperatures as a part of the complete boiler test is noted with gratification (30, 35, 50), although it is regrettable that high-velocity thermocouples are not always used for this determination.

It is impossible to mention individually all those who have cooperated in this investigation. Grateful acknowledgment is particularly due to the operating companies, who by lending the use of their facilities and personnel, have made this investigation possible. The names of the various power plants have been deleted by request.

Discussion

Steam-Turbine Leaving Losses and Vacuum Corrections[1]

ERNEST L. ROBINSON.[2] Professor Helander has presented a detailed set of computations of the effect of leaving velocity at the wheel annulus on vacuum corrections for steam-turbine performance. The corrections are based, as they should be, on a particular known performance and the author wisely qualifies his methods as suitable for use in the field where manufacturers' corrections are not available, and his basic theoretical analysis of the steam action in the last-stage bucket exit seems to be correct.

There are, however, a number of influences that must be taken into account in preparing the vacuum corrections for steam-turbine performance. The most important of these is the leaving-velocity loss from the last-stage wheel and this he has considered. Another important element is the pressure drop through the exhaust hood from the wheel annulus to the exhaust flange, which occurs despite considerable excess area. These two influences are closely inter-related and only an approximate analysis of the actual leaving loss can be made without taking account of the variation of pressure due to drop through the hood. Omitting the exhaust-hood loss, however, does give a first approximation to the vacuum corrections since when the exhaust-hood loss is larger, the leaving loss is less. Certain upstream effects are also to be reckoned with for a stage or two preceding the last, particularly at light loads. We understand from the author that these latter effects, while not evaluated, are allowed for in Appendix B if certain factors are known.

Manufacturers' vacuum corrections attempt to evaluate all these influences with the best available knowledge as to the performance of the several elements, supplemented with empirical corrections to the theoretical calculations following analyses of many actual tests. It would be our recommendation that where important decisions are involved, actual tests at various vacuums be carried out or the manufacturers' vacuum corrections, which are based on a wide knowledge of such tests, be used.

C. HAROLD BERRY.[3] The determination of vacuum corrections is an important undertaking in connection with an acceptance test of a steam turbine. The A.S.M.E. Test Code for Steam Turbines now requires that vacuum corrections be established by prior agreement between the manufacturer and the purchaser, either in the purchase contract or in a separate agreement, or else that the corrections be found by auxiliary tests. The first alternative is tantamount to accepting the manufacturer's correction curves; if the purchaser is unwilling to do this, he must conduct a costly series of tests.

Some readers may be of the opinion that Professor Helander has developed another method for securing the desired corrections that will avoid the difficulties of the foregoing alternatives. That this is not the case seems evident from the fact that items 2 to 6 and 28 in the table on page 154 of the original paper are stated to rest upon information furnished by the manufacturer. In the case of a test, item 5 would be known from the test results, and some of the other items might be obtained by sufficiently skillful measurement; but in the end the computed results will rest upon data furnished by the manufacturer and accepted by the purchaser. If the purchaser is willing to accept basic data, he will probably be equally willing to accept the final result. Thus it appears to me that this method should not find a place in the A.S.M.E. Test Codes.

The writer speaks as chairman of Power Test Codes Individual Committee No. 6, which is now engaged in the revision of the Test Code for Steam Turbines. He does not, however, speak for the Committee, since there has been insufficient time for a poll of its membership.

JOHN A. DENT.[4] Both designers and users of turbines will find Professor Helander's paper useful in the estimation of leaving losses and vacuum correction. The influence of critical speed and the limitations of possible vacuum at different loads are clearly brought out. While at first glance the procedure seems rather complicated the development is entirely logical and with a little study and practice can be applied with a reasonable expenditure of time and work.

The problem of determining leaving losses is exceedingly complex, and many variables enter its solution. The author is careful to point out that his method gives only a reasonable approximation and calls attention to some of the neglected variables which may influence the result, namely, leakage, moisture, and variation in nozzle efficiency. Other items which might be mentioned are:

(*a*) Variation in leaving velocity across section of jet
(*b*) Variation in leaving velocity from root to tip of blade
(*c*) Variation in gaging from root to tip.

Under (*a*) it should be remembered that the discharge varies as the mean velocity across the jet, while the kinetic energy varies with the "root mean square" of the velocity. Ordinarily the error in using mean velocity for computing kinetic energy is quite small.

The error in computing kinetic energy from the leaving velocity at mean-blade speed may be considerable in some cases, and entirely negligible in others. For example if the tangential component of the relative velocity is equal to the mean-blade speed, the absolute velocity leaving is a minimum at the middle of the blade, and increases both toward root and tip. If the kinetic energy is calculated on the basis of the velocity at the middle of the blade the result will obviously be too low. In the accompanying diagram, Fig. 1, *OA* is the relative velocity, *AB* the mean-blade speed, *AC* the root-blade speed, and *AD* the tip-blade speed. Then *OB* is the absolute velocity at the middle of the blade, *OC* at the root, and *OD* at the tip. Plainly, the mean leaving velocity is greater than *OB*.

The writer made a few calculations on the magnitude of this error using as an example a two-foot blade mounted on a six-foot drum revolving at 1800 rpm. A straight blade was assumed with

a constant gaging giving sin α = 0.45. The figures chosen correspond to a mean-blade speed of 754 ft per sec and a tip speed of 942 ft per sec.

At a relative velocity of 850 ft per sec the kinetic energy was 108 per cent of that found by assuming the leaving velocity corresponding to the mean-blade speed. At 1000 ft per sec the ratio dropped to 103.4 per cent and at 1270 ft per sec became 100 per cent. A maximum of 115 per cent was found at 582 ft per sec.

No attempt has been made to evaluate the effect of change of gaging from root to tip. Such an investigation would require a

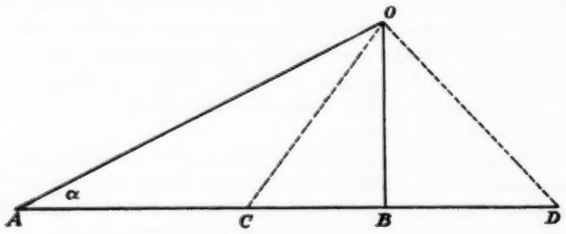

FIG. 1

detailed study of the design of blading used in any individual turbine. Such procedure is far beyond the intended scope of the author's paper. The writer wishes merely to call attention to this factor as one of the variables whose influence has been neglected.

The determination of the critical conditions is one of the most interesting and important contributions in the paper. The curves and approximate formulas developed by the author will do much to save time and labor in this calculation. The data supplied are almost the exact reverse of those given in impulse-turbine nozzles. There a nozzle of given dimensions is supplied with steam of known pressure and quality, and the discharge is easily computed. In the present instance a given discharge is delivered at a known pressure, but unknown quality, and the critical conditions have to be found. A method of successive approximations is used. The author shows that a correct solution is quickly reached. In fact the first approximation appears to be well within the limits of accuracy of the method, but the author properly refuses to take this for granted and carries through the second approximation, showing that his first assumptions were close to the truth.

The writer wishes to express appreciation of the paper and to welcome it as a valuable contribution to our knowledge of the turbine.

AUTHOR'S CLOSURE

The procedure for evaluating steam-turbine vacuum corrections proposed in the paper was prepared principally for use in making economic and heat-balance studies of the kind usually undertaken before the purchase of turbines and condensers to determine among other data, the vacuum which probably would be the most economical and, therefore, the approximate vacuum for which the turbines and their condensers should be designed.

In view of the uncertainty of data other than vacuum corrections, such as cost data and load curves, which must be estimated or assumed for these preliminary studies, it was felt inadvisable to introduce refinements that might add much to the complexity of the problem of evaluating approximate vacuum corrections and yet have but a small influence on final conclusions. For this reason, and also because precise data on the design of blades and exhaust hoods are not available usually for preliminary studies, the factors to which Professor Dent and Mr. Robinson appropriately call attention were ignored.

Where the necessary data are available and precise results are desired, exhaust-hood losses should be calculated and leaving losses should be more accurately evaluated taking into account, as Professor Dent suggests, variations in gaging from root to tip as well as variations in blade speed from root to tip. When variations in gaging and in blade speed from root to tip are taken into account, the equation for leaving losses takes the form of an integral which can be evaluated graphically if it cannot conveniently be evaluated analytically.

In this connection, it may be well to point out that in evaluating vacuum corrections, two leaving losses calculated for different vacua are subtracted and their errors may be compensatory to some extent. Table 1 of this discussion shows this to be the

TABLE 1 ERROR IN CHANGE IN LEAVING LOSSES ACCOMPANYING A CHANGE IN RELATIVE VELOCITY BASED UPON DATA PRESENTED BY PROFESSOR DENT[a]

Approx. leaving losses, Btu per lb	2.48	2.95	4.46	6.00
Error in leaving losses, per cent	15.50	8.00	3.40	1.60
Absolute error in leaving losses, Btu per lb	0.383	0.235	0.151	0.097
Absolute error in change in leaving losses, Btu per lb	Base	0.148	0.232	0.286
	...	Base	0.084	0.138
	...	...	Base	0.054
Error in change in leaving losses, per cent of increment of relative kinetic energy[a]	Base	1.95	1.75	1.65
	...	Base	1.50	1.40
	...	...	Base	1.30

[a] Increment of relative kinetic energy = [(Terminal rel. vel.)^2 — (Base rel. vel.)^2]/50,000.

case for the conditions assumed by Professor Dent. It shows also, for these conditions, that when leaving losses for two different relative velocities are evaluated at the mean diameter, the error in their difference is but a small fraction of the conversion of energy required to accelerate the steam from the lower to the higher velocity, and therefore may be ignored where approximate data are satisfactory.

In the writer's sample calculations, if leaving losses had been evaluated by taking into account variations in blade speed from root to tip on the assumption that straight blades of constant gaging are employed, then the calculated vacuum correction factor, Item 58 on page 155 of the paper, would have changed from 4.60 per cent to 4.67 per cent under Case 1 and from 1.33 per cent to 1.38 per cent under Case 2. For the purposes for which these estimated vacuum corrections are likely to be used, these differences are negligible.

The foregoing considerations do not in any sense detract from the force and value of Professor Dent's criticisms and suggestions. For conditions other than those here investigated the error introduced by evaluating leaving losses at the mean diameter may have a greater effect on the vacuum correction; and as previously stated, where precise values of leaving losses and vacuum corrections are desired, the factors Professor Dent discusses should be considered. The author believes, however, that where the data needed for evaluating leaving losses precisely are not available, his procedure will give approximations of vacuum corrections satisfactory for use in preliminary studies.

The author wishes to thank Professor Dent, Mr. Robinson, and Professor Berry for the discussions they have contributed. Their points of view and criticisms have helped to clarify the intent of the paper and the limitations of the procedure proposed. He agrees with Professor Berry that the procedure outlined for evaluating vacuum corrections should not be made a part of the A.S.M.E. test code.

The Psychrograph[1]

WARREN VIESSMAN.[2] The Norris-Westinghouse psychrograph chart is ingenious, and its invention is a material contribution to the design of air-conditioning installations.

The recognition and use of the heat-ratio lines of sensible heat to total heat through a point of known condition, as a locus of all changes of psychrometric conditions of the air under constant-heat ratio (as represented by a point on the chart, and as stated in the first theorem in the paper) offers an accurate and convenient method of determining the saturation temperature of a mixture of air leaving the washer, and greatly simplifies the work of the air-conditioning engineer.

The second theorem given in the paper is useful in establishing the condition of the air entering the washer, and also the condition of the air entering the room, when a by-pass washer with make-up air, as shown in Fig. 1 of this discussion is used. The straight line connecting the two points covering the conditions of the two quantities to be mixed is the locus of all conditions of the mixed air.

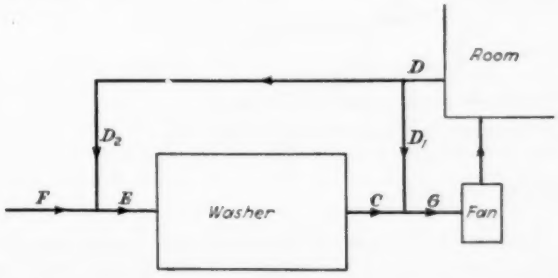

FIG. 1 DIAGRAM OF CONNECTIONS FOR A BY-PASS WASHER WITH LETTERS CORRESPONDING TO THOSE GIVEN IN EXAMPLE 5. FIG. 5, OF THE PAPER

The chart as constructed is easily read and of much larger scale for the same overall size than the usual chart. The values as read from the chart check to within three significant figures with those obtained from tables and by calculation.

In his Fig. 5, the author has solved a typical by-pass air-washer problem. The letters on the chart in Fig. 5 of the paper, representing conditions at various points, correspond with those on Fig. 1 of this discussion.

In this discussion let C = quantity of air leaving washer, lb per min; D_1 = quantity of room air of condition D recirculating and by-passing the washer, lb per min; D_2 = quantity of room air of condition D recirculating and entering the washer, lb per min; E = quantity of air entering washer to be conditioned, lb per min; F = quantity of outside ventilation air entering washer, lb per min; G = quantity of conditioned and recirculated air entering the room, lb per min; t_e = temperature of air leaving washer, deg F, dry bulb; t_d = temperature of room air recirculated, deg F, dry bulb; t_s = temperature of air entering the washer, deg F, dry bulb; t_f = temperature of outside air, deg F, dry bulb; and t_g = temperature of air entering room, deg F, dry bulb.

The quantity of conditioned and recirculated air G entering the room is determined by the temperature differential desired between the entering air and the room air. The quantity of outside ventilation air F entering the washer is usually expressed as a percentage of G.

The quantity of air E entering the washer to be conditioned is

$$E = \frac{\text{Total heat to be removed from room, Btu per hr}}{0.24 \times 60 \text{ (room wet-bulb temp} - t_e)}$$

which is equal to the quantity of air C leaving the air washer, or $C = E$.

The quantity of room air D_1 of condition D recirculating and by-passing the washer is equal to the quantity of conditioned and recirculated air G entering the room minus the quantity of air C leaving the washer, or $D_1 = G - C$.

The quantity of room air D_2 of condition D recirculating and entering the washer is equal to the quantity of air E entering the washer to be conditioned minus the quantity of outside ventilation air F entering the washer, or $D_2 = E - F$. Since $D_1 = G - D$, and $D_2 = E - F$, it is seen that $D_1 + D_2 = G - F$.

The temperature of the air t_e leaving the washer is obtained on the Norris Psychrograph by the intersection of the heat-ratio line through the room condition with the saturation curve, and is 52 F in example 5, Fig. 5, of the paper.

The temperature t_d of the room air recirculated, the temperature t_f of the outside air, and the temperature t_g of the entering air, are selected design temperatures. The temperature t_s of the air entering the washer is equal to $(D_2 t_d + t_f F)/E$.

From the foregoing relationships it is seen that the determination of t_e, the temperature of the air leaving the washer, from the Norris Psychrograph readily simplifies a series of relationships which otherwise would be more difficult to solve. The location of t_s and t_g on the locus lines of the chart immediately establishes the condition of the air entering the washer and the air entering the room.

In example 5 given by the author, which is solved in Fig. 5 of the paper, the total heat load of the room was 100,000 Btu for which 59.1 lb of ventilation air was required. The air recirculated through the washer was 118.3 lb per min.

The total heat of outside air F entering the washer at 78 F wet bulb = 40.64 Btu per lb, and the total heat of outside air F leaving the room at t_d deg and 50 per cent relative humidity = 30.80 Btu per lb. Therefore, the heat removed from the ventilation air above room temperature = 40.64 — 30.80 = 9.84 Btu per lb. Hence, the heat removed per hour = 59.1 × 60 × 9.84 = 35,000 Btu per hr. The refrigeration required would then be (100,000 + 35,000)/12,000 = 11.3 tons, which checks with 11.44 obtained by the author in his example 5.

Again, the total heat of recirculated air D_2 to the washer = 30.80 Btu per lb, and the total heat of recirculated air D_2 from the washer at 52 F wet bulb = 21.30 Btu per lb. Therefore, the heat removed from the recirculated air D_2 = 30.80 — 21.30 = 9.50 Btu per lb, and since 118.3 lb per min is circulated, the heat removed per min = 118.3 × 9.50 = 1130 Btu per min. The total heat of outside air F to the washer at 78 F wet bulb = 40.64 Btu per lb, and the total heat of outside air F from the washer at 52 F wet bulb = 21.30 Btu per lb. Therefore, the heat removed from the outside air F = 40.64 — 21.30 = 19.34 Btu per lb, and since 59.1 lb per min pass through the washer, the total heat removed per minute = 59.1 × 19.34 = 1150 Btu per min. The refrigeration required would then be (1130 + 1150)/200 = 11.4, which again checks with 11.44 obtained by the author in his example 5, Fig. 5.

The scale on the Norris Psychrograph giving cubic feet per pound of dry air and vapor present is useful in changing pounds of air to cubic feet for the various conditions when determining fan and duct sizes. The determination of air leakage by use of the Psychrograph will undoubtedly be of service to operating and construction personnel in the locating and the correcting of faults in equipment.

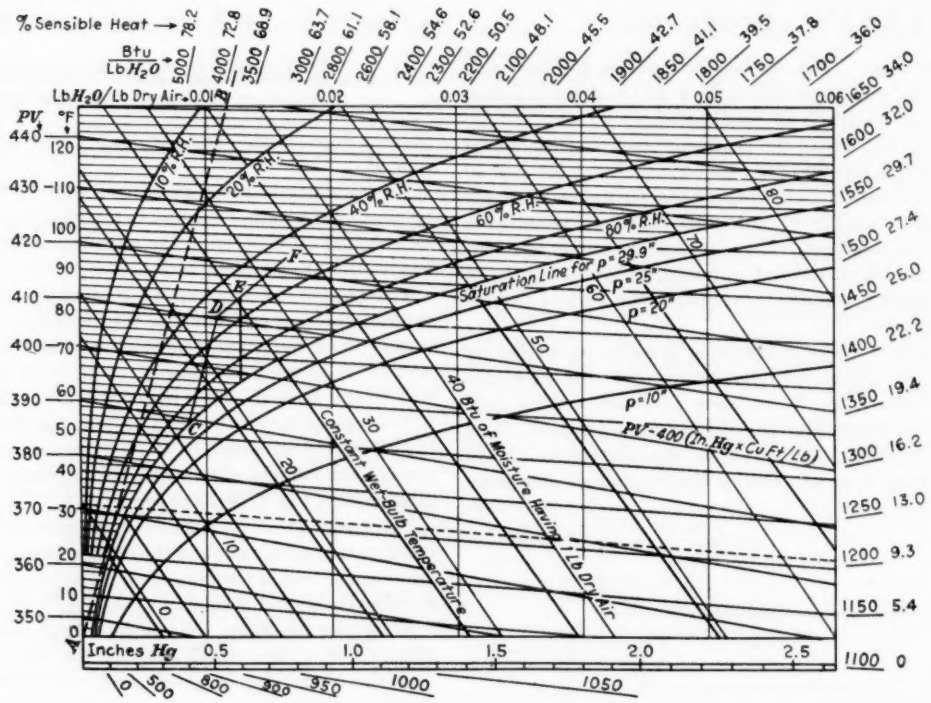

FIG. 2 MOLLIER WATER-MIXTURE CHART

ARNOLD WEISSELBERG.[3] Graphical solutions of air-conditioning problems as recommended by the author are so well established that the merit of such procedure need not be stressed further.

The need for the development of a new chart, such as the author's Psychrograph, for this purpose is open to question in view of the existence of the Mollier water-air-mixture chart which accomplishes the same results in just as simple a manner and is perhaps more convenient to use because it has only one temperature scale compared to three such scales on the author's Psychrograph.

In the Mollier chart the marginal scale furnishes the amount of total heat per pound of moisture removed, which is another way of expressing the ratio of sensible heat to total heat in the author's paper. To make this scale conform exactly to that of the Psychrograph, it is only necessary to divide the heat content of one pound of water at the average temperature of 70 F or 1090 Btu by the scale values and deduct the value of the ratio from unity in order to express the marginal scale in the percentages of the Psychrograph.

[3] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

The procedure is now the same with both charts, except that greater accuracy may be claimed for the Mollier chart, since therein the sensible heat of the vapor in the air is also taken into consideration. This is shown on Fig. 2 of this discussion wherein the writer solves the author's example 5, which in the paper is solved in Fig. 5.

In the second paragraph of theorem 2 on page 229 of the paper, the author states that in case the line joining two points crosses the saturation curve, the locus of possible mixtures will follow the saturation curve instead of crossing it. The word "may" should be used rather than "will" inasmuch as the author himself indicates in the same paragraph that the quality of the mixture will be somewhat uncertain.

In the writer's opinion the chief value of the paper lies in the interesting graphical solution to a variety of problems which are especially adapted to demonstrate the advantages of graphical treatment of an air-conditioning problem. In that respect the author has done an excellent job and the fact that he could have used other charts, which, as has been stated in this discussion, are at least as good for the purpose, appears to be of secondary importance.

Fatigue of Shafts at Fitted Members, With a Related Photoelastic Analysis

By R. E. PETERSON[1] and A. M. WAHL,[2] EAST PITTSBURGH, PA.

This paper deals primarily with the fatigue of shafts with press-fitted members, a problem frequently arising in connection with rotating machinery involving gears, wheels, couplings, rotors, etc. Failures at the edge of fitted members are not uncommon in practice. A survey is made of existing data, after which a report of fatigue tests on the press-fit problem carried out at the Westinghouse Research Laboratories is given. A related photoelastic investigation and stress analysis is also reported. Practical expedients for increasing the strength of shafts with fitted members are given. Suggestions for future research along the foregoing lines are made throughout the paper.

ALTHOUGH nearly all shafting carries such machine elements as gears, pulleys, wheels, couplings, rotors, etc., but few data have been available on which to estimate the effect of these members on the endurance strength of the shaft, with the result that sometimes rather surprising failures occur.

A report by Dr. Kühnel of the German State Railways lists, in Table 1, twenty-three fatigue failures of axles at the wheel fit. From tests of specimens taken from the broken axles, it was concluded that the physical properties were such as to correspond to normal material of that type. Recent researches have shown that in the case of a shaft subjected to alternating stresses a press fit introduces a combined stress-concentration and rubbing-corrosion effect of such magnitude as to weaken the shaft to a degree not generally suspected. Hence the surprising failures in perfectly normal material. It is proposed in this paper to review the available data, contained chiefly in two German publications, and then to supplement this by a report of similar work carried out intermittently over a period of years at the Westinghouse Research Laboratories. The photoelastic study and stress analysis were made quite recently in an attempt to explain some of the observed effects.

Review of Published Data

Fatigue tests by Kühnel[3] as given in Table 2, showed that a shaft with a press-fitted collar had but 56 per cent of the endurance strength of a shaft with a large contour radius, i.e., practically no stress concentration in the latter case corresponding approximately to the ordinary "endurance limit." Specimens having the same contour as the press-fit specimens, but cut from a solid bar, Table 2, gave the same endurance limit as the press-fit specimens.

In Table 3, results are shown of tests made at the Darmstadt Materials Testing Laboratory.[4] Here again it will be noticed that a shaft with a press-fit member had only about half the endurance strength of the shaft material without stress concentration. It is of interest to note that the "obvious" expedient of rounding the sharp corner, shown at 7 and 8, Table 3, was not very effective in raising the strength, particularly as compared with a groove turned in the face of the collar, 5. It is further apparent, from 4, that rolling of the shaft surface increased the press-fit strength to a surprising degree, and when this expedient was combined with grooving the hub face, 6, full shaft strength was obtained. It should also be mentioned that other methods of increasing surface strength, such as case hardening and nitriding, were also very effective in increasing the press-fit endurance strength (not shown in Table 3 since complete endurance-limit data were not available).

Westinghouse Fatigue Tests of Fitted Members

An investigation of the fatigue of shafts with press-fitted collars was started at the Westinghouse Research Laboratories in January 1931 in connection with the design of shafts for motors and gears. It was felt at that time that three of the main effects present in the press-fit fatigue problem were: stress concentration, a three-dimensional stress system, and rubbing corrosion,[5] and that the tests should include some study of separate variables if possible. Three series were decided on as follows: (*a*) Heavy press fit; (*b*) very light press fit; (*c*) solid specimen of same outline dimension as press-fit specimen. In (*b*) the pressure variable is practically eliminated, or at least reduced to small magnitude, although bending may introduce some increase of stress at the corners in this case, and in (*c*) pressure and rubbing-corrosion effects are not present. The aforementioned program included series 1–5 in Table 5, while series 6 and 7 were added quite re-

[1] Manager, Mechanics Division, Westinghouse Research Laboratories. Assoc-Mem. A.S.M.E. Mr. Peterson received his B.S. in mechanical engineering from the University of Illinois in 1925, and one year later his M.S. in theoretical and applied mechanics from the same institution. In September, 1926, he entered the employ of the Westinghouse Company in the railway-motor engineering department, and in January, 1928, was transferred to the research department. During 1926–1929 he was also part-time instructor in analytical mechanics and strength of materials at Carnegie Institute of Technology. In 1930 he was made section engineer in charge of strength of materials, Westinghouse Research Laboratories, and in 1931 was appointed to his present position.

[2] Westinghouse Research Laboratories. Assoc-Mem. A.S.M.E. Dr. Wahl received his education at Grinnell College and Iowa State College, being graduated from the mechanical engineering course of the latter in 1925. He then entered the employ of the Westinghouse Electric & Manufacturing Company as a graduate student. In 1927 he received his M.S. and in 1932 his Ph.D. degree from the University of Pittsburgh. Since 1926 he has been engaged at the research laboratories of the company on problems of applied mechanics, particularly in the field of stress analysis. He was the recipient of the 1929 A.S.M.E. Junior Award.

Contributed by the Applied Mechanics Division and presented at the Annual Meeting, New York, N. Y., December 3 to 7, 1934, of The American Society of Mechanical Engineers.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until May 10, 1935, for publication at a later date.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

cently as a result of the publication of the interesting results obtained at Darmstadt[4] on grooving and rolling. In planning the tests cited it was decided to use as large specimens as feasible in order to obtain as accurate a fit allowance as possible.[6] The equipment available[7] permitted the use of a $1^5/_8$ in. shaft diameter, allowing for the weakening effect of the press fit. The material used for both shafts and collars was medium carbon axle steel, 0.42 per cent C, the properties of which are given in Table 5.

[6] More recent tests have shown the desirability of using as large specimens as possible for any fatigue tests involving stress concentration, since small specimens show relatively low stress-concentration effect in some cases while large specimens tend to show higher stress-concentration effect approaching theoretical values as a seemingly general tendency. Data are given in "Model Testing as Applied to Strength of Materials," by R. E. Peterson, Trans. A.S.M.E., 1933, vol. 55, paper APM-55-11, p. 79.

The specimen dimensions are given in Fig. 1. Fig. 2 is a view of the test set-up.

The collar bore and the critical shaft diameter were accurately machined to give the desired press-fit allowance. In connection with series 6 and 7, careful measurements of the diameters were made. With exception of series 1 the pressing was done in a hydraulic testing machine, so that accurate data on the axial load during pressing were obtained as given in Table 4. From these two sets of data it has been possible to estimate the average radial pressure by two independent methods. Making use of the axial pressing load

$$p = \frac{P}{\pi d l \mu} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

where p = radial pressure, lb per sq in.
P = pressing load, lb
d = shaft diameter, in.
l = length of collar, in.
μ = coefficient of friction

The only doubtful factor is the coefficient of friction. As a result of a literature survey together with extensive data of his own, Baugher[8] concluded that, "a general average of coefficient of friction realized when pressing in shafts would be probably in the neighborhood of 0.15. . ." This value was used in calculating the pressures given in column 5 of Table 4.

(*Endurance Limit = 31,700 lb per sq in.*)

The other method is to make use of the difference of measured diameters in connection with the Lamé equation[9]

$$p = \frac{Ef}{2dD^2}(D^2 - d^2) \quad \ldots\ldots\ldots\ldots\ldots [2]$$

where f = difference in diameters, in.
D = diameter of collar, in.
E = modulus of elasticity, lb per sq in.
Other notation as for Equation [1].

The calculated values for the cases where measurements were made are given in column 6 of Table 4. It will be seen that while the agreement between the results of the two methods is not by any means exact, yet if one considers the assumptions made and the inherent inaccuracies involved, the agreement seems quite reasonable. The widest discrepancies occur in connection with the rolled shafts and this may be due to the fact that some of these surfaces were slightly wavy due to plastic flow, so that the coefficient of friction was probably quite different from the assumed value. It should also be mentioned that some difficulty was encountered in pressing the plain collars on to the shafts due to the relatively sharp collar edge, resulting in higher pressing loads and in severe load fluctuations. This also rendered the subsequent radial-pressure calculations of doubtful accuracy. The grooved collars, however, pressed on to the shafts smoothly. In all cases a light mineral oil[10] was used as a lubricant in the pressing operation.

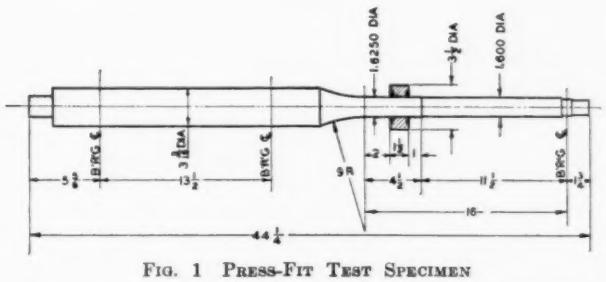

FIG. 1 PRESS-FIT TEST SPECIMEN

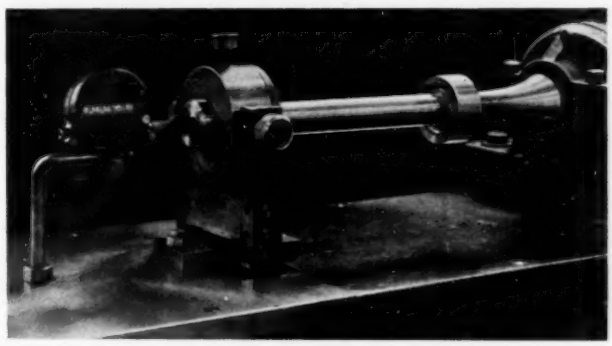

FIG. 2 FATIGUE TEST SET-UP (GROOVED COLLAR)

With regard to the surface rolling of fatigue specimens, considerable work done in German laboratories[11] has shown that the ordinary endurance limit can be increased 5 to 30 per cent, depending on material, by rolling under sufficient pressure to deform the surface plastically. This expedient, as mentioned previously,[4] was also found to be particularly effective in raising the endurance strength of press fits.

Fig. 3 is a drawing of the rolling apparatus used in connection with the Westinghouse tests. Fig. 4 is a view of the rolling apparatus in position. The specimen to be rolled is set up in a lathe and rotated slowly while the roll frame, being in equilibrium with respect to normal forces, is easily held against friction torque from rotating. By exerting sufficient lateral pressure against the frame it can also be caused to travel slowly in an

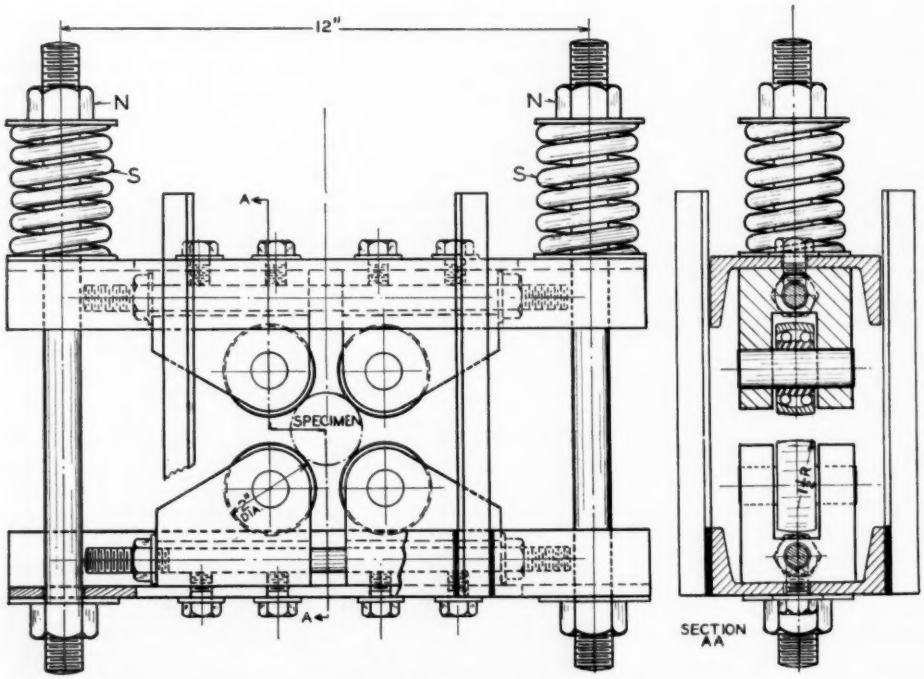

FIG. 3 APPARATUS FOR ROLLING FATIGUE SPECIMENS

axial direction along the specimen; for high rolling pressures, a power feed for traversing is desirable. The rollers are made from ball bearings, the outer surface being ground to a $1^1/_2$-in. contour radius[12] to obviate a "digging in" action which previously

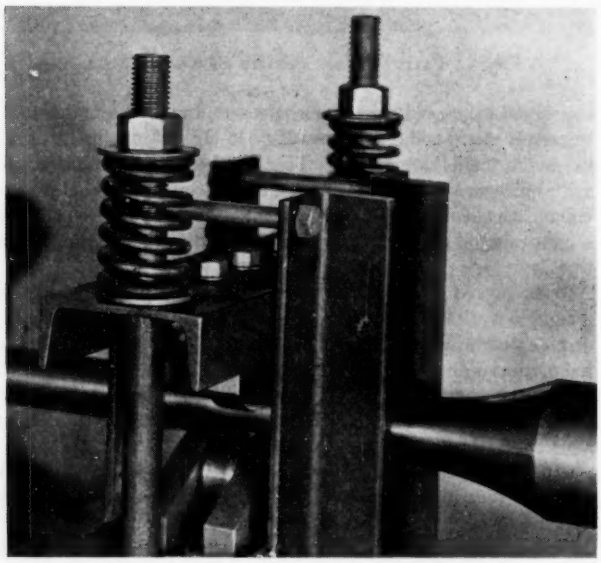

FIG. 4 ROLLING APPARATUS IN POSITION

tended to occur during axial traverse. The desired roller pressure is readily obtained by turning nuts N, Fig. 3, until the calibrated springs S are the proper length.

The roller load used in preparing series 7 was 400 lb. Two additional specimens were rolled with 800-lb load. If one calculates stresses according to the elasticity equations of Thomas and Hoersch[13] then, for example, for a load of 400 lb a maximum stress of 320,000 lb per sq in. is obtained. It is of course obvious that no such stress is reached, but that plastic deformation occurs, so that increasing the load results mainly in increasing the depth of the plastic region. Measurements of diameter before and after rolling showed that for a load of 400 lb the decrease was approximately 0.0008–0.0010 in.

With regard to the reason for the increase of fatigue strength due to rolling, considerable difference of opinion exists.[14] Prof. O. Föppl, of Wöhler Institut, Braunschweig, attributes the increase of fatigue strength to a fundamental change in the material in the outer layer of the specimen due to rolling, resulting in a denser material having a closer and differently oriented molecular structure, a changed microstructure, and a somewhat higher specific weight. Prof. A. Thum, of Darmstadt, believes that the increase is due to favorable residual compressive stresses at the surface as a result of rolling. It is not inconceivable that both effects are present. Further research with an attempt to isolate the above variables would be interesting and illuminating.

DISCUSSION OF FATIGUE RESULTS

The results of the Westinghouse fatigue tests are shown in Fig. 5 and summarized in Table 5. It will be noticed that all results are compared with the ordinary endurance limit of 0.3-inch-diameter beam specimens of the shaft material, 31,700 lb per sq in. Previous size-effect tests without stress-concentration effect of steel purchased under the same specification showed that the effect, if any, was not large.[6]

In Table 5 as well as Tables 2 and 3, fatigue-stress-concentration factors K, as ordinarily defined and as used in design formulas, are given.

$$K = \frac{\text{Ordinary endurance limit of specimen with large contour radius}}{\text{Endurance limit with stress concentration at critical section}}$$

In the press-fit tests where not only stress concentration is involved, but also a rubbing-corrosion effect, the term "fatigue-stress-concentration factor" is not an accurate one, but since we could not find a better term it was decided that for this paper we would adhere to "fatigue-stress-concentration factor," defined as follows in the press-fit case:

$$K = \frac{\text{Ordinary endurance limit of specimen with large contour radius}}{\text{Endurance limit of press-fit specimen } \left(S = \frac{M}{\pi d^3/32}\right)}$$

[12] One test was made of a specimen rolled with flat rollers, Fig. 5; all others were rolled with $1^1/_2$-in. contour radius roller.

[13] "Stresses Due to the Pressure of One Elastic Solid Upon Another," by H. R. Thomas and V. A. Hoersch, Univ. of Illinois Exp. Sta. Bulletin No. 212.

[14] See for example the published letters of O. Föppl and A. Thum under the heading "Steigerung der Dauerhaltbarkeit durch Oberflächendrucken" in *Zeit. V.D.I.*, vol. 77, 1933, p. 1335.

Comparing series 2 of Table 5 with the German results given in Tables 2 and 3, it will be noticed that the decrease in endurance strength is of the same order for all cases, roughly about half. One might expect that the difference between 50 per cent, Westinghouse tests, and 55 per cent, Darmstadt tests, might be greater because of size effect,[6] the Westinghouse specimens being $1^5/_8$ in. in diameter and the Darmstadt specimens 0.55 in. in diameter. This is probably due to the fact that the 0.42 per cent C steel used in the Westinghouse tests is less sensitive to stress-concentration effects in fatigue than the 0.57 per cent C steel used in the Darmstadt tests.

Comparing series 2 and 3, it is apparent that radial pressure is an important variable. As was pointed out in discussing the original test plans, the heavy press fit involves: stress concentration, a three-dimensional stress system at the point of failure, and rubbing corrosion.[5] The very light press fit involves *mainly rubbing corrosion*, with possibly some stress increase at the corners due to bending. It would therefore appear that the decrease in endurance strength of an ordinary heavy press fit is due to a localized stress system acting on a material weakened by rubbing corrosion.

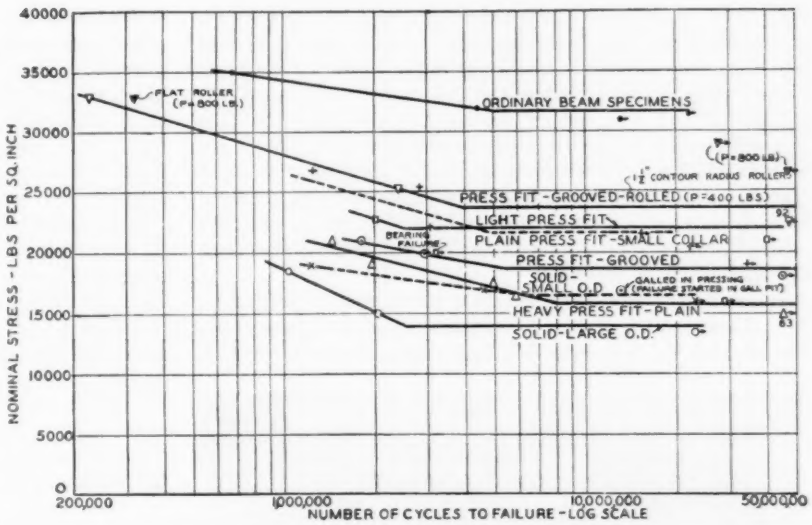

FIG. 5 FATIGUE-TEST DATA OF PRESS-FIT INVESTIGATION

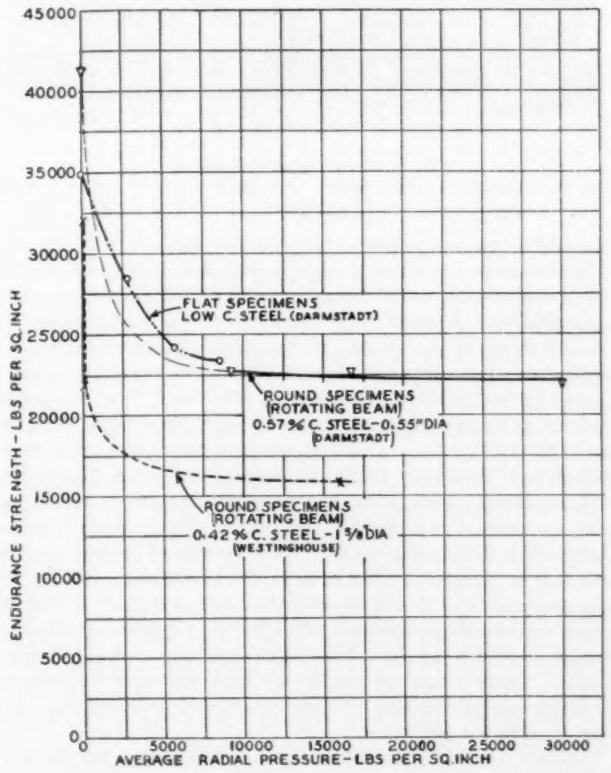
In connection with rubbing corrosion, a fatigue test was made with the press-fitted collar and adjacent shaft portions completely packed in heavy grease, the idea being to exclude air in an attempt to prevent rubbing corrosion. It was found that the life was not effectively prolonged and that rubbing corrosion had occurred. It would be interesting to run small press-fit fatigue specimens in a neutral atmosphere to see how rubbing corrosion is modified. In this connection the tests of wear of metals in various atmospheres being carried out at the National Bureau of Standards will be of interest.

In Fig. 6 a plot of all available radial-pressure data as affecting endurance strength is shown. In the case of the Darmstadt tests, it appears that over a wide range the endurance strength is independent of pressure. This is probably because a condition of yielding has been reached at the surface of the collar, in which case the maximum stress peak no longer increases with increase of allowance. In Fig. 6 dotted lines have been drawn toward zero pressure to connect up with the ordinary endurance limits. With the limited data available the form of these curves is not definitely known, but it seems reasonable to assume that their general shape would be such as indicated.

Returning to Table 5, one might expect that series 1 would show an even lower endurance limit than series 2, because of size effect. The difference may be due to two reasons. The pressure in the case of series 1, although not determined, was probably less than 5000 lb per sq in. (estimated from Equation [2]) because the collar is a relatively thin one for the customary maximum allowance of 0.001 inch per inch of diameter. The length of fit in series 1 is much shorter in proportion to the shaft diameter than in series 2, thus decreasing considerably the stress concentration due to bending.

The solid specimens of the same contour as the press-fit specimens were included in the original program in order to throw some light on the relative stress-concentration effects. The endurance strength of the solid comparison specimens, series 4, Table 5, was found to be 14,000 lb per sq in., somewhat lower than the corresponding value of the heavy press fit, 15,800 lb per sq in. Some comments will be made on the relation of these



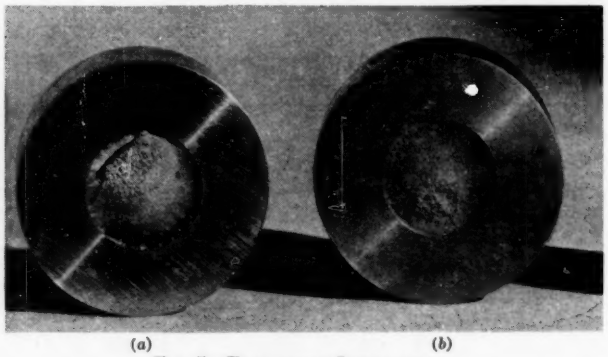


FIG. 6 EFFECT OF PRESS-FIT PRESSURE ON ENDURANCE STRENGTH

values in connection with the photoelastic analysis described later in the paper. Due to a mistake a series of "solid" specimens was made with a small outside diameter, $1^{15}/_{16}$ in., series 5, but the results are interesting so the data are included in Fig. 5 and Table 5. The endurance strength was found to be 16,500 lb per sq in. as compared with 14,000 for the larger outside diameter specimens. The difference is apparently due only to difference in stress concentration, and should be readily shown photoelastically.

With regard to the grooved construction, the Darmstadt tests, Table 3, series 5, showed a 31 per cent increase over the

plain press fit, which is the usual construction of this type encountered in practice; while our tests, Table 5, series 6, showed an 18 per cent increase. The comparative figures do not seem unreasonable if one considers the difference in materials and specimens, and furthermore demonstrate definitely that the grooved construction is worth considering for certain design applications. A study of the form and size of the groove lip might result in some further increase in strength although practical limitations must be considered in this connection also; for example, one cannot make the lip so thin that special precautions in handling will be necessary.

By combining grooving and rolling the German investigators were able to obtain full shaft strength, failure occurring away from the press fit, Table 3, series 6. Their rolling pressures were not

(a) (b)

FIG. 7 FRACTURED SPECIMENS

[(a) Plain press fit (heavy pressure); (b) "Solid" specimen of same contour as (a).]

stated,[4] so an independent study of this variable was started. This would be advisable in any case since the larger specimens to be comparable, would require heavier rolling loads to produce greater depth of plastic flow. The first rolling load selected, P = 400 lb, resulted in a 50 per cent improvement of endurance strength as compared with the plain press fit, Table 5, series 7, compared with series 2. A specimen rolled with P = 800 lb did not fail at a stress of 26,500 lb per sq in., the test being stopped at 41,000,000 cycles. A second specimen also rolled with P = 800 lb but stressed at 29,000 lb per sq in. had run 29,000,000 cycles without failure at the time this paper was sent in, indicating that an increase of at least 84 per cent can be obtained as compared with the plain press fit. Another way of looking at this result is to compare 29,000 with 31,800 (the endurance limit of the material) and it will be seen that rolling with P = 800 lb raises the endurance strength of a shaft with a grooved collar to within at least 9 per cent of the endurance limit of the shaft material. There seems no doubt but that full shaft endurance strength can be obtained by a combination of grooving and rolling of sufficient intensity.

Strictly speaking, the stress-concentration factor for series 7 should have been obtained by comparison with the endurance strength of a rolled-beam specimen, without collar. Such tests were not made, however, but it would be interesting to know if the stress-concentration factor agrees with that of series 6. The same comment applies to series 4 and 6 of Table 3.

The typical appearance of the fractured surfaces of a plain press-fit specimen, series 2, and a "solid" specimen, series 4, is shown in Fig. 7. The "solid" specimens had totally enclosed well-defined rupture areas displaced from the axis, as is customary in specimens of this kind.[16] The press-fit specimens, however, showed irregular rupture areas, some of which were totally enclosed, some segmental in form, but as a whole not following any clear-cut order. This is to be expected since due to small surface irregularities the pressure actually is not perfectly uniform and consequently the edge stresses must vary somewhat around the periphery. "Beach marks"[15] were quite pronounced on the fracture surfaces of the press-fit specimens, showing that cracks originate at a number of places on the periphery.

Failure generally started on the shaft surface inside the press fit, varying from 0.02 in. to 0.25 in. from the edge of the collar, except in the case of two highly stressed rolled specimens, breaking at 224,000 and 313,000 cycles, where failure started right at the edge. The explanation may be as follows. In press-fit tests, rubbing corrosion causes considerable reddish brown oxide powder to accumulate at the edge of the collar fit after the test has been run for some time. This may be considered equivalent to the wearing away of some of the material for a distance in from the edge, with a consequent shift of peak stress. In the case of the highly stressed specimens, the total life was only 3 to 4½ hr

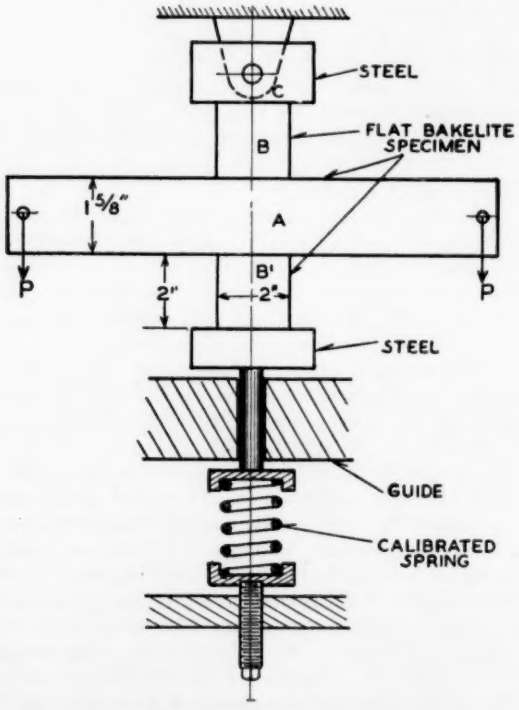

FIG. 8 PRESS-FIT TEST ARRANGEMENT

so that the opportunity for corrosion and wear was not the same as in the other specimens which lasted over 1,000,000 cycles.

PHOTOELASTIC TESTS AND LATERAL-STRAIN MEASUREMENTS

In order to simulate the stress conditions occurring in press fits, some tests were made using an arrangement shown schematically in Fig. 8. Essentially it consists of a flat bar of bakelite A representing the shaft, which is squeezed between two flat bakelite pieces B, B', representing the hub or collar to simulate the press-fit pressures produced by the fit allowance. Loads on these blocks are produced by the calibrated spring as indicated, while a pin C attached to the frame allows the two blocks to adjust themselves to compensate for slight inaccuracies in machining. Bending moments are produced by the loads shown to simulate the conditions of a shaft subjected to the combined action of a press-fit pressure produced by a collar and an alternating

[15] The radial displacement depends on the stress. See "Stress Concentration Phenomena in Fatigue of Metals," R. E. Peterson, Trans. A.S.M.E., 1933, vol. 55, paper APM-55-19, p. 157.

bending stress. Fig. 9 is a view of the complete apparatus in the testing machine.

To determine the principal stress differences, photoelastic tests were made by means of this apparatus in conjunction with the well-known fringe method[16] (monochromatic light being used). The photoelastic specimens were made of C-25 bakelite plates approximately 0.34 in. thick. In machining these specimens, light cuts were taken in a milling machine and the final 0.001 in. or so was ground off using a surface grinder. This was done in order to eliminate, as far as possible, irregularities along the contact surfaces, since tests using the lateral extensometer described later showed that very slight irregularities, of the order of 0.0005 in. in 2-in. length, had a marked effect on the stress distribution.

Because of the relatively large size of the photoelastic model it was found advisable to take four fringe photographs and fit them together as indicated, for example, in Fig. 11. The following different cases were tested:

Case 1. Plain Press Fit. In this case, shown in Fig. 10*a* a nominal press-fit pressure of 1480 lb per sq in. and a nominal bending stress of 2020 lb per sq in. were used. The stress conditions in this test correspond approximately to the fatigue tests wherein the nominal bending stress at the endurance limit was about one-third greater than the nominal compressive stress due to the press-fit pressure. Fig. 11 comprises the combined fringe photographs for this case.

Case 2. Plain Press Fit With Edge Beveled Off, the Nominal Stresses Being as in Case 1. In this case, shown in Fig. 10*c*, the bevel was made by taking a very light cut, as shown, to simulate the wear which occurs at the edge due to rubbing corrosion under continuous fatigue stressing. Fig. 12 is a photograph for this case.

Case 3. Press Fit With Grooved Construction, the Nominal Stresses as in Case 1. This piece, Fig. 10*b*, was tested to determine the effect of the groove in reducing the stress concentration; Fig. 13 is a fringe photograph representing this case.

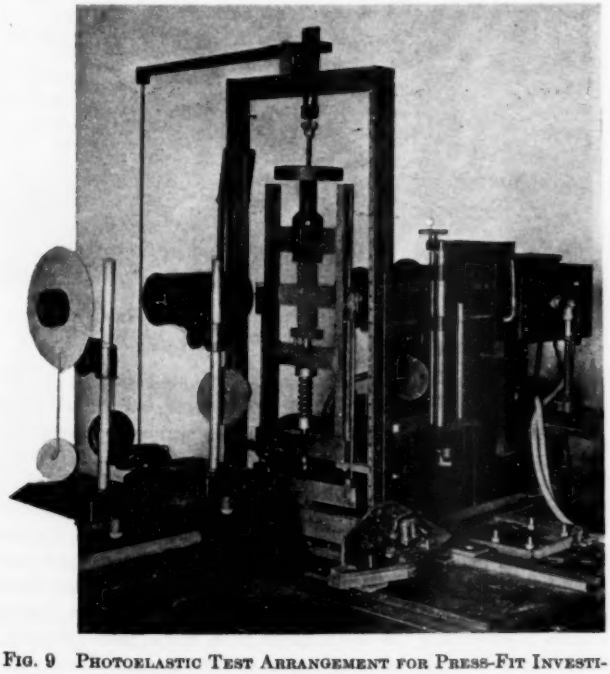

FIG. 9 PHOTOELASTIC TEST ARRANGEMENT FOR PRESS-FIT INVESTIGATION

[16] Z. Tuzi, Sci. Papers, Inst. Phys. and Chem. Research, Tokyo, vol. 8, p. 247, and vol. 12, p. 21. M. M. Frocht, Trans. A.S.M.E., 1931, vol. 53, paper APM-53-11.

To determine the sum of the principal stresses, a recently developed lateral extensometer[17] was used. Referring to Fig. 14, the extensometer consists essentially of a frame *D* and a movable bar *B*, which is constrained to move in a direction parallel with its length by the spring steel strips *C*, *C'*. These springs exert pressure, causing the points *P* and *P'* to bear firmly against the specimen, the friction produced by this pressure being sufficient

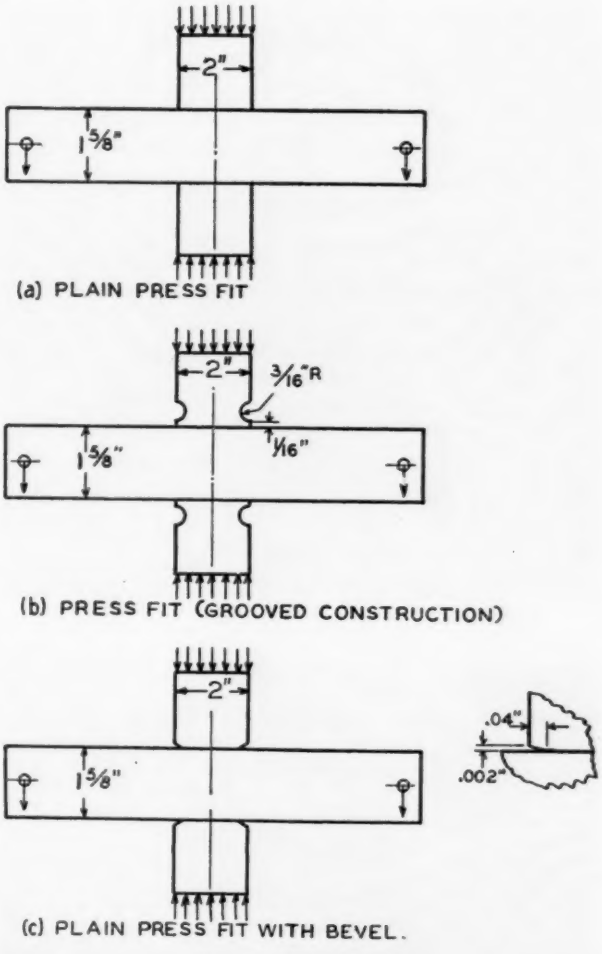

FIG. 10 CASES TESTED

to hold the points in one position during the test. Any lateral extension or contraction of the specimen will cause a relative movement of points *P* and *P'*, and hence of the bar *B*, with respect to the frame *D*. This movement is indicated by a Huggenberger extensometer which is clamped as shown. The screw *A* is used mainly for convenience in holding the points in one position while shifting the instrument from one location to another on the test specimen. Fig. 15 is a photograph of the extensometer while Fig. 16 is another view of the instrument in position on the test specimen.

By means of the balancing weight *E* shown in Figs. 14 to 16, the center of gravity of the instrument may be adjusted to coincide with the line of action of the resultant force produced by the springs, Fig. 16. Since the points *P* and *P'* thus carry practically no weight the friction is sufficient to hold them firmly in one position during the loading of the specimen. This is of advantage since if even a small amount of slippage of the points should

[17] A complete discussion of this extensometer will be published later.

occur, the resulting reading would probably be considerably in error due to slight variations in the thickness. If, for example, due to this cause, a change of only 0.00005 inch in the distance between points P and P' should occur, a considerable error in the extensometer readings would result. It is, of course, necessary to load the specimen once for each point at which a lateral-strain measurement is made.

FIG. 11 FRINGE PHOTOGRAPH OF PLAIN PRESS FIT

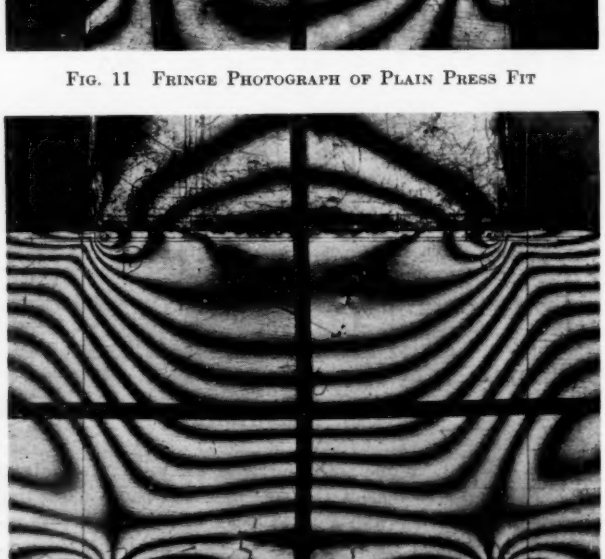

FIG. 12 FRINGE PHOTOGRAPH OF PLAIN PRESS FIT WITH BEVEL

To calibrate the instrument, it was clamped to a bar of bakelite subjected to a known bending moment, from which the stress could be computed. As a check it was also clamped to a bar in tension. Both of these methods gave practically identical results. For bakelite specimens of about 0.34 in. thickness the estimated possible error in measuring the lateral strains corresponded to an error of less than 100 lb per sq in. in the sum of the principal stresses $\sigma_1 + \sigma_2$, which is small compared with the peak value of approximately 5000 lb per sq in. registered at certain points.

Tests were made on specimens corresponding with cases 1 and 3, the principal stress sum being measured along the lines of contact between the hub and the shaft, and also somewhat outside these, along the edges. Because of the small size of the extensometer points, it was found possible to take measurements within 0.03 in. of the edge, and these were considered to be at the edge, although this involves some error. The measurements along the edge outside the hub were corrected to take this into account (the correction amounting to about 4 per cent). The taking of several measurements near the edge and then extrapolating to the edge was tried in a few cases, but it was found that the difference amounted to but a few per cent in these cases, and it was felt that this small difference did not warrant the extra time and labor involved in making a complete set of such measurements.

STRESS ANALYSIS AND COMPARISON WITH FATIGUE DATA

The distribution of the principal stress sums $\sigma_1 + \sigma_2$ as found by the lateral extensometer along the edge of the bar A, Fig. 8, for cases 1 and 3 together with the corresponding stress differences $\sigma_1 - \sigma_2$ as found by photoelastic tests are shown in Fig. 17 for the plain press fit, and in Fig. 18 for the press fit with the grooved construction. All points on the curves represent the averages between values found on the two opposite sides of the specimen to eliminate the effect of slight eccentricities of loading of the compression blocks B and B', Fig. 8. In determining the peak stresses on the compression side for cases 1 and 2 the extrapolation method described in a previous publication[18] was used because of the rapid change in stress difference near these points. From the $(\sigma_1 + \sigma_2)$ and $(\sigma_1 - \sigma_2)$ curves, the dotted curves representing the distribution of σ_1 and σ_2 were obtained. The σ_1 curves near the corner were drawn to connect with the triangular points representing the photoelastic-test results since the latter are considered more accurate at these locations than are the points representing $\sigma_1 + \sigma_2$ obtained by means of the

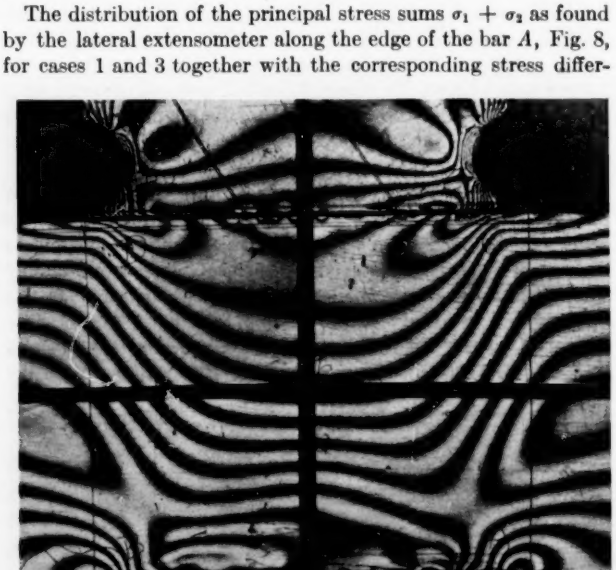

FIG. 13 FRINGE PHOTOGRAPH OF PRESS FIT, GROOVED CONSTRUCTION

[18] "Stress Concentration Produced by Holes and Notches," by A. M. Wahl and R. Beeuwkes, Trans. A.S.M.E., 1934, vol. 56, paper APM-56-11.

lateral extensometer. This is because the fairly rapid change in the values of $\sigma_1 + \sigma_2$ at such points is not completely followed by the change in lateral strain since the finite thickness of the specimen tends to hinder lateral contraction or expansion for a short distance from the corner. The directions of the stresses σ_1 and σ_2 near the corner are indicated approximately in Figs. 17 and 18. It may be seen that at a short distance from the corner the $(\sigma_1 + \sigma_2)$ curves approach the $(\sigma_1 - \sigma_2)$ curves within the limits of experimental error, as they should, since $\sigma_2 = 0$ at these points. This is a further check on the accuracy of the lateral-strain measurements. The complete distribution of the stresses σ_1 and σ_2 is shown to a smaller scale for cases 1 and 3 in Figs. 19 and 20. On the tension side these curves may be considered to give a rough indication of the variation of axial stresses and normal

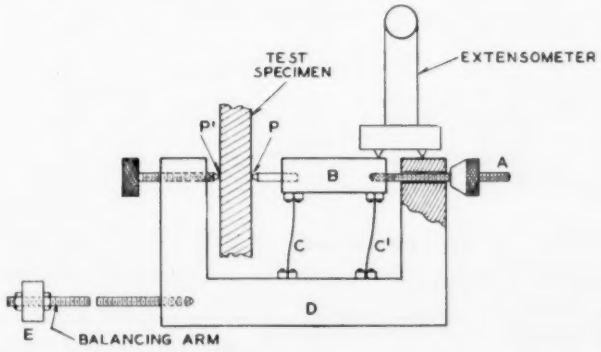

FIG. 14 DRAWING SHOWING CONSTRUCTION OF LATERAL EXTENSOMETER

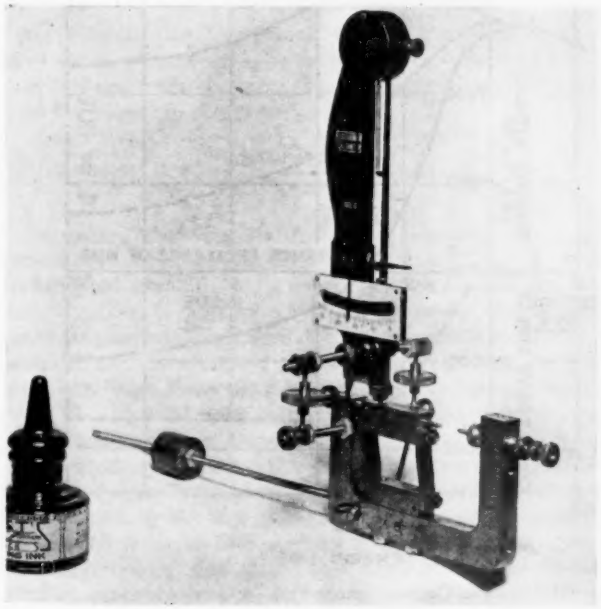

FIG. 15 LATERAL EXTENSOMETER

pressures, respectively, along the contact surfaces; on the compression side, because of the rotation of the principal stress directions, this correspondence does not exist except near the corners.

The tests made on the specimen of case 2, which represents a plain press fit with wear, showed that the stress distribution and also the values of peak stresses were not greatly different from the corresponding results obtained for the tests on the plain press fit without wear, case 1. Consequently the photoelastic results can be considered to represent approximately the fatigue specimens even after some rubbing corrosion has taken place.

In determining the reduction in strength due to the stress concentration produced by the press fit, the *maximum-shear theory* of strength will be taken as a basis,[19] i.e., the highest range in shearing stress among several planes during a complete cycle of bending will be compared with the nominal range of shearing

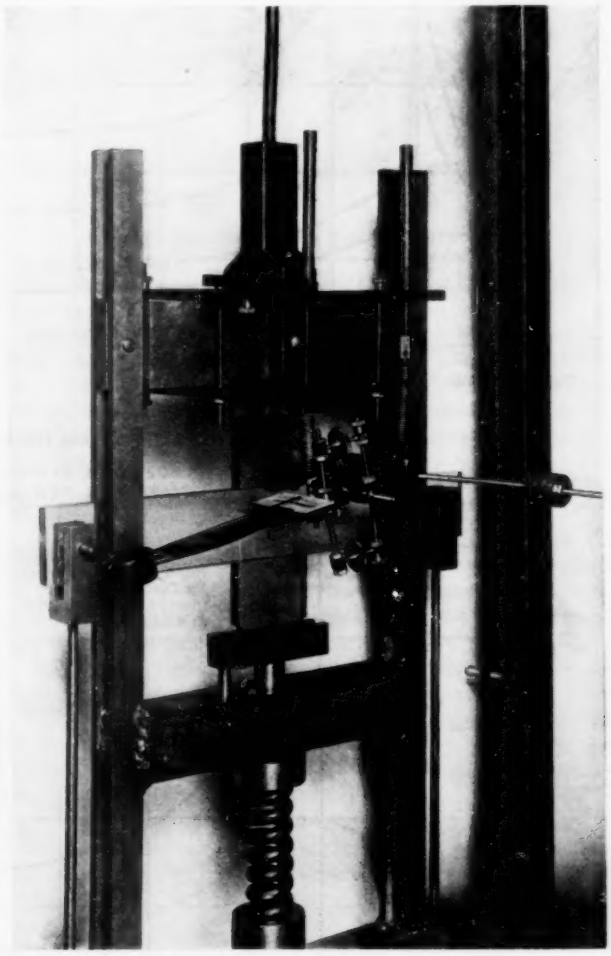

FIG. 16 LATERAL EXTENSOMETER IN POSITION ON TEST SPECIMEN

stress as computed from the known moment acting on the test specimen. The reason for considering several planes is that there is, in general, a rotation of the plane of maximum shearing stress during bending. An examination of the isoclinic lines in the photoelastic apparatus, however, indicated that for points near the edge of the collar where the fatigue failures occur, it would be sufficiently accurate to assume the directions of maximum shear for the worst conditions at 45 deg to either the radial and axial, or to the axial and circumferential directions. (This was checked up by calculating the shear-stress range on several planes, taking into account the rotation of the principal stress

[19] Dr. H. J. Gough has found from his work on specimens of single crystals and aggregates of a few crystals that fatigue fractures are initiated along the plane of maximum resolved shearing stress, but that failure may proceed across the specimen in another direction, depending on the stress distribution. See his Edgar Marburg Lecture, "Crystalline Structure in Relation to Failure of Metals, Especially by Fatigue," Proc. A.S.T.M., 1933, part 2, p. 3.

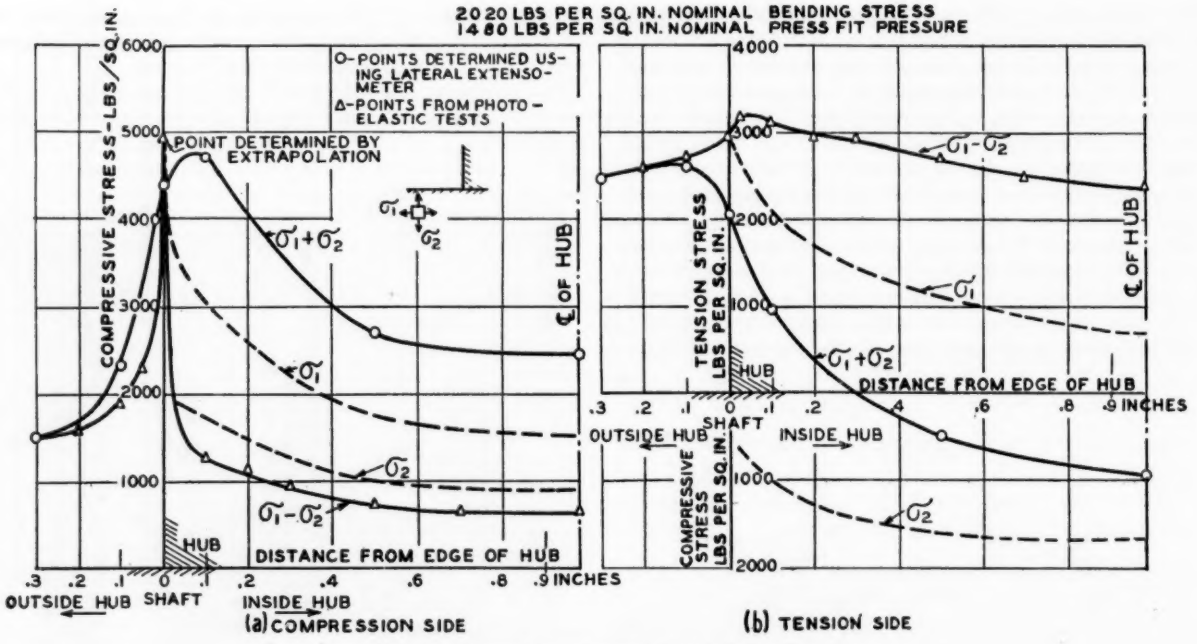

FIG. 17 STRESS DISTRIBUTION, PLAIN PRESS FIT

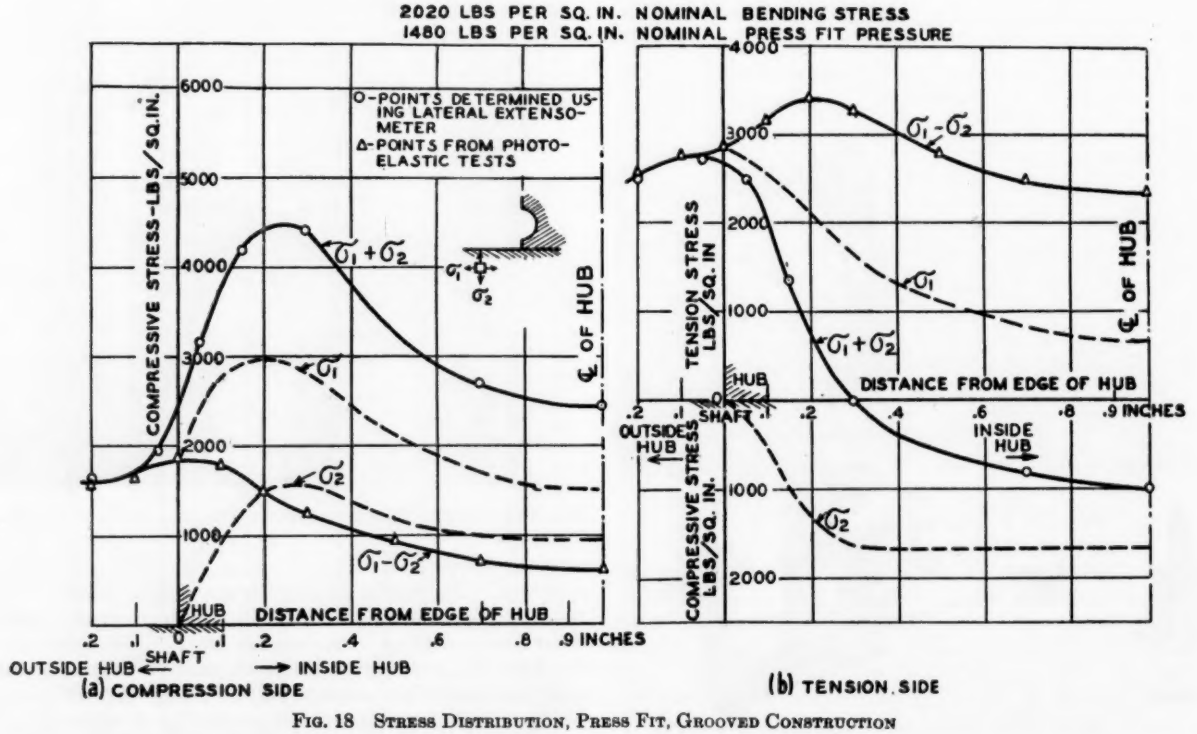

FIG. 18 STRESS DISTRIBUTION, PRESS FIT, GROOVED CONSTRUCTION

directions as shown by the isoclinic lines.) Hence, considering an actual shaft and assuming σ_3 as the stress in the circumferential direction, the principal stresses σ_1, σ_2, and σ_3 near the edge of the collar may be taken in the axial, radial, and circumferential directions, respectively.[20] In addition the further assumption will be made that the circumferential stress σ_3 does not change appreciably during bending, this assumption being supported by some rough estimates of the deflection produced by the change in normal pressure, during bending, on the shaft surface.[21] Hence the ranges in shearing stress to be considered are those in $\sigma_1 - \sigma_3$ and in σ_1 only.

[20] The von Mises-Hencky distortion-energy theory was also applied to this case but the final results did not differ greatly from those obtained using the maximum-shear theory. Since the directions of the principal stresses do not enter into the calculations in the former case this indicates that the above assumptions regarding the planes of maximum shear are not greatly in error.

[21] The other extreme assumption, i.e., that $\sigma_3 = \sigma_2$ during bending, will give a slightly lower stress-concentration factor in the case of the notched collar, the difference being only around 8 per cent. It is believed that the assumption σ_3 = constant is nearer the truth for an actual shaft.

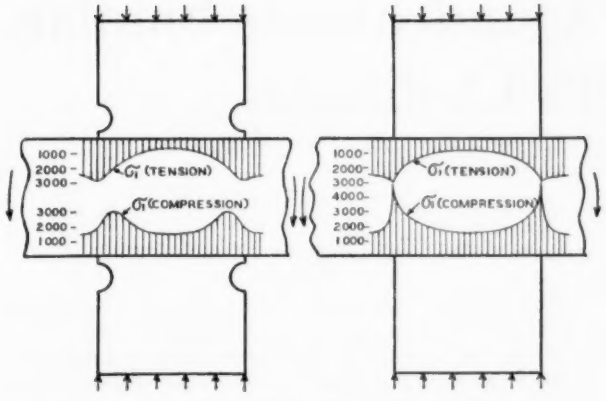

FIG. 19 DISTRIBUTION OF PRINCIPAL STRESSES, σ_1

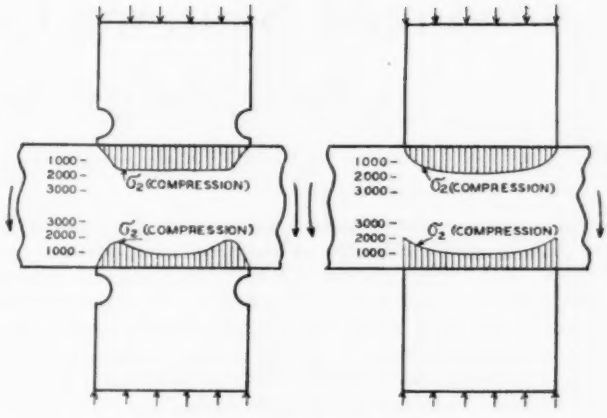

FIG. 20 DISTRIBUTION OF PRINCIPAL STRESSES, σ_2

We thus define the photoelastic stress-concentration factor as

$$K_p = \frac{(\sigma_1 - \sigma_2)_{max} - (\sigma_1 - \sigma_2)_{min}}{2\sigma} \quad \text{or} \quad \frac{(\sigma_1)_{max} - (\sigma_1)_{min}}{2\sigma}$$

depending on which is larger. In these expressions, σ is the nominal stress due to bending. Thus for the plain press fit it may be shown, as in Fig. 17, that the point giving the highest stress-concentration factor is right at the edge of the collar. For this case, where $\sigma = 2020$ lb per sq in.

$$K_p = \frac{4940 + 2940}{4040} = 1.95$$

Likewise for the case of the press fit with the grooved construction the worst case was found to be the range in $\sigma_1 - \sigma_3$ which is that in σ_1 (σ_3 being taken constant) at a point approximately 0.1 inch from the edge. In this case

$$K_p = \frac{2600 + 2800}{4040} = 1.34$$

Comparing these figures with the fatigue-stress-concentration factors obtained in the Darmstadt tests, Table 3, i.e., $K = 1.8$ for the plain press fit and 1.4 for the grooved construction, it is seen that there is fair agreement. In the case of the Westinghouse fatigue tests, the values of stress-concentration factors K as found, i.e., $K = 2.0$ and 1.7 for the plain and grooved constructions, respectively, show agreement for the case of the plain press fit while the fatigue-test value for the notched construction is somewhat higher than the photoelastic test value.

In general, it can be said that the fatigue-stress-concentration factors are closer to the photoelastic stress-concentration factors than is ordinarily the case. (Usually the former are considerably less than the latter.) This may be due to the fact that in a press-fit fatigue test, the shaft material at the point of failure is weakened by rubbing corrosion, and consequently the fatigue-stress-concentration factor, which would otherwise be lower, is increased.

The reason for the superiority of the grooved construction in the fatigue tests, is clearly shown by Figs. 19 and 20 to be due to the elimination of stress peaks at the corners.

It will be recalled that fatigue tests on a specimen cut out of a solid bar and having the same contour as the press-fit specimens showed a higher fatigue-stress-concentration factor. A photoelastic test was made to check this and it was found that the solid piece with a sharp corner had higher stress concentration than did the corresponding press-fit specimen.

CONCLUSIONS

(1) An ordinary press-fit member was found to decrease the endurance strength of a shaft to roughly half the endurance limit of the shaft material (as determined from specimens without stress concentration). This has also been independently found at two German laboratories.

(2) For very light press-fit pressures the endurance strength of a shaft is somewhat higher than for heavy pressures.

(3) German tests indicate that beyond a certain pressure, the endurance strength is independent of pressure. It appears that rubbing corrosion is an important factor in reducing endurance strength.

(4) Two expedients for increasing the endurance strength of shafts with press-fitted members, i.e., using a grooved construction, and rolling the shaft surface, were found to be very effective.

(5) Photoelastic tests combined with a stress analysis showed interesting results of fundamental value. The reason for the effectiveness of the grooved construction was shown by photoelastic tests to be due to reduction of stress peaks at the corners.

ACKNOWLEDGMENTS

The authors appreciate the interest of Prof. S. Timoshenko of the University of Michigan and Dr. L. W. Chubb, director of Westinghouse Research Laboratories. Acknowledgment is also made of the assistance of F. Cassel in the fatigue tests and R. Beeuwkes in some of the preliminary photoelastic tests. The authors also wish to thank Dr. S. Way for information on the theoretical aspects of the rolling process, and for his reading of the manuscript. Some discussions have been had with O. G. Horger, of Ann Arbor, and his comments have been of value.

Ordinate Systems for Quadratures Similar to Tchebycheff's Ordinates

By GEORGE B. KARELITZ,[1] NEW YORK, N. Y.

The author presents a geometrical interpretation of Tchebycheff's rule for calculating quadratures and shows that other systems of ordinates can be chosen which will be as valid as Tchebycheff's. A system of ordinates is proposed, the virtue of which lies in the fact that the longitudinal location of the center of gravity of the ship's lines can be obtained with good accuracy without increasing the errors of area calculations.

NAVAL architects continually use rules of approximate quadrature for computing the displacement and stability of ships. The determination of the various elements of hull geometry resolves itself into finding values of curvilinear areas such as shown in Fig. 1*a*. The principal rules for calculating these ordinates are (*a*) the trapezoidal, (*b*) Simpson's rule, and (*c*) Tchebycheff's rule.

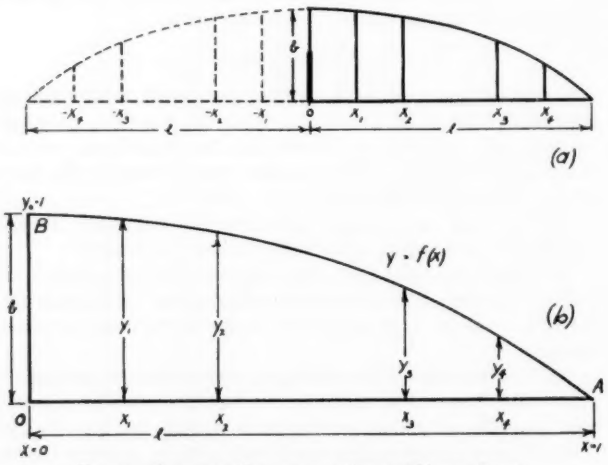

FIG. 1 GENERAL SHAPE OF A SHIP'S WATER LINE

The trapezoidal rule requires the base $2l$ to be divided into n equal parts after which the perpendicular ordinates, $y_0, y_1 \ldots y_{n+1}$, are scaled off at the division points and the segments of the curvilinear boundary are replaced by straight lines. The area then becomes

$$S = \frac{2l}{n}\left(\tfrac{1}{2}y_0 + y_1 + y_2 \ldots + y_n + \tfrac{1}{2}y_{n+1}\right)$$

Simpson's "first" rule requires the base $2l$ to be divided into an *even* number of n equal parts, after which perpendicular ordinates are erected and scaled off at the division points, and each pair of adjacent segments is replaced by a parabolic segment through the three points on the curve. The area can then be expressed as:

$$S = \frac{2l}{3n}\left(y_0 + 4y_1 + 2y_2 + 4y_3 + \ldots + 2y_{n-1} + 4y_n + y_{n+1}\right)$$

The trapezoidal rule is accurate to $^1/_3$ per cent with 21 ordinates (l divided into ten parts), and to 0.2 per cent with 41 ordinates (l divided into 20 parts). Simpson's rule is accurate to within 0.1 per cent with 21 ordinates, but the rule requires the application of multipliers 2 and 4. Therefore, much arithmetical work is involved for completely computing the displacement and stability of a hull.

Tchebycheff's rule employs fewer ordinates while giving the same high accuracy and because of this advantage is gaining favor with naval architects,[2] especially for stability calculations where its usefulness is particularly striking. The ordinates are not, however, equidistant, but are taken as listed in Table 1. A simple geometrical derivation of these coefficients, comparable to the geometrical demonstration of the trapezoidal rule and Simpson's rule, has not been given to date.

TABLE 1 TCHEBYCHEFF'S ORDINATES

Number of ordinate	Distance from middle of base in fractions of half-length				
$n = 2$		0.57735			
$n = 3$	0	0.70711			
$n = 4$		0.18759	0.79465		
$n = 5$	0	0.37455	0.83250		
$n = 6$		0.26664	0.42252	0.86625	
$n = 7$	0	0.32391	0.52966	0.88386	
$n = 9$	0	0.16791	0.52876	0.60102	0.91159

The area is $S = \frac{2l}{n}(y_1 + y_2 + \ldots + y_n)$

TCHEBYCHEFF'S ORDINATES

Tchebycheff's derivation[3] can be interpreted, as shown by Kryloff,[4] in the following manner.

Find $C_n, x_1, x_2, x_3 \ldots x_n$ such that

$$\int_{-1}^{+1} f(x)\,dx = C_n\left[f(x_1) + f(x_2) + \ldots + f(x_n)\right] \ldots [1]$$

will be exact for any function $f(x)$, where

$$f(x) = a_0 + a_1x + a_2x^2 + \ldots + a_{n-1}x^{n-1} + a_nx^n$$

[1] Associate Professor, Department of Mechanical Engineering, Columbia University. Mem. A.S.M.E. Mr. Karelitz was born in Russia in 1895 and received degrees in naval architecture and mechanical engineering from the Imperial Polytechnic Institute at Petrograd in 1918. For three years he was special engineer with the Waterways of Communication in Russia. He came to the United States in 1922 and has since been connected with the Westinghouse Electric & Manufacturing Company in the capacities of research engineer, manager of the mechanics division of the Pittsburgh Research Laboratories, manager of the transportation division of the South Philadelphia Works engineering department, and consulting engineer. He began his work at Columbia in 1930.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until May 10, 1935, for publication at a later date.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] "The Naval Constructor," by George Simpson, D. Van Nostrand Co., New York, 1914.

[3] "Sur les Quadratures," by P. L. Tchebycheff, *Journal de Mathematiques*, Liouville, vol. 19, 1874.

[4] "Approximate Calculations," by A. N. Kryloff, Institute of Ways and Communications, Petrograd, 1911.

From Equation [1]

$$\int_{-1}^{+1} f(x)\,dx = \int_{-1}^{+1} (a_0 + a_1 x + \ldots + a_{n-1} x^{n-1} + a_n x^n)\,dx$$

$$= 2\left(a_0 + \frac{a_2}{3} + \frac{a_4}{5} + \frac{a_6}{7} + \ldots\right)$$

$$= C_n[f(x_1) + f(x_2) + \ldots + f(x_n)] \ldots\ldots\ldots [2]$$

$$= C_n\left\{n a_0 + a_1 \sum_1^n x_i + a_2 \sum_1^n x_i^2 + \ldots + a_{n-1} \sum_1^n x_i^{n-1} + a_n \sum_1^n x_i^n\right\}$$

This holding for any value of $a_0, a_1 \ldots a_{n-1}, a_n$, $(n+1)$ equalities can be written:

$$\left.\begin{aligned} & nC_n = 2 \text{ or } C_n = \frac{2}{n} \\ & x_1 + x_2 + x_3 + \ldots + x_n = 0 \\ & x_1^2 + x_2^2 + x_3^2 + \ldots x_n^2 = \frac{n}{3} \\ & \ldots\ldots\ldots\ldots\ldots\ldots \\ & \ldots\ldots\ldots\ldots\ldots\ldots \\ & x_1^n + x_2^n + x_3^n + \ldots x_n^n = \frac{n}{n+1} \text{ or } 0 \end{aligned}\right\} \ldots\ldots [3]$$

It will be seen that the system contains n equations, which yield the values of $x_1, x_2, \ldots x_n$.

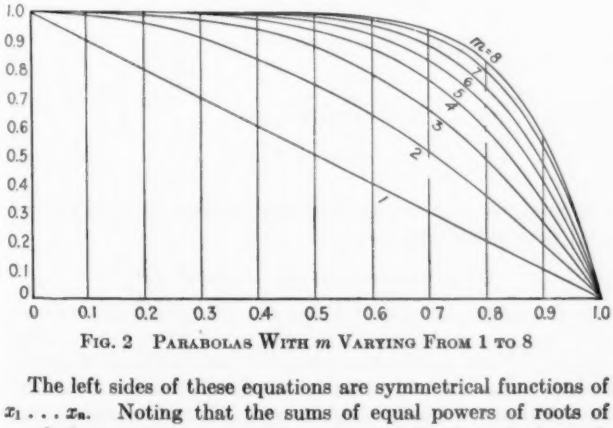

FIG. 2 PARABOLAS WITH m VARYING FROM 1 TO 8

The left sides of these equations are symmetrical functions of $x_1 \ldots x_n$. Noting that the sums of equal powers of roots of an algebraic equation are expressed rationally through the coefficients of the equation, we can write an equation

$$F(x) = x^n + A_1 x^{n-1} + A_2 x^{n-2} + \ldots + A_{n-1} x + A_n = 0 \ldots [4]$$

such that $x_1, \ldots, x_n$ will be its roots.

To find the coefficients $A_1 \ldots A_n$, we use the well-known Newton's formulas[5] for like powers of the roots of Equation [4].

Denoting $\sum_1^n x_i = s_1$; $\sum_1^n x_i^2 = s_2$; $\ldots$ $\sum_1^n x_i^{n-1} = s_{n-1}$

we can write:

$$A_1 + s_1 = 0$$
$$2A_2 + s_1 A_1 + s_2 = 0$$
$$3A_3 + s_1 A_2 + s_2 A_1 + s_3 = 0$$
$$(n-1)A_{n-1} + s_1 A_{n-2} + s_2 A_{n-3} + \ldots + s_{n-1} = 0$$

Substituting in these formulas the values of $s_1 \ldots s_{n-1}$ from Equations [3]

$$A_1 = 0$$
$$2A_2 + \frac{n}{3} = 0$$
$$A_3 = 0$$
$$4A_4 + \frac{n}{3} A_2 + \frac{n}{5} = 0$$
$$A_5 = 0$$
$$6A_6 + \frac{n}{3} A_4 + \frac{n}{5} A_2 + \frac{n}{7} = 0, \text{ etc.}$$

For each value of n we are able now to set up a function

$$F(x) = x^n + A_1 x_1^{n-1} + \ldots + A_{n-1} x + A_n = 0$$

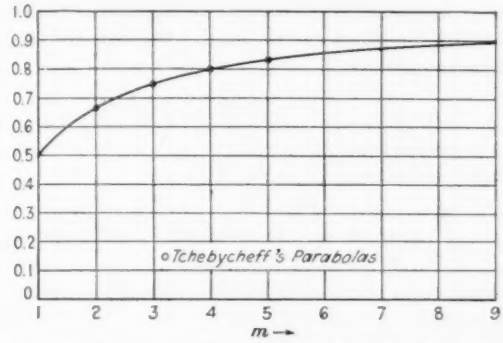

FIG. 3 MEAN ORDINATES OF PARABOLAS PLOTTED AGAINST VALUE OF m

For various ordinate numbers, this function is given in Table 2. The equation for $n = 8$ gives imaginary roots. The other equations yield the roots listed in Table 3, which determine the so-called Tchebycheff's ordinates.

TABLE 2 VALUES OF THE FUNCTION $F(x)$ FOR GIVEN ORDINATE NUMBERS

Ordinate numbers	Values of the function $F(x)$
$n = 2$	$F(x) = x^2 - 1/3 = 0$
$n = 3$	$x^3 - 1/2\,x = 0$
$n = 4$	$x^4 - 2/3\,x^2 + 1/45 = 0$
$n = 5$	$x^5 - 5/6\,x^3 + 7/12\,x = 0$
$n = 6$	$x^6 - x^4 + 1/5\,x^2 - 1/105 = 0$
$n = 7$	$x^7 - 7/6\,x^5 + 119/360\,x^3 - 149/6480\,x = 0$
$n = 8$	$x^8 - 4/3\,x^6 + 22/45\,x^4 - 148/2835\,x^2 - 43/42525 = 0$
$n = 9$	$x^9 - 3/2\,x^7 + 27/40\,x^5 - 57/560\,x^3 + 53/22400\,x = 0$

TABLE 3 VALUES OF TCHEBYCHEFF'S ORDINATES

Ordinate numbers	Values of abscissas
$n = 2$	$x_1 = -x_2 = 0.57735$
$n = 3$	$x_1 = -x_3 = 0.70711$; $x_2 = 0$
$n = 4$	$x_1 = -x_4 = 0.79465$; $x_2 = -x_3 = 0.18759$
$n = 5$	$x_1 = -x_5 = 0.83250$; $x_2 = -x_4 = 0.37454$; $x_3 = 0$
$n = 6$	$x_1 = -x_6 = 0.86625$; $x_2 = -x_5 = 0.42252$; $x_3 = -x_4 = 0.26664$
$n = 7$	$x_1 = -x_7 = 0.88386$; $x_2 = -x_6 = 0.52966$; $x_3 = -x_5 = 0.32391$; $x_4 = 0$
$n = 9$	$x_1 = -x_9 = 0.91159$; $x_2 = -x_8 = 0.60102$; $x_3 = -x_7 = 0.52876$; $x_4 = -x_6 = 0.16791$; $x_5 = 0$

STANDARD PARABOLAS

A ship's water line has the general appearance of that of Fig. 1*a*. Denoting the ratio of the abscissas to the half length l as x

[5] "Elementary Theory of Equations," by L. E. Dickson, John Wiley & Sons, 1914, p. 69, or other algebra manual.

$\left(\frac{\text{abscissa}}{l} = x\right)$ and the ratio of the ordinate to the maximum half width b as y $\left(\frac{\text{ordinate}}{b} = y\right)$, the area S of AOB, Fig. 1*b*, is equal to

$$S = bl \int_0^1 y\, dx$$

where $y = 1$ at $x = 0$; $y = 0$ at $x = 1$; and $\frac{dy}{dx} = 0$ at $x = 0$.

Tchebycheff's problem of finding the mean ordinate can now be stated as follows:

$$\int_0^1 y\, dx = \frac{1}{k}(y_1 + y_2 + y_3 + \ldots + y_k) \ldots\ldots [5]$$

or, if the ordinate at $y_0 = 1$ at $x = 0$, is to be taken into account

$$\int_0^1 y\, dx = \frac{1}{k + 1/2}\left(\frac{1}{2} + y_1 + y_2 + y_3 + \ldots + y_k\right) \ldots [6]$$

We will take k curves $y = f(x)$, which would have the general character as shown in Fig. 1*b* and find such values of $x_1, \ldots x_k$ that the conditions of Equation [5] and Equation [6] would be fulfilled exactly for the k curves taken. The simplest functions of this type are parabolas

$$y = 1 - x^m \ldots\ldots [7]$$

where m is greater than 1.

The mean ordinate of [7] is equal to

$$\int_0^1 y\, dx = \int_0^1 (1 - x^m) dx = \frac{m}{m+1} \ldots\ldots [8]$$

Substituting the result of Equation [8] in Equations [5] and [6], we obtain, respectively,

$$\frac{m}{m+1} = \frac{1}{k}(y_1 + \ldots + y_k) \ldots\ldots [9]$$

$$\frac{m}{m+1} = \frac{1}{k + 1/2}(1/2 + y_1 + \ldots + y_k) \ldots\ldots [10]$$

Equations [9] and [10] can be rewritten, respectively, as

$$\frac{m}{m+1} = \frac{1}{k}(1 - x_1^m + 1 - x_2^m + 1 - x_3^m + \ldots + 1 - x_k^m)$$

or

$$x_1^m + x_2^m + \ldots + x_k^m = \frac{k}{m+1} \ldots\ldots [11]$$

and

$$\frac{m}{m+1} = \frac{1}{k + 1/2}\left(\frac{1}{2} + 1 - x_1^m + 1 - x_2^m + \ldots + 1 - x_k^m\right)$$

or

$$x_1^m + x_2^m + \ldots + x_k^m = \frac{2k+1}{2(m+1)} \ldots\ldots [12]$$

In both instances, i.e., whether middle ordinate y_0 be used or not, k standard parabolas (k values of m) must be chosen to provide k equations for $x_1 \ldots x_k$.

Now, assuming that we choose the standard parabolas as listed in Table 4, the values of the roots as determined from Equations [11] and [12] will be those listed in Table 5.

TABLE 4 ORDINATES FOR STANDARD PARABOLAS AS CHOSEN

Number of ordinates in Fig. 1*a*	Value of k: Ordinate y_0 not taken, Equation [11]	Ordinate y_0 taken, Equation [12]	Standard parabolas chosen	Mean Ordinates
2	1		$m = 2$	0.6667
3		1	2	
4	2		$m = 2,3$	0.6667
5		2	2,3	0.7500
6	3		$m = 2,3,4$	0.6667
				0.7500

[a] Equation [11] gives imaginary roots for $k = 4$.

TABLE 5 VALUES OF ROOTS AS DETERMINED FROM EQUATIONS [11] AND [12]

Number of ordinates	Equations [11] or [12]	Roots
2	$x_1^2 = \frac{1}{3}$	$x_1 = 0.5774$
3	$x_0 = 0;\ x_1^2 = \frac{3}{6} = \frac{1}{2}$	$x_1 = 0.7071$
4	$x_1^2 + x_2^2 = \frac{2}{3}$; $x_1^3 + x_2^3 = \frac{2}{4}$	$x_1 = 0.1876$; $x_2 = 0.7947$
5	$x_0 = 0;\ x_1^2 + x_2^2 = \frac{5}{6}$; $x_1^3 + x_2^3 = \frac{5}{8}$	$x_1 = 0.3745$; $x_2 = 0.8325$
6	$x_1^2 + x_2^2 + x_3^2 = \frac{3}{3}$; $x_1^3 + x_2^3 + x_3^3 = \frac{3}{4}$; $x_1^4 + x_2^4 + x_3^4 = \frac{3}{5}$	$x_1 = 0.2666$; $x_2 = 0.4225$; $x_3 = 0.8663$
7	$x_0 = 0;\ x_1^2 + x_2^2 + x_3^2 = \frac{7}{6}$; $x_1^3 + x_2^3 + x_3^3 = \frac{7}{8}$; $x_1^4 + x_2^4 + x_3^4 = \frac{7}{10}$	$x_1 = 0.3239$; $x_2 = 0.5297$; $x_3 = 0.8839$
9	$x_0 = 0;\ x_1^2 + x_2^2 + x_3^2 + x_4^2 = \frac{9}{6}$; $x_1^3 + x_2^3 + x_3^3 + x_4^3 = \frac{9}{8}$; $x_1^4 + x_2^4 + x_3^4 + x_4^4 = \frac{9}{10}$; $x_1^5 + x_2^5 + x_3^5 + x_4^5 = \frac{9}{12}$	$x_1 = 0.1679$; $x_2 = 0.5288$; $x_3 = 0.6010$; $x_4 = 0.9116$

It is evident that the standard parabolas chosen as in Table 4 yield Tchebycheff ordinates.

The Proposed System of Ordinates

It is evident that the foregoing choice of standard parabolas is by no means unique and that an infinite number of other combinations of values of m_i (not necessarily integral) can be chosen for each value of k. It would be reasonable for naval architects, for instance, to choose such standard parabolas which would cover a wider range of mean ordinates, and furthermore, parabolas with areas varying by equal increments. (See Fig. 3.)

Moreover, the longitudinal location of the center of gravity of the area included by the lines is required in naval architecture, or the integral

$$M = \int_0^1 xy\, dx$$

It has been noticed that Tchebycheff ordinates do not give this moment with satisfactory accuracy. The function $y = f(x)$ can be written

$$y = 1 - a_2 x^2 - a_3 x^3 - a_4 x^4 - a_5 x^5 - \ldots$$

provided that $a_2 + a_3 + a_4 + \ldots = 1$

then

$$\int_0^1 xy\,dx = \int_0^1 (1 - a_2x^2 - a_3x^4 - a_4x^5 - \ldots)dx - \int^1 (1 - x)\,dx$$

Now, Tchebycheff's ordinates are well suited to evaluate the first term of this integral, but will give the value of the second term with considerable error. It is, therefore, imperative to include the parabola with $m = 1$, or $y = (1 - x)$ as a standard parabola.

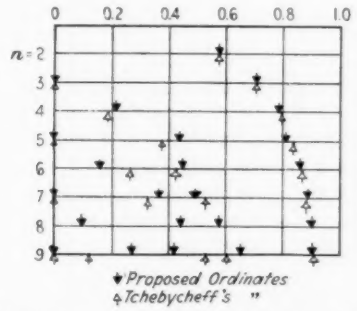
TABLE 8 RECOMMENDED ORDINATES FOR SHIPBUILDING COMPUTATIONS

Number of ordinates	Abscissas as determined from equations in Table 7
$n = 2$	$x_1 = -x_2 = 0.57735$
$n = 3$	$x_1 = -x_3 = 0.70711$; $x_2 = 0$
$n = 4$	$x_1 = -x_4 = 0.21133$; $x_2 = -3 = 0.78868$
$n = 5$	$x_1 = -x_5 = 0.43406$; $x_2 = -x_4 = 0.81594$; $x_3 = 0$
$n = 6$	$x_1 = -x_6 = 0.15821$; $x_2 = -x_5 = 0.47755$; $x_3 = -x_4 = 0.86424$
$n = 7$	$x_1 = -x_7 = 0.36574$; $x_2 = -x_6 = 0.49872$; $x_3 = -x_5 = 0.88554$; $x_4 = 0$
$n = 8$	$x_1 = -x_8 = 0.09780$; $x_2 = -x_7 = 0.42543$; $x_3 = -x_6 = 0.57659$; $x_4 = -x_5 = 0.90018$
$n = 9$	$x_1 = -x_9 = 0.27047$; $x_2 = -x_8 = 0.41791$; $x_3 = -x_7 = 0.65263$; $x_4 = -x_6 = 0.90900$; $x_5 = 0$

On the basis of the foregoing observations, the standard parabolas listed in Table 6 are suggested. Substituting in Equations [11] and [12] the values of k and m as given in Table 6, we obtain equations for $x_1 \ldots x_k$ that are listed in Table 7. The roots of these equations were found by successive approximation to the sixth decimal place and are tabulated in Table 8. It is recommended that these abscissas be used in shipbuilding computations instead of Tchebycheff's ordinates. These suggested ordinates are compared graphically with Tchebycheff's ordinates in Fig. 4.

Empirical Verification

The two curves shown in Fig. 5 have the general character of waterlines. Curve a has the equation $y = 0.7\,(1 - x^3) + 0.3\,(1 - x^6)^2$, while curve b has the equation $y = \left(0.935 \cos \frac{\pi}{2} x\right) + \left(0.065 \cos \frac{3\pi}{2} x\right)$. The areas and moments of these curves, when



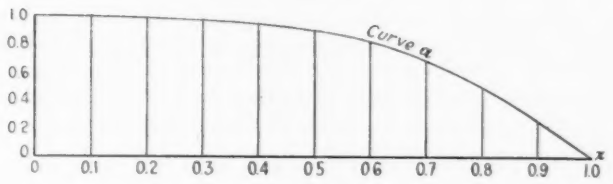


FIG. 4 COMPARISON OF TCHEBYCHEFF'S AND THE PROPOSED ORDINATES

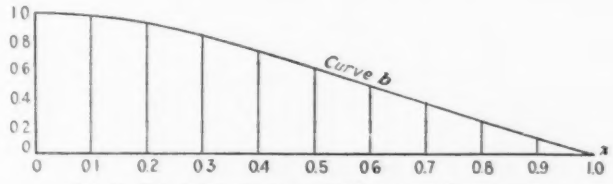

FIG. 5 TEST CURVES FOR THE PROPOSED ORDINATES

calculated analytically and by approximate quadrature rules, are given in Table 9.

Application of the Proposed Ordinates

Referring to Fig. 1*a* and taking ordinates at abscissas indicated in Table 8

$$\int_{-1}^{+1} y\,dx = 2/n \sum_1^n y_i \ldots\ldots\ldots\ldots [13]$$

where $n = 2k$ or $(2k + 1)$.

This equality is exact not only for a line composed of two symmetrically disposed standard parabolas, but is always exact for

(1) $y = a_0$, since in this case $\int_{-1}^{+1} y\,dx = 2a_0$ and $\sum_1^n y_i = n\,a_0$

(2) $y = 1 - x^{2m+1}$ with $m = 0, 1, 2 \ldots$ since in this case $\int_{-1}^{+1} (1 - x^{2m+1})\,dx = 2$ and $\sum_1^n y_i = n$ in view of the fact that

$$y_{-k} + y_{+k} = (1 + x_k{}^{2m+1}) + (1 - x_k{}^{2m+1}) = 2$$

It is, therefore, evident that a function having $y = a$ at $x = -1$ and $y = b$ at $x = +1$ can be integrated by the proposed rule. Indeed, taking $y = c$ at $x = 0$, we can write

$$y = b - \frac{b-a}{2}\left[d_1(1-x) + d_3(1-x^3) + d_5(1-x^5) + \ldots\right] + \left(c - \frac{b+a}{2}\right)\left[d_2(1-x^2) + d_4(1-x^4) + d_6(1-x^6) + \ldots\right]$$

where $d_1 + d_3 + d_5 + \ldots = 1$

and $d_2 + d_4 + d_6 + \ldots = 1$

and $$\frac{b-a}{2} d_1 = \left|\frac{dy}{dx}\right|_{x=0}$$

The integrals of the first and second terms are expressed exactly by Equation [13] while the third term is integrated with an approximation demonstrated above.

The proposed ordinates are, therefore, as universal in their application as the ordinates of Tchebycheff.

TABLE 9 COMPARISON OF VALUES COMPUTED BY THE VARIOUS QUADRATURE RULES

Conclusion

It should be noted that the choice of standard parabolas for determination of $x_1, x_2 \ldots x_k$ in the foregoing was dictated primarily by the requirements of the geometry of a hull. Other applications may dictate the choice of different standard parabolas.

The author is indebted to Prof. L. Siceloff for his criticism and suggestions and to Miss Vera Mintz for her assistance with the numerical computations.

Buckling of Flat Curved Bars and Slightly Curved Plates

By S. TIMOSHENKO,[1] ANN ARBOR, MICH.

This paper considers the case of the flat arch and the slightly curved plate, with uniformly distributed load, which may fail not as a result of high stresses and yielding of the material but because of instability, and it is shown how the critical load at which buckling occurs may be calculated. The case of the bimetallic strips used as part of thermostats is also considered.

IF A flat arch is submitted to the action of a uniformly distributed load, Fig. 1, the failure of the structure may occur not as a result of high stresses and yielding of the material, but because of instability. The compressed arch may buckle and take the position indicated in the figure by the dotted line. In the following discussion it is shown how the critical load, at which buckling occurs, can be calculated.

To simplify the calculations, assume that the center line of the arch is initially given by the equation

$$y_1 = a \sin \pi x/l \ldots\ldots\ldots\ldots\ldots\ldots [a]$$

and that the ends of the arch are hinged. The following notation is used:

q = the intensity of the uniform load
EI = the flexural rigidity of the arch

$$u = \frac{5}{384} \frac{ql^4}{EI} \frac{1}{a} \ldots\ldots\ldots\ldots\ldots\ldots [b]$$

is the ratio of the deflection, calculated as for a beam, to the rise of the arch
H = the thrust of the arch

$$\alpha = Hl^2/\pi^2 EI \ldots\ldots\ldots\ldots\ldots\ldots [c]$$

is the ratio of the thrust to Euler's load. Then the center line of the arch after loading, assuming that it is symmetrical with respect to the middle, can be represented with sufficient accuracy by the following equation[2]

$$y_2 = \frac{a(1-u)}{1-\alpha} \sin \frac{\pi x}{l} \ldots\ldots\ldots\ldots\ldots\ldots [d]$$

This equation can be used not only for $u < 1$, but also for $u > 1$, i.e., in the cases where the deflection of the curved bar, calculated as for a simple beam, is larger than the initial rise of the arch. The quantity α can also be larger than one, but it must be smaller than four since for $\alpha = 4$, buckling of the arch with an inflection point at the middle occurs and the assumption of Equation [d] that the arch remains symmetrical with respect to the middle is no longer fulfilled.

Assuming first that $u < 1$, we find, from Equation [d], that y_2 is positive if $\alpha < 1$, and negative when $\alpha > 1$. This means that the arch has the form shown in Fig. 1 by the full line if the thrust is smaller than the Euler load for a bar with hinged ends, and the same arch can be kept deflected downward, as shown in the figure by the dotted line, if a thrust larger than the Euler load is applied. When $u > 1$, y_2 is positive for $\alpha > 1$, and it becomes negative for $\alpha < 1$.

The actual shape of the arch, after loading, can be determined only when the quantity α, i.e., the thrust H, is known. The equation for calculating the thrust H is obtained by putting the change in length of the span due to deflection equal to the compression of the bar due to thrust. Assuming for flat curves that the compressive force along the length of the bar is constant and equal to H, we obtain the equation

$$\frac{Hl}{AE} = \frac{1}{2}\int_0^l \left(\frac{dy_1}{dx}\right)^2 dx - \frac{1}{2}\int_0^l \left(\frac{dy_2}{dx}\right)^2 dx \ldots\ldots [e]$$

in which A is the cross-sectional area of the bar. Substituting

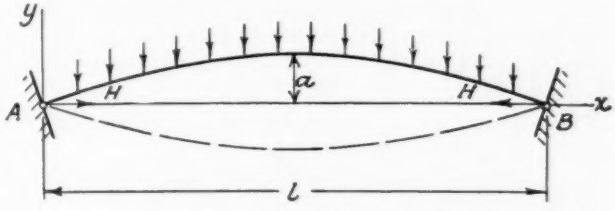

FIG. 1

for y_1 and y_2 their expressions [a] and [d] and integrating, we obtain

$$(1-u)^2 = (1-m\alpha)(1-\alpha)^2 \ldots\ldots\ldots\ldots\ldots [f]$$

in which

$$m = \frac{4I}{Aa^2} \ldots\ldots\ldots\ldots\ldots\ldots [g]$$

For a given arch the quantity m is easily calculated and if the load q is given, the quantity u can be determined from Equation [b]. Then, the corresponding value of α and the thrust H are obtained from Equation [f]. Since this equation is not linear, more than one real root for α can be obtained under certain conditions, which indicates that there are several possible forms of equilibrium, and the stability of these forms must be investigated.

Considering the right side of Equation [f] as a function of α, we find that for $m < 1$ this function has a minimum equal to 0 for $\alpha = 1$ and a maximum for $\alpha = (2+m)/3m$. The magnitude of this maximum is

$$\frac{4}{27} \frac{(1-m)^3}{m^2} \ldots\ldots\ldots\ldots\ldots\ldots [h]$$

In Fig. 2 the right side of Equation [f] is represented graphically for the case where $m = 1/2$. For this value of m the maximum

---

Dr. Timoshenko was educated in Russia and was called to the Polytechnic Institute of Kiev to occupy the chair of applied mathematics. For five years he was professor of applied mechanics in various engineering schools of St. Petersburg, and professor of applied mechanics at the Polytechnic Institute in Zagreb, Jugoslavia. In 1923 he entered the research department of the Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa., leaving in 1927 to assume his present position.

[2] See author's "Strength of Materials," vol. 2, p. 422.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until May 10, 1935, for publication at a later date.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

occurs at $\alpha = {}^5/_3$ and the magnitude of this maximum, from Equation [h], is ${}^2/_{27}$. If the load q is of such magnitude that the left side of Equation [f] is larger than this maximum, we obtain only one real solution for α, which indicates that only one form of equilibrium is possible, hence the equilibrium is stable. If the left side of Equation [f] is smaller than the quantity [h], three solutions for α are obtained as shown by intersection points s,

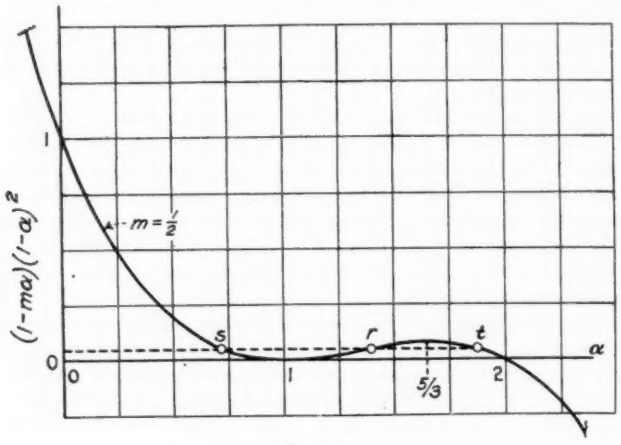

FIG. 2

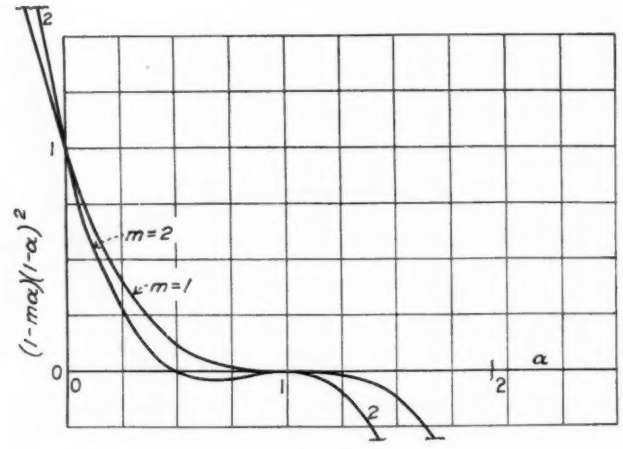

FIG. 3

r, and t in Fig. 2 and the question of stability of the corresponding forms of equilibrium must be considered. Applying these conclusions in the numerical example just cited we find that the equilibrium is always stable if

$$(1 - u)^2 > 2/27$$

which is equivalent to the conditions

$$\left.\begin{aligned} u &< \left(1 - \sqrt{\frac{2}{27}}\right) \\ u &> \left(1 + \sqrt{\frac{2}{27}}\right) \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [i]$$

The first of these conditions corresponds to the form of equilibrium convex upward, as shown in Fig. 1 by the full line, and the second to the form convex downward, as indicated in the figure by the dotted line.

For any value of m smaller than 1 the conditions of stability, equivalent to conditions [i], are

$$\left.\begin{aligned} u &< \left(1 - \sqrt{\frac{4}{27}\,\frac{(1-m)^2}{m^2}}\right) \\ u &> \left(1 + \sqrt{\frac{4}{27}\,\frac{(1-m)^2}{m^2}}\right) \end{aligned}\right\} \quad \ldots\ldots\ldots [j]$$

Hence, conditions that make possible more than one form of equilibrium and where an investigation of stability is necessary are

$$\left.\begin{aligned} u &> \left(1 - \sqrt{\frac{4}{27}\,\frac{(1-m)^2}{m^2}}\right) \\ u &< \left(1 + \sqrt{\frac{4}{27}\,\frac{(1-m)^2}{m^2}}\right) \end{aligned}\right\} \quad \ldots\ldots\ldots [k]$$

If $m \geqq 1$, Equation [f] has only one real root, as can be seen from Fig. 3, in which the right side of Equation [f] is represented by curves for $m = 2$ and $m = 1$. It is seen that for any positive value for $(1 - u)^2$ we obtain only one value for α, which is less than unity. Hence for $m \geqq 1$ there is only one possible form of equilibrium which will be stable. The question of instability will arise only if $m < 1$, and the load is within the limits indicated by conditions [k].

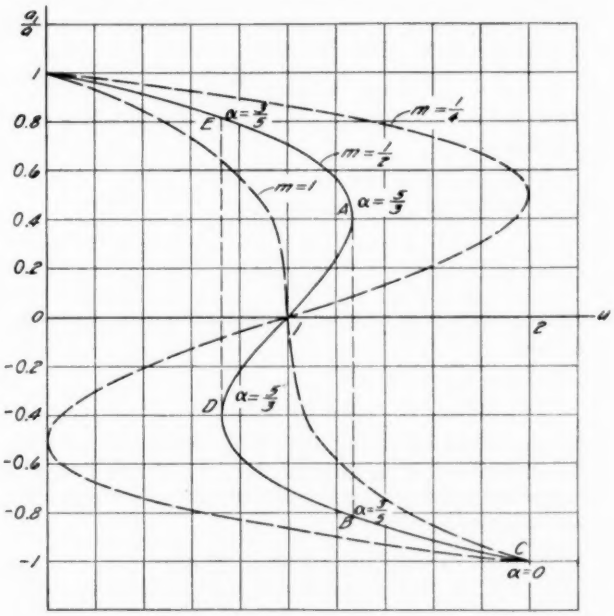

FIG. 4

In the investigation of the stability it is advantageous to represent graphically the rise of the arch as a function of the load or as a function of the quantity u. By using Equation [d] this rise is

$$a_1 = \frac{a(1-u)}{1-\alpha} \quad \ldots\ldots\ldots\ldots\ldots [l]$$

By taking in each particular case a series of values of α the corresponding values of u can be calculated from Equation [f] and the rise a_1 from Equation [l]. In Fig. 4 the values of a_1/a are plotted against u. The full line represents the case where $m = {}^1/_2$, and the two dotted lines the cases $m = {}^1/_4$ and $m = 1$. Considering the case $m = {}^1/_2$, it is seen from the curve that the deflection gradually increases with increasing of the load up to the point A which corresponds to the maximum (at $\alpha = {}^5/_3$) on the curve shown in Fig. 2. Beginning at this point further de-

flection continues with the decreasing of u, i.e., with the decreasing of the load q. This fact indicates that the point A, i.e., for

$$(1 - u)^2 = 2/27$$

the form of equilibrium of the arch shown in Fig. 1 by the full line becomes unstable and the arch buckles downward as shown by the dotted line. The sag of this new form of equilibrium is given in Fig. 4 by the position of the point B. This new form of equilibrium is stable and any further increase of the load produces a gradual increase in deflection as is shown by the portion BC of the curve in Fig. 4. The thrust H during this loading decreases. It becomes zero at the point C and becomes negative with a further increase of the load. If, starting from the point B, we begin to diminish the load the deflection of the arch gradually diminishes up to the point D. At this point the load becomes insufficient to keep the arch deflected convex downward and it buckles upward to the position given in Fig. 4 by the point E. From this discussion we see that there exists a possibility of having more than one form of equilibrium in the region limited by the vertical lines ED and AB which corresponds to the conditions [i]. In the general case this region is defined by the conditions [k] and we conclude that the critical load at which the arch will buckle convex downward is determined from the equation

$$u = 1 + \sqrt{\frac{4}{27}\frac{(1 - m)^2}{m^2}} \quad \ldots\ldots\ldots\ldots [1]$$

From the curves in Fig. 4 it may be concluded that the region in which more than one form of equilibrium is possible becomes smaller and smaller with the increase of m, and when m becomes equal to one the two limits given by [k] coincide, hence, beginning from this value of m only one form of equilibrium is possible.

In the foregoing discussion it was assumed that a uniformly distributed load is acting on the arch, but the results obtained can be used in all cases in which the deflection of the arch, considered as a beam, can be represented with sufficient accuracy by the sine curve. Taking, for instance, a concentrated vertical load P applied at the middle of the arch, the critical value of this load is obtained from Equation [1],[3] it being only necessary to substitute in this equation

$$u = \frac{Pl^3}{48EI}\frac{1}{a} \quad \ldots\ldots\ldots\ldots [m]$$

In an analogous manner the problem can be solved also if the load P is applied at some point other than the middle. It is only necessary to substitute in Equation [m] the corresponding deflection at the middle of the beam for $Pl^3/48EI$.

The results of the foregoing discussion can be used in investigating buckling of a bimetallic strip submitted to a variation of temperature. Such strips are used as a part of instruments (thermostats) serving for regulating temperature. Simple considerations show that due to difference in coefficients of expansion of the two metals a straight bimetallic strip becomes curved when temperature changes. The curvature can be calculated from the equation[4]

$$\frac{1}{\rho} = \frac{3}{2}\frac{(\epsilon_2 - \epsilon_1)(t - t_0)}{h} \quad \ldots\ldots\ldots\ldots [2]$$

in which ϵ_1 and ϵ_2 are coefficients of thermal expansion (it is assumed $\epsilon_2 > \epsilon_1$), h is the thickness of the strip, and $t - t_0$ is the rise of temperature. Thus the curvature of a bimetallic strip produced by heating is proportional to the rise in temperature and to the difference of the two coefficients of expansion and inversely proportional to the thickness of the strip. Equation [2] derived for two metals with equal moduli can also be used with sufficient accuracy in the case in which the materials have somewhat different moduli of elasticity as, for instance, in the case of monel metal and nickel steel.[5]

Having the curvature, the deflection at the middle of the strip, supported at both ends, due to increase of temperature $(t - t_0)$ is obtained as for a flat arc of a circle, and is equal to

$$\delta = \frac{l^2}{8\rho} \quad \ldots\ldots\ldots\ldots [n]$$

in which l is the length of the strip and ρ the radius of curvature determined from [2].

Let us now consider a bimetallic strip which has a slight initial curvature and assume that the ends of the strip are hinged as shown in Fig. 1 by the full line. If the metal on the concave side has a larger coefficient of thermal expansion than the metal on the convex side, the strip will deflect downward during heating and a thrust H will be produced as a result of this deflection. At a certain temperature, depending on the proportions of the strip and on the difference of the coefficients of expansion of the two metals, the form of the strip shown in Fig. 1 by the full line becomes unstable and the strip buckles suddenly downward as indicated by the dotted line. In a thermostat the source of heating is cut off at the moment of buckling of the strip and cooling begins which results finally in buckling of the strip in the upward direction, thus turning on the source of heat again. This phenomena is analogous to that of buckling of a flat arch during loading and unloading, just discussed. To determine the temperature at which buckling occurs we need only to use the deflection [n] instead of the deflection produced by loading, and Equation [1] becomes

$$\frac{l^2}{8\rho a} = 1 + \sqrt{\frac{4}{27}\frac{(1 - m)^2}{m^2}}$$

Using for the curvature expression [2], the temperature t_1, at which buckling of the strip in a downward direction occurs, is obtained from the equation

$$\frac{3}{16}\frac{l^2}{ah}(\epsilon_2 - \epsilon_1)(t_1 - t_0) = 1 + \sqrt{\frac{4}{27}\frac{(1 - m)^2}{m^2}} \quad \ldots\ldots [3]$$

The temperature t_2, at which the strip buckles in an upward direction after cooling, is obtained from the first of the inequality [k]. Hence

$$\frac{3}{16}\frac{l^2}{ah}(\epsilon_2 - \epsilon_1)(t_2 - t_0) = 1 - \sqrt{\frac{4}{27}\frac{(1 - m)^2}{m^2}} \quad \ldots\ldots [4]$$

Taking, for instance, $l/h = 100$, $\epsilon_2 - \epsilon_1 = 4 \times 10^{-6}$, and the values of $m = h^2/3a^2$, such as is given in the first line of Table 1, the ratios of the initial rise a of the strip to its thickness are such as are given in the second line of the table. The values of $(t_1 - t_0)$, calculated from Equation [3], and $(t_2 - t_0)$, calculated from Equation [4], are given in the third and fourth lines of the table, respectively.

It is seen from the table that the temperature of buckling t_1 in-

[3] This particular problem has been discussed by Navier, "Résumé des lecons sur l'application de la mécanique," second edition, p. 273, Paris, 1833. See also C. B. Biezeno, Koninklijke Akademie van Wetenschappen te Amsterdam, Proceedings, vol. 32, 1929, p. 990. The case when the center line of the arch is not a flat curve has been considered by A. Nadai, Technische Blättern, nos. 3 and 4, Prag, 1915.

[4] See author's "Strength of Materials," vol. 1, p. 245.

[5] A more general investigation of bending and buckling of bimetallic strips is given in the author's paper, see *Journal Optical Society of America*, vol. 11, 1925, p. 233.

$t_1 - t_0$ =	104	137	217	307
$t_2 - t_0$ =	83	79	50	0

creases with the increase of the initial curvature and at the same time the temperature t_2 decreases, so that the sensitivity of the thermostat, given by the difference $(t_1 - t_2)$, decreases rapidly with the increase of the temperature action t_1. The conditions can be improved by introducing elastic supports for the bimetallic strip.

If, under the action of the thrust H, the distance between the supports increases by some quantity βH proportional to H, the equation for calculating the thrust becomes

$$\frac{Hl}{AE} + \beta H = \frac{1}{2}\int_0^l \left(\frac{dy_1}{dx}\right)^2 dx - \frac{1}{2}\int_0^l \left(\frac{dy_2}{dx}\right)^2 dx$$

and, instead of Equation [f] we obtain

$$(1 - u)^2 = (1 - m_1\alpha)(1 - \alpha)^2 \ldots\ldots\ldots\ldots [o]$$

in which

$$m_1 = m\left(1 + \frac{\beta AE}{l}\right) \ldots\ldots\ldots\ldots [p]$$

It is seen that the operation of a bimetallic strip with elastic supports can be investigated in the same manner as it was before.

It is only necessary to introduce, instead of the quantity m, a new quantity m_1 depending on the elasticity of supports. By a suitable adjustment of this elasticity the desired sensitivity of the thermostat can be obtained.[6]

A Theoretical Investigation of the Maximum-Lift Coefficient

By Th. von Kármán[1] and Clark B. Millikan[2]

In the present paper the application of a laminar boundary-layer theory, previously developed by the authors, to the problem of the maximum-lift coefficient of airfoils is discussed. The calculations are carried through in detail for a first approximation, called a single-roof profile, to the potential velocity distribution over the upper surface of an airfoil. The results indicate a large variation in $C_{L\max}$ with turbulence but the quantitative dependence on Reynolds' number and turbulence is not satisfactory. The calculations are then repeated for a so-called double-roof profile which approximates to the flow over the upper surface of an N.A.C.A. 2412 airfoil. These results are compared with those obtained from an experimental investigation on the same airfoil. The agreement is considered to indicate that for moderate values of R and $C_{L\max}$ the phenomenon of the maximum-lift coefficient is controlled by a contest between the separation and transition points of the laminar boundary layer over the nose of the airfoil. The difficulties involved in extending the theory to larger values of R, or to airfoils whose C_L vs. α curves are not approximately linear up to the stall, are mentioned.

1—Introduction

THE PROBLEM of the maximum lift of airfoils has concerned the authors greatly since there were first discovered in the spring of 1932 serious discrepancies in this characteristic between results obtained in the wind tunnel of the Guggenheim Aeronautics Laboratory at the California Institute of Technology (GALCIT) and those reported from certain other wind tunnels. An elaborate experimental investigation by the junior author and A. L. Klein[3] indicated that the value of $C_{L\max}$ for a given airfoil was strongly affected both by Reynolds' number and by the degree of turbulence in the tunnel wind stream. It had long been known that the maximum-lift behavior was intimately connected with the separation of the boundary layer from the upper surface of an airfoil, but it had in general been supposed that for practically important Reynolds' numbers this phenomenon involved only the turbulent state of the boundary layer. The great dependence of $C_{L\max}$ on the degree of free-stream turbulence, as revealed by the aforementioned experiments, made the authors suspect that the boundary layer at a separation point may be sometimes turbulent and sometimes laminar. The free-stream turbulence would then have a great influence in determining which of the two régimes was in effect for a particular case, and it is easy to see that the separation phenomenon might be importantly influenced by the possible existence of these alternative types of flow in the boundary layer. It is well known that a turbulent boundary layer resists separation much more effectively than does a laminar one. Hence an early transition of the boundary layer from the laminar to the turbulent state, induced by large external turbulence, might delay the separation and increase the maximum lift. The quantitative discussion of such an hypothesis requires an analysis of the laminar boundary layer, and in particular a determination of its separation point and its thickness at that point.

The existing methods for the calculation of a laminar boundary layer with a more or less arbitrary pressure distribution were felt to be unsatisfactory for this purpose. Accordingly, an entirely new procedure was developed which has been presented in detail in a previous paper by the authors.[4] In the present paper the application of this boundary-layer analysis to the problem of the maximum-lift coefficient will be discussed. The explicit aim of this paper is, then, to investigate the dependence of $C_{L\max}$ on Reynolds' number and free-stream turbulence over the regions available for normal wind-tunnel tests.

2—Outline of the Basic Procedure[5]

The boundary-layer theory is based on the assumption that the influence of friction is restricted to the neighborhood of the walls and does not essentially change the outside flow. Its application is, therefore, restricted to those cases in which the outside flow is known. Hence, we are able to investigate whether or not a given flow pattern about an airfoil, involving a certain magnitude of the lift and a certain pressure distribution, is possible without separation of the flow from the surface, but we are not able to determine flow patterns with separation.

In view of the restricted possibilities of the theory we are led to a kind of inverse method to determine the maximum value of the lift coefficient C_L as a function of Reynolds' number and the degree

of turbulence. We start with a given value of C_L and inquire whether or not the potential flow which would produce the assumed lift in a non-viscous fluid can be maintained in a viscous fluid without separation, i.e., whether or not the influence of the friction will be restricted to the boundary layer.

It is easily seen that the problem put in this form is not quite identical with the original problem of the maximum lift. Let us neglect for a moment the possibility of turbulence in the boundary layer. Then the possible values of C_L would be given by flow patterns which do not lead to separation of the laminar boundary layer, and the limiting values of C_L would correspond to the flow with separation just at the trailing edge. Now it is a well-known result of the laminar boundary-layer theory that for geometrically similar bodies the location of the separation point is independent of the Reynolds number. Thus we should conclude that $C_{L\max}$ determined in this way gives only an inferior limit, because flow patterns with separation may give higher lifts than those with separation at the trailing edge, but it is certain that any value below this calculated $C_{L\max}$ can be reached without separation. For this reason the actual values of $C_{L\max}$ may be higher than those determined from the "no separation" criterion, and may be variable with Reynolds' number.

Fortunately, the case in which the boundary layer is laminar along the whole or a considerable part of the airfoil is without practical importance. In the practical range of Reynolds' numbers, both in the case of full-scale airfoils in flight and in that of normal wind-tunnel tests, the laminar régime is restricted to a small portion of the chord. Hence, if the laminar boundary layer separates from the airfoil before transition to the turbulent régime occurs, the separation occurs not far from the leading edge. Such a separation must clearly lead to an abrupt drop in the lift coefficient, such as experiments actually reveal. As a matter of fact, for most modern "efficient" airfoil sections, the experimental $C_L = f(\alpha)$ curves (α = angle of attack) are almost straight up to the stalling point, as would be the case for the pure potential flow, and show a more or less sharp break at the stalling point. Thus in the practically important range we can assume that C_L values which lead to separation of the laminar layer prior to the change to the turbulent state are impossible for such airfoils. Our considerations may, however, not be valid for airfoils in which the C_L vs. α curves have a considerable curvature well before the stall is reached.

Before discussing the second alternative, that the laminar layer becomes turbulent before it reaches the separation point, let us review briefly the pertinent experimental facts for the boundary layer along a flat plate placed parallel with a uniform flow. It is convenient to introduce two Reynolds' numbers for such a boundary-layer flow. The basic-flow Reynolds number R is defined in terms of the characteristic length of the problem, i.e., the length of the plate or airfoil in the direction of flow, and of the free-stream velocity far from the airfoil or plate. The boundary-layer Reynolds number R_δ is defined in terms of the boundary-layer thickness δ at any point along the surface, and of the velocity just outside the boundary layer at this point. The two definitions are $R = U_0 l/\nu$ and $R_\delta = U\delta/\nu$ where U_0 is the undisturbed velocity, l the chord of airfoil or plate, U the potential velocity just outside the boundary layer, δ the boundary-layer thickness at the same point along the surface, and ν coefficient of kinematic viscosity. The definition of the boundary-layer thickness is somewhat arbitrary, but using the same definition throughout the discussion, the results are independent of the definition.

For the flow along a flat plate which we are discussing for the moment, the boundary layer starting from the upstream edge of the plate is laminar in character even though the outside flow is highly turbulent or fluctuating. The boundary-layer thickness increases continuously as one goes downstream from the leading edge, so that the boundary-layer Reynolds number R_δ varies in the same way. For any given type of turbulence or fluctuations in the outside flow there exists a certain value of R_δ at which the laminar régime in the boundary layer becomes unstable and a transition occurs to a turbulent state of flow. Actually there is a region of finite length along the plate in which this transition from the laminar to the so-called "fully developed" turbulent

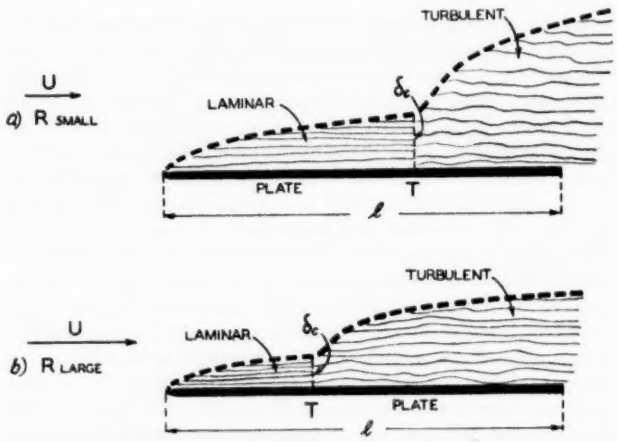

FIG. 1 THE BOUNDARY LAYER ALONG A FLAT PLATE AT TWO REYNOLDS' NUMBERS

régime takes place. For simplicity in both discussion and calculation it is, however, customary to assume that the transition is instantaneous and occurs at a definite point which we shall refer to as the transition point, and which will be indicated by a subscript $(\,)_t$. The boundary-layer Reynolds number at which the transition occurs is called the critical Reynolds number and will be denoted by R_{δ_c}. The variation of R_δ with the basic Reynolds number of the flow, at a given point along the plate, is given by the relation $R_\delta \sim \sqrt{R}$. Assuming the state of turbulence in the outer flow to be independent of the value of R, it follows that for a given air stream R_{δ_c} is also independent of R. Consequently, the transition point, i.e., the point at which R_δ reaches the value R_{δ_c}, moves upstream along the plate as R increases. The conditions for two values of R are indicated schematically in Fig. 1. R_{δ_c} is experimentally found to be independent of R for a given air stream, but to vary with the degree of outside turbulence in such a way that it decreases as the turbulence increases. The observed values of R_{δ_c} lie between about 10,000 for very smooth flows and 1500 for very turbulent flows.

We assume, with considerable experimental justification, that very similar phenomena occur for the boundary layer over the upper surface of an airfoil. In other words, for any given external air flow there is a definite value of R_{δ_c} such that, when the boundary-layer Reynolds number reaches this value, there is a transition point downstream from which the airfoil boundary layer is turbulent, while upstream it is laminar.

We have already discussed the case in which the laminar layer separates before the change to the turbulent régime. This will obviously take place if, for the calculated Reynolds number of the laminar layer at the separation point R_{δ_s}, we have the inequality $R_{\delta_s} < R_{\delta_c}$. In the opposite case when $R_{\delta_s} > R_{\delta_c}$, the layer becomes turbulent before separation and whether or not the value of C_L considered can be reached, obviously depends on the behavior of the turbulent layer. Unfortunately, the theory of the turbulent boundary layer is not as yet so far advanced as to furnish a definite answer to this question. However, it is well known that the turbulent layer exhibits a considerably higher re-

sistance to separation than does the laminar layer. Hence we consider first the idealized case that the turbulent layer clings under all circumstances to the airfoil surface, i.e., we neglect the possibility of separation for the turbulent layer. This neglecting of the possibility of separation of a turbulent boundary layer implies that as $R \to \infty$ indefinitely large values of C_L could be reached, and obviously imposes limitations on the range of validity of the theory. We discuss this in more detail in a later section of this paper entitled "Comparison With Experiment and Region of Validity of the Theory."

With this assumption (no separation of a turbulent boundary layer) the following procedure leads to a family of $C_{L\max}$-curves giving $C_{L\max}$ as a function of Reynolds' number for different degrees of turbulence in the outside stream: We start with an assumed potential-velocity distribution corresponding to a definite value of C_L. From this we calculate the laminar separation point, which will occur at a fixed point on the upper surface of the airfoil. The corresponding value of R_{δ_s} will be proportional to $\sqrt{R}$. We now consider an external flow with a definite degree of turbulence so that R_{δ_c} has a definite value independent of R. If we start with small enough values of R then R_{δ_s} will be less than R_{δ_c}, separation will occur, and the boundary layer will behave as in (*a*) of Fig. 2. The assumed potential flow can obviously not occur and the assumed C_L will not be obtainable. If, now, we increase R, R_{δ_s} increases continuously until it finally equals and then surpasses the constant value of R_{δ_c}.

We can alternatively describe this process in the following way: For small values of R, the transition point is downstream from the separation point (case *a*); with increasing R, the transition point moves upstream, while the location of the separation point is independent of R. When $R_{\delta_s} = R_{\delta_c}$, the two points coincide. A still further increase of R leads now to case (*b*), i.e., the boundary layer at the calculated separation point is turbulent and so clings to the airfoil surface, the assumed potential flow can occur and the assumed C_L is reached. If we repeat the calculations for a series of potential-velocity distributions (i.e., lift coefficients), we get a definite value, of R for each C_L, above which the C_L value is attained and below which it is not. Plotting C_L against R we

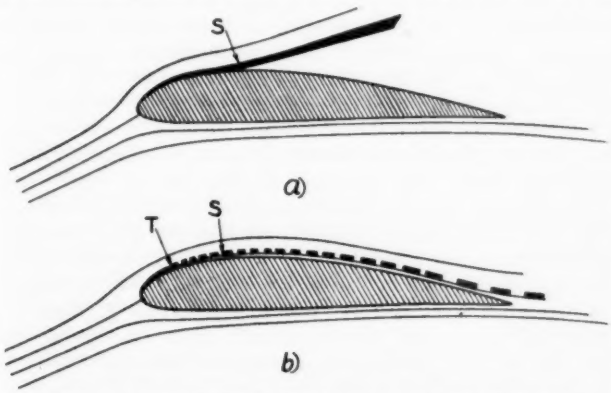

FIG. 2 ALTERNATIVE FLOWS ABOUT AN AIRFOIL SECTION

therefore obtain a curve giving the maximum C_L which can be obtained at any R for a given type of air flow. Again repeating for other values of R_{δ_c} we finally get a family of curves giving $C_{L\max} = f(R)$ for a series of flows characterized by different amounts of external turbulence.

3—BOUNDARY-LAYER NOTATION EMPLOYED

In the following sections we consider the application of the procedure just described to certain special cases. The laminar boundary-layer characteristics are determined using the boundary-layer theory given in the preceding paper by the authors (loc. cit.). The conventions adopted in the preceding paper will also be followed here and are the following: All quantities are dimensionless, lengths being divided by the characteristic length which is taken as the airfoil chord, and velocities being divided by the characteristic velocity taken as the free-stream velocity far from the airfoil. The basic Reynolds number R is then defined in terms of these characteristic quantities. The dimensionless potential velocity just outside of the boundary layer is denoted by U, the dimensionless distance measured along the upper surface of the airfoil from the stagnation point by x, and the dimensionless boundary-layer thickness by δ. R_δ, the boundary-layer Reynolds number, is defined in terms of the actual boundary-layer thickness and the actual potential velocity just outside of the boundary layer at an arbitrary point along the surface. The subscripts $(\ )_s$ and $(\ )_t$ denote, respectively, separation point (of the laminar layer) and transition point (from the laminar to the turbulent régime). R_{δ_c} is the value of R_δ at which the transition occurs, and is a constant for a particular external flow.

In the boundary-layer analysis mentioned above it is found convenient to introduce an alternative variable, in addition to x, to give the distance downstream from the stagnation point along the airfoil upper surface. This variable is defined by $\varphi = \int_0^x U dx$ and is identical with the value of the external-flow potential function at the point x.

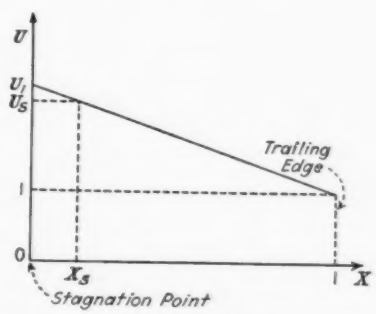

FIG. 3 THE SINGLE-ROOF PROFILE $U = U(x)$

In the paper mentioned, formulas are given for determining the separation point and the value of R_{δ_s} for the laminar boundary layer corresponding to any function $U^2(\varphi)$ which may be represented by one or two polynomials in φ. In the succeeding sections two general types of such flows are considered in detail.

4—THE "SINGLE-ROOF" PROFILE

The "single-roof" profile, represented in Fig. 3, is a first, crude approximation to the potential-flow distribution over the upper surface of an airfoil. It is developed by assuming that the velocity is a linear function of the distance downstream from the stagnation point, while the rapid increase in the velocity from zero to its maximum value U_1 is replaced by a discontinuous jump. It is also assumed that the stagnation point coincides with the leading edge; so that $x = 1$ corresponds to the trailing edge. It will be noticed that the velocity at the trailing edge has been taken equal to the undisturbed free-stream velocity, so that U(trailing edge) = 1. The latter restriction was imposed after a study of the calculated potential-velocity distributions around several airfoils, and is in good accordance with the corresponding experimental velocity distributions.

The single-roof profile has two advantages, first the boundary-layer calculations are especially simple, and second, plausible assumptions lead to a very easy determination of C_L as a function of the maximum velocity U_1. The assumption which was made in the latter connection was that the upper surface contributes all of the lift, i.e., the average pressure over the bottom surface is the same as that at the upper-surface trailing edge, which in turn equals the static pressure far from the airfoil. From this assumption, and using the Bernoulli theorem, we easily obtain the relation

$$C_L = \frac{1}{3}(U_1 - 1)(U_1 + 2) \quad [1]$$

connecting C_L and the maximum velocity U_1.

Turning now to the application of the boundary-layer analysis to this single-roof profile, we shall make use of results presented in the previous paper by the authors (loc. cit.), in which the laminar boundary-layer theory is worked out in some detail for this example. Equations [38] and [41] in the paper cited, furnish the result that the laminar separation point occurs at the position along the surface where $U_1^2/U^2 = 1.241$, i.e.,

$$U_s = 0.897\, U_1 \quad [2]$$

In addition, Equations [44] give the value of the boundary-layer Reynolds number at this separation point as

$$R_{\delta_s} = 2.18 \frac{U_1}{\sqrt{U_1 - 1}} \sqrt{R} \quad [3]$$

These are the only results of the laminar boundary-layer analysis which we shall need in this section.

If U_s as given by Equation [2] is less than 1 there is obviously no separation point on the airfoil surface. Hence $U_1 = 1/0.897 = 1.115$ is a limiting value below which the flow always clings to the airfoil without separation. The corresponding value of C_L from Equation [1] is $C_L = 0.120$. Hence $C_{L\max} = 0.120$ is a lower limit which can always be reached for a flow without separation, no matter how small the Reynolds number. (The Reynolds number must, of course, be large enough so that the basic assumptions of the boundary-layer theory remain valid.) If the possibility of a turbulent boundary layer were excluded this would also be the largest possible value of $C_{L\max}$ according to our simplified assumptions for the phenomenon as they were outlined in section 2, "Outline of the Basic Procedure." However, the assumptions already discussed regarding the transition to and behavior of a turbulent boundary layer alter the matter completely, and require a more elaborate analysis to obtain values of $C_{L\max}$. In the following paragraph we shall outline the calculations leading to the determination of these values.

We remember that for a given degree of turbulence in the external flow there exists a definite value of R_{δ_c}. For a fixed value of U_1, (i.e., of C_L) $R_{\delta_s} = R_{\delta_c}$ is a limiting case such that this C_L is just achieved. If R is decreased R_{δ_s} is decreased and the assumed value of C_L is not reached. Conversely, if R is increased the assumed C_L will always be realized. In order to determine this limiting case we actually calculate $R_{\delta_s}/\sqrt{R}$ as a function of C_L from Equations [1] and [3]. Then putting R_{δ_s} equal to a series of numerical values R_{δ_c}, we obtain a corresponding series of functions $R(C_L)$ or $C_L(R)$. The curves of C_L vs. R determined in this way are really curves of $C_{L\max}$ vs. R for various degrees of external turbulence, since each curve gives a definite value of R above which a given value of C_L will always be reached and below which it can never be reached. The results of such a calculation are plotted in Fig. 4, the regions in which a given C_L can be attained being indicated by the cross-hatching at one side of the curves. The values of R_{δ_c} are given by the numbers without subscripts and represent various degrees of external turbulence. Thus 1000 corresponds to a high degree of turbulence and 10,000 to a low degree.

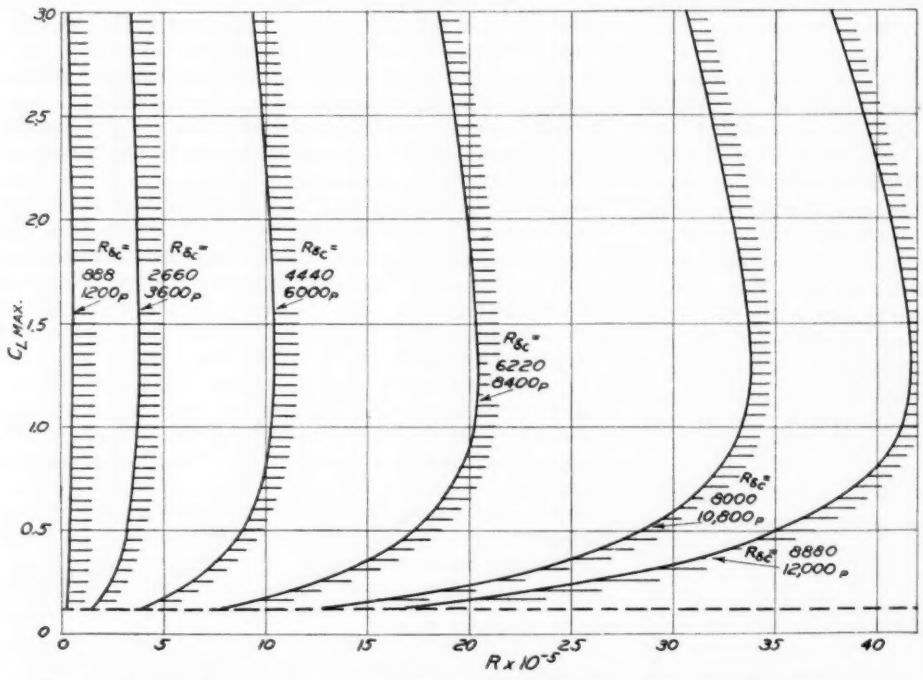

FIG. 4 $C_{L\max}$ AS FUNCTION OF R AND EXTERNAL TURBULENCE FOR THE SINGLE-ROOF PROFILE

The results are very interesting in that they reveal an extremely large dependence of $C_{L\max}$ on external turbulence, so that our basic conception of the phenomenon is, to some extent, justified. However, the dependence on Reynolds' number is entirely unsatisfactory and indicates that the single-roof profile is too crude an approximation to yield any quantitative results.

Before passing on to the refinements required to improve the results, it might be mentioned that the familiar Pohlhausen boundary-layer method may be simply applied to this case. The boundary-layer analysis has already been given by the authors (loc. cit.), and the application of the results to the $C_{L\max}$ problem follows exactly the procedure just discussed. It is easy to see that identically the same curves are obtained as followed from our boundary-layer theory. The only difference is that the values of R_{δ_c} associated with a particular curve are different for the two methods. The Pohlhausen values have been included in Fig. 4 with a subscript $(\ )_p$.

5—THE "DOUBLE-ROOF" PROFILE AND ITS APPLICATION TO THE MAXIMUM-LIFT ANALYSIS OF THE N.A.C.A. 2412 AIRFOIL

It has been mentioned above that the authors' boundary-layer analysis has been developed for external flows such that $U^2(\varphi)$ may be represented by one or two polynomials in φ. The single-roof profile corresponds to one of the simplest cases of such a flow, i.e., U^2 is given by a single linear function of φ. In the present section we consider a somewhat more complicated case in which U^2 is given by two linear functions of φ, and there is an

actual stagnation point at the origin of x. Such a flow may be described analytically as follows:

$$\left.\begin{aligned} &\text{For } 0 \leqslant \varphi \leqslant \varphi_1; \quad U^2 = b\varphi \\ &\text{For } \varphi_1 \leqslant \varphi; \quad U^2 = (b+\beta)\,\varphi_1 - \beta\varphi \end{aligned}\right\} \ldots\ldots [4]$$

where φ_1 is a fixed value of φ, and b and β are positive constants. We call such a velocity distribution a "double-roof" profile, the reason being obvious from Fig. 5 where the profile has been represented schematically by the full lines.

For our present purposes we need only two results of the boundary-layer analysis, which, just as in the case of the single-roof profile, are the position of the laminar separation point φ_s, and the value of the boundary-layer Reynolds number at this point, R_{δ_s}. From section 14 of the earlier paper we obtain

$$\left.\begin{aligned} \varphi_s &= \varphi_1\,\theta_s \\ R_{\delta_s}/\sqrt{R} &= \sqrt{\varphi_1}\,\Delta^*_s \end{aligned}\right\} \ldots\ldots [5]$$

where θ_s and Δ^*_s are given in Fig. 6 as functions of $r = \beta/b$. The necessary laminar boundary-layer characteristics are accordingly given in terms of the double-roof parameters φ_1 and r.

The experimental investigation of the maximum-lift phenomenon mentioned at the beginning of the paper dealt with wind-tunnel measurements on a rectangular airfoil with the N.A.C.A.

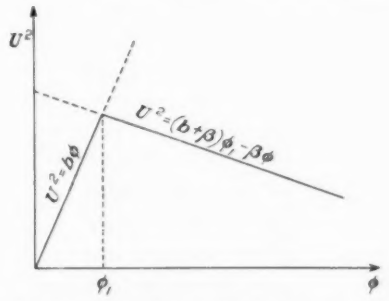

FIG. 5 THE DOUBLE-ROOF PROFILE, $U^2 = U^2(\varphi)$

2412 profile whose ordinates and general characteristics have previously been published.[6] It was natural, therefore, to base the theoretical considerations upon the same airfoil section, which is a very efficient one of moderate thickness and small camber. Accordingly the potential-velocity distribution over the 2412 profile for a two-dimensional flow was calculated by Theodorsen's method for a series of values of airfoil-lift coefficient C_L. Since Theodorsen's method has been described in extenso[7] no details of the calculation will be repeated here. For the problem in hand we require only the velocity distribution over the upper surface of the airfoil for some distance downstream of the separation point. The functions $U^2(\varphi)$ determined for this region are given by the full lines of Fig. 7, corresponding to calculated values of C_L from 0.8 to 1.8. For the sake of clearness the curves are not extended quite down to the stagnation point origin.

It appears that all of the functions $U^2(\varphi)$ given in Fig. 7 can be fairly satisfactorily approximated by double-roof profiles for the region upstream from the separation point. Such an approximation seems to be especially justified by the fact that the main purpose of the investigation is to discover the physical bases for the variation of $C_{L\max}$ with turbulence and Reynolds' number rather than to deduce the precise quantitative dependence of

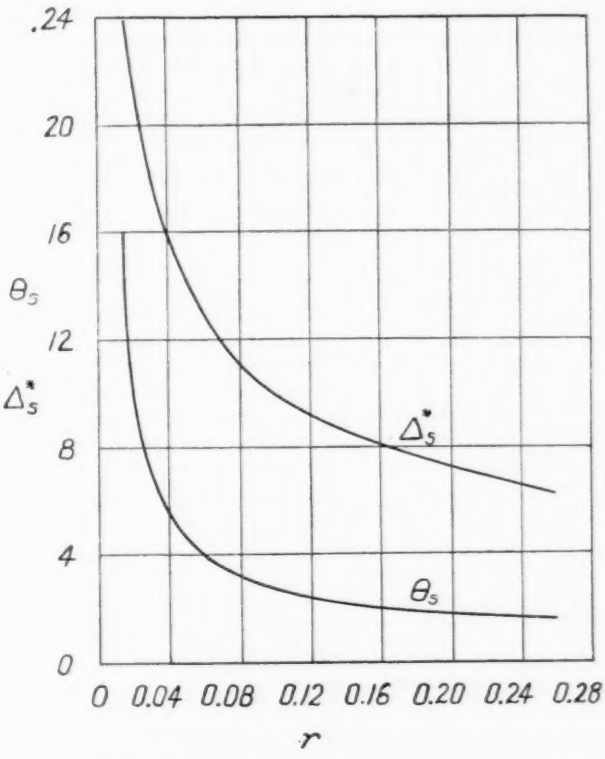

FIG. 6 GENERAL FUNCTIONS GIVING SEPARATION-POINT CHARACTERISTICS FOR THE DOUBLE-ROOF PROFILE

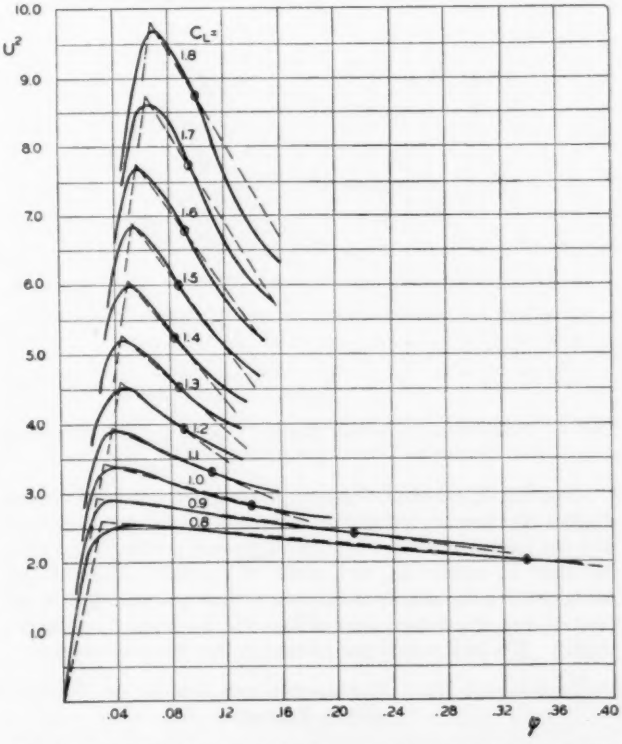

FIG. 7 POTENTIAL-VELOCITY DISTRIBUTIONS FOR THE N.A.C.A. 2412 AIRFOIL, AND THE APPROXIMATING DOUBLE-ROOF PROFILES

$C_{L\max}$ on these two variables. All the further calculations are, therefore, made with double-roof profiles chosen so as to approximate as closely as possible to the solid curves of Fig. 7 between the stagnation and separation points. The double-roof profiles are indicated by the dotted lines in Fig. 7, and the oval symbols give the values of φ_s as determined from Equations [5] and Fig. 6. $R_{\delta_s}/\sqrt{R}$, obtained in the same way, is plotted as a function of C_L in Fig. 8.

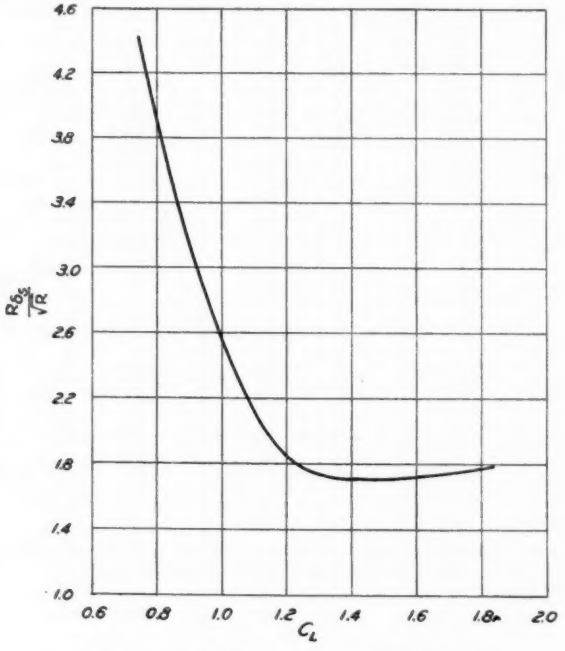

FIG. 8 $R_{\delta_s}/\sqrt{R}$ VS. C_L FOR 2412 AIRFOIL

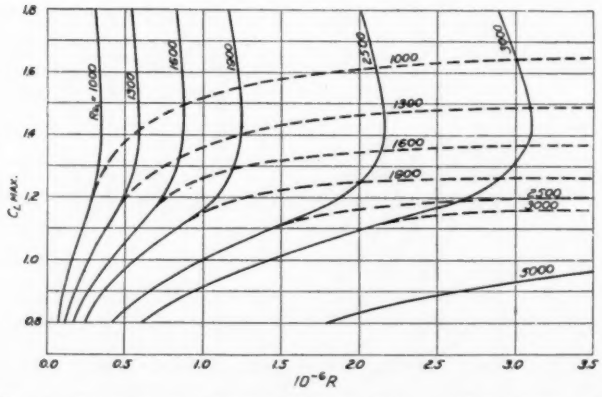

FIG. 9 THEORETICAL CURVES GIVING $C_{L\max}$ AS FUNCTION OF R AND EXTERNAL TURBULENCE FOR THE 2412 AIRFOIL

Using Fig. 8, curves of $C_{L\max}$ vs. R are determined for various degrees of external turbulence in exactly the same manner as was outlined in section 4 for the single-roof profile. It is only necessary to equate R_{δ_s} to a series of constant values of R_{δ_c}, characterizing the degree of external turbulence, and then to determine from Fig. 8 the values of R at which a given C_L is just attained. The final results are plotted in Fig. 9 as solid curves.

6—COMPARISON WITH EXPERIMENT AND REGION OF VALIDITY OF THE THEORY

Before discussing the theoretical results, it will be desirable to consider the results of the experimental investigation of the same problem, to which reference has already been made. As has been stated, the experiments were performed in the Guggenheim Aeronautics Laboratory at the California Institute of Technology wind tunnel on a model of the N.A.C.A. 2412 airfoil. In order to obtain a series of degrees of turbulence a wire grid or screen was placed at a number of distances upstream from the model. With the grid close to the model the degree of turbulence at the airfoil is high, with the grid far away the turbulence is low. At each position of the grid measurements were taken at from six to fifteen different Reynolds' numbers. The results as far as $C_{L\max}$ is concerned are presented in Fig. 10. Each curve corresponds to a grid position, i.e., to a given degree of turbulence and therefore

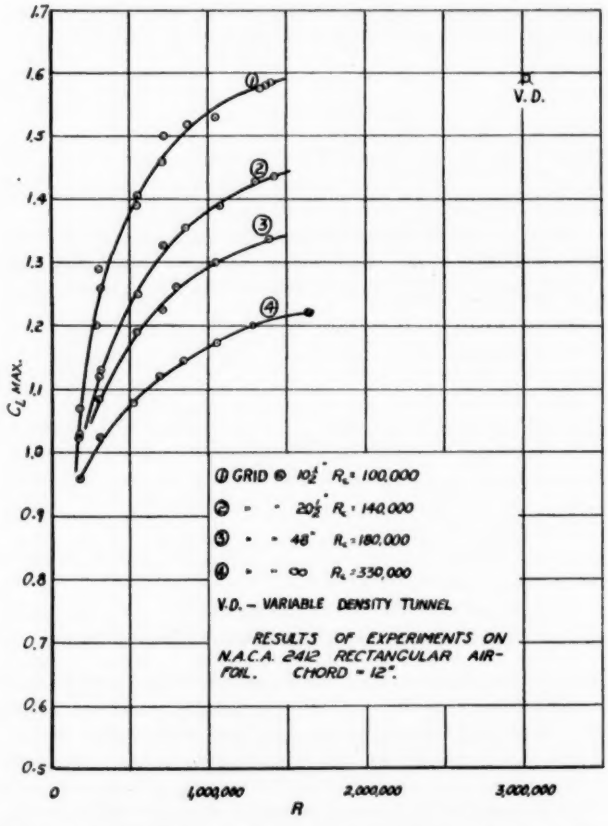

FIG. 10 EXPERIMENTAL CURVES CORRESPONDING TO FIG. 9, TAKEN FROM WIND-TUNNEL TESTS ON A 2412 AIRFOIL

to a definite value of R_{δ_c}. In other words, the curves are directly comparable with those of Fig. 9. It should be noted that the degree of turbulence for each of the curves of Fig. 10 has been indicated by giving the critical Reynolds number R_c, at which a sphere has a drag coefficient[8] $C_D = 0.3$. Just as in the case of R_{δ_c}, a low value of R_c corresponds to a high degree of turbulence and vice versa.

Comparing the two figures we see that for $C_{L\max} \leq 1.2$ the theoretical curves for $1000 \leq R_{\delta_c} \leq 1900$ exhibit a very similar character to the four experimental curves. In this region then the theory gives a qualitatively satisfactory prediction of the dependence of $C_{L\max}$ on R and free-stream turbulence. Above $C_L = 1.2$ the theory diverges more and more from experiment. In section 2 it was pointed out that one of the basic assumptions of the theory, namely, that of the non-existence of a separation

[8] "Effect of Turbulence in Wind Tunnel Measurements," by H. L. Dryden and A. M. Kuethe. N.A.C.A. Technical Report No. 342, 1929.

point for a turbulent boundary layer, implied that infinitely large values of $C_{L_{max}}$ could theoretically be reached. It is obvious that this assumption represents a considerable oversimplification, since it is quite certain that somewhat similar laws actually govern the separation of laminar and turbulent boundary layers. The portions of the theoretical curves which are concave upward or have negative slopes are believed to be in error because of this oversimplification in the basic assumptions of the theory. The dotted curves of Fig. 9 represent the authors' judgment as to the nature of the curves which would be obtained if it were possible to determine the separation-point characteristics of a turbulent boundary layer. The relatively low values of R_{δ_e} for the theoretical curves which furnish the best approximation to the experimental results are not at all surprising when the unstable nature of boundary-layer profiles near a separation point is remembered.

The comparatively good agreement between the theoretical and experimental curves for moderate values of $C_{L_{max}}$ and R, as well as the quite understandable nature of the discrepancies at higher values of $C_{L_{max}}$ or R, seems to demonstrate conclusively that the physical basis for the large dependence of $C_{L_{max}}$ on these two parameters, in the normal wind-tunnel range, has been correctly determined as residing in a kind of contest between the separation point of the laminar boundary layer over the upper surface of an airfoil, and the transition point to a turbulent boundary-layer régime. This is physically the same picture as was used by Prandtl many years ago to explain the phenomenon of the sudden drop in the drag coefficient of a sphere and its dependence on external turbulence and Reynolds' number.

The extension of the present theory so as to obtain valid results for large values of $C_{L_{max}}$ and of R depends upon the development and application of a satisfactory theory of the separation characteristics of a turbulent boundary layer, and such a theory has, unfortunately, not yet been developed. The discussion of airfoils whose lift does not increase approximately linearly with angle of attack up to the stall would appear to present still further difficulties, but such airfoils are not widely used in practice and consequently are not of great immediate interest.[9]

7—Conclusions

In the present paper the application of a laminar boundary-layer theory previously developed by the authors to the problem of the maximum-lift coefficient of airfoils is discussed. The calculations are carried through in detail for a first approximation, called a single-roof profile, to the potential velocity distribution over the upper surface of an airfoil. The results indicate a large variation in $C_{L_{max}}$ with turbulence but the quantitative dependence on Reynolds' number and turbulence is not satisfactory. The calculations are then repeated for a so-called double-roof profile which approximates to the flow over the upper surface of an N.A.C.A. 2412 airfoil. These results are compared with those obtained from an experimental investigation on the same airfoil. The agreement is considered to indicate that for moderate values of R and $C_{L_{max}}$ the phenomenon of the maximum-lift coefficient is controlled by a contest between the separation and transition points of the laminar boundary layer over the nose of the airfoil. Finally, the difficulties involved in extending the theory to larger values of R, or to airfoils whose $C_{L_{max}}$ vs. α curves are not approximately linear up to the stall, are mentioned.

[9] It might be mentioned that, since the present paper was written, additional experiments have been made and reported by one of the present authors: ("Further Experiments on the Variation of the Maximum-Lift Coefficient With Turbulence and Reynolds' Number," by Clark B. Millikan, A.S.M.E. Transactions, November, 1934.) These experiments were made with rather unconventional airfoil profiles, whose lift curves had considerable curvature below the stall. As might have been expected, the dependence of $C_{L_{max}}$ on Reynolds' number and turbulence was quite different from that for conventional airfoils like the 2412. The desirability of an extension of the present theory in order to explain the maximum-lift phenomenon for some unconventional profiles has, therefore, been experimentally demonstrated.

Review of Recent Research Work in Fluid Mechanics

By Th. von KÁRMÁN,[1] W. BOLLAY,[2] and A. J. IPPEN[3]

I—General

DURING the period reviewed, the first volume of the "Aerodynamic Theory" edited by W. F. Durand (1)[4] was published. This contains a section on the mathematical aids necessary for hydrodynamics and aerodynamics by W. F. Durand, a presentation of general fluid dynamics by W. F. Durand and M. Munk, and an historical sketch of the development of aerodynamics by R. Giacomelli.

In the magazine *Science* W. F. Durand (2) gave an article on the development of our knowledge of fluid dynamics. A. Eula (3) discussed the present state and aims of the experimental research in aerodynamics. J. Bukowski (4) published a book on the experimental technique used in aerodynamics. The book of H. Richter (5) deals with the fundamental laws and the results of experimental research concerning flow in pipes. R. Spronck (6) discussed in a review the general ideas of hydraulics.

II—Potential Flow

W. G. Bickley (7) calculated the two-dimensional potential flow around obstacles of rectangular shape. L. Dufour (8) investigated the flow produced in a perfect fluid by movement of an elliptic cylinder. B. Caldonazzo (9) computed the non-stationary potential flow produced by movement, especially by oscillation of a plane airfoil and found some generalized form of the well-known Kutta-Joukowski theorem. B. Demtchenko (10) gave a proof of the validity of the latter theorem for compressible fluids; in his publication he referred to an old and practically unknown paper of M. A. Tchapliguine, in which this author successfully extended the Helmholtz-Kirchhoff method of free jets to compressible fluids. C. Jakob (11) applied Tchapliguine's method to calculation of the pressures acting on an obstacle in a compressible field.

III—Laminar Flow in Viscous Fluids

J. N. Goodier (12) pointed out the analogous character of the differential equation for the stream function in the case of the two-dimensional flow of a viscous fluid and of the equation for Airy's function and showed that this analogy can be used for practical solution of some problems. W. Müller (13) investigated the analogy between heat and vorticity transfer in the case of laminar motion. In a second paper W. Müller (14) investigated some problems of non-stationary flow in viscous fluids. H. Schlichting (15) calculated the expansion of a fluid jet in the case of laminar motion. M. Lippke (16) gave a contribution to the theory of capillar-tube viscosimeters, computing the necessary corrections (Hagenbach's correction). The case of the laminar flow of a viscous fluid entering into a pipe was treated by G. Vogelpohl (17). S. Goldstein and A. Fage (18) investigated theoretically and experimentally the case of two-dimensional steady flow of viscous fluid behind a solid body. They compared the results of the boundary-layer theory with those obtained by Filon's method and compared both calculations with the experiment. L. Loitzansky (19) gave a new method for calculation of the separation point in the case of a laminar boundary layer. H. J. Luckert (20) gave a method for integration of the equations of the laminar boundary layer, using the transformation of the equations by von Mises. N. A. V. Piercy and H. F. Winny (21) calculated the case of the laminar boundary layer along a flat plate comparing the results obtained by Oseen's method with those obtained by Prandtl and Blasius. C. W. Oseen (22) developed further his well-known method for integration of the equations of viscous fluids. T. E. Garstang (23) applied Oseen's approximate equations to the flow of a viscous fluid past spinning bodies. T. Gustafson (24) applied the theory of Oseen and Zeilon to the flow around a rotating cylinder, especially in the case of vanishing viscosity. H. B. Squire (25) investigated the problem of the flow of a fluid with vanishing viscosity ($\lim \nu \to 0$) from a general point of view, especially the location of the point of separation in this limiting case.

The stability of laminar flow in viscous fluid was the subject of a second paper by H. B. Squire (26). He investigated the stability of the flow between two parallel walls for three-dimensional disturbances and showed that this case can be reduced to that of two-dimensional disturbances.

IV—Turbulence and Skin Friction

Research on turbulence made considerable progress during the last year, the practical importance of the turbulence becoming more fully realized. As to publications giving a review of the state of knowledge of the subject and recent advances, the articles of von Kármán (27), Dryden (28), Fage (29), and Loitzansky (30) are to be mentioned. J. M. Burgers (31) continued his researches on the application of statistical methods to the turbulence problem. W. Tollmien (32) made a critical investigation on Burger's methods. G. D. Mattioli (33) advanced a new theory of the turbulent interchange with several applications; a paper by G. Dedebant, Ph. Schereschewsky, and Ph. Wehrle (34) deals with statistical similitude of the mechanism of turbulence.

Papers dealing with special problems in the field of turbulence: H. Kurzweg (35) and L. Schiller (36) investigated the origin of turbulent flow experimentally. H. Schlichting (37) continued his theoretical investigations of the development of turbulence in a boundary layer along a flat plate. J. L. Synge (38) investigated the statistics of heterogeneous fluids rotating between two cylinders. The articles of A. M. Kuethe and F. L. Wattendorf (39), H. Reichardt (40), A. Fage (41), L. F. G. Simmons and C. Salter (42), and H. C. H. Townend (43) contain chiefly measurements on the magnitude and distribution of turbulent velocity fluctuation. E. Förthmann (44) investigated the intermingling of turbulent flows with different velocities (theory of jets).

F. Wendt (45) published measurements on turbulent flow between rotating cylinders. A. Thom and S. R. Sengupta (46) measured the torque acting on a cylinder which rotates in an air stream. R. J. Cornish's (47) article deals with flow through fine eccentric clearances. R. Gregorig (48) measured the pressure drop in straight and curved pipes in the case of large Reynolds

[4] This and similar numbers in parentheses refer to the bibliography at the end of the paper.

number. O. Fritzsche and H. Richter (49) measured fluid resistance in curved pipes. Chr. Kentner (50) investigated losses, pressure and velocity distribution in a vertical bend. Also a paper of O. Miyagi (51) deals with flow in curved pipes. J. Allen (52) and P. Vuille (53) made investigations on laminar and turbulent flow in open channels. The latter investigated especially the influence of roughness. B. Randisi's paper (54) deals with the influence of turbulence on aerodynamic characteristics of airfoils; E. Ower and R. Warden (55) criticized the methods of producing artificial turbulence in wind tunnels. H. Bouasse (56) investigated the behavior of turbulent fluid jets in several cases, especially their reaction on obstacles. J. A. Kiebel (57) gave a review of the problem of atmospheric turbulence; H. Köhler (58) published special investigations on atmospheric turbulence; H. Ertel (59) investigated magnitude and distribution of the turbulent exchange coefficient in layers near the ground.

K. E. Schoenherr (60) reviewed the experimental material concerning the frictional resistance of flat surfaces moving through a fluid, gave a new formula for the skin-friction based on von Kármán's turbulence theory and contributed interesting experimental facts to the problem of the transition between laminar and turbulent boundary layer. A. Fage's paper (61) deals with the skin-friction of flat plates below the critical Reynolds number. L. Prandtl and H. Schlichting (62) published calculations on the skin friction of rough plates. F. Gebers (63) investigated the influence of the shape of plates on their frictional resistance. H. F. Nordström (64) discussed the problem of frictional resistance of ships.

V—Vortex Motion

Quite a number of articles published in the last year dealt with the generation and motion of vortex systems. F. Tricomi (65) tried to give a new illustrative interpretation of the curl in fluid motion. A. Masotti's paper (66) deals with the general theory of vortex-source combinations. W. B. Morton (67) and A. Kneschke (68) discussed the points of relative rest of parallel vortices. E. Laura (69), W. W. Golubeff (70), and L. S. Da Rios (71) discussed the stability of systems of vortex filaments in different arrangements. E. Paul (72) and A. Miyadzu (73) calculated the motion of a vortex near different boundaries. V. Garten's paper (74) deals with the motion of a vortex column with a cross-section of finite area. A. Ratib (75) calculated the effect of viscosity on eddies. N. W. Akimoff (76), O. Nomoto, Y. Sakagami, and Y. Fujii (77), and finally H. F. Winny (78) published experimental investigations on vortex systems; the latter investigated the interesting case of a vortex system generated behind a sphere moving in a fluid. J. Letzmann (79) made interesting theoretical and experimental investigations regarding atmospheric vortices.

VI—Waves and Ship Resistance

Miss M. L. Dubreil-Jacotin's paper (80) deals with the exact determination of the shape of waves with finite height. M. Schuler (81) investigated breaking of waterwaves on the ocean. A. Dimpker (82) investigated the waves produced by the oscillation of a plate on the water surface. E. G. Barrillon (83) gave an introduction to the theory of wave resistance which is worth mentioning. C. Wigley (84) gave a résumé of the advance made since 1930 in the calculation of the resistance and shape of waves generated by the motion of a ship. Th. von Kármán (85) reported at the Cambridge Congress on (*a*) the minimum wave-resistance of cylindrical bodies, (*b*) the resistance of a gliding plane surface of infinite span and (*c*) the resistance of a gliding plane surface with finite aspect ratio. T. H. Havelock (86) made new contributions to the calculation of wave resistance. L. Sretenskij's paper (87) deals with the problem of a flat plate gliding on the water surface. H. Wagner (88) gave a general review of the problems of gliding of bodies over a water surface. G. Weinblum (89) investigated the wave resistance of boats with rounded shapes. W. Graff (90) investigated the wake resistance of such shapes. S. Truscott (91) gave a description of the new high-speed towing basin for testing of seaplane float models. L. J. Coombes (92) presented data concerning wall interference, depth effect, and scale effect in tank tests on sea-plane models. H. E. Saunders and A. S. Pitoe (93) reported on full-scale trials of a destroyer, H. E. Saunders (94) on tests with three geometrically similar ship models, K. Helm (95) on model test of a river boat in flowing water. O. Schlichting (96) gave a method to compute resistance of boats moving in shallow water. W. G. A. Perring (97) made a theoretical study of the stability of sea-planes and compared his results with those from model tests. S. Watanabe (98) continued his investigations on impact of a plate on the water surface; this problem has some importance for the correct landing of floats.

VII—Cavitation

Interesting experimental investigations on the mechanism of cavitation have been carried out under Hunsaker (99) at M.I.T., especially the flow through a diffuser being investigated. D. Riabouchinsky (100) published some considerations on the possible types of fluid motion with cavitation. E. F. Eggert (101) reported at the meeting of the Society of Naval Architects and Marine Engineers on experiments carried out in the U. S. Experimental Model Basin on propeller cavitation. P. de Haller (102) and H. Schröter (103) dealt with the problem of corrosion by cavitation.

VIII—Lift and Drag

Streamlining, Wing Theory. E. V. Huntington (104) investigated the air resistance of falling spheres. S. Nikitine (105) made some observations on possible reduction of the drag of a body in a liquid by producing a layer of air at the surface of the body. F. Westendorp (106) published investigations on resistance of railway train models. R. H. Heald (107) investigated the aerodynamic characteristics of automobile models. Other papers about streamlining of automobiles by W. E. Lay (108), M. C. Horine, P. Altman, H. G. Winter, E. G. Reid, R. H. Upson (109), and M. Platt (110) are to be mentioned.

J. E. Garrick (111) calculated the theoretical pressure distribution for a large number of airfoils, using Theodorsen's method. F. Weinig (112) calculated the influence of the shape of the leading edge on the pressure distribution in the case of symmetrical profiles. A. Betz (113) and J. Stüper (114) tried to develop methods which would facilitate the computation of the real pressure distribution on airfoils, i.e., the correction of the theoretical pressure distribution due to viscosity and boundary layer. M. Biot (115) calculated the induced drag of a wing with dihedral. L. Poggi (116) improved the present method of calculation of auto-rotative moments, taking into account the velocities induced by the trailing vortices. He found that the deviations from the results obtained by the usual "strip-method" are in many cases quite considerable. A. Dufaure de Lajarte (117) investigated critically the usual applications of the first order wing theory to the calculation of the down-wash behind a wing. W. S. Diehl (118) gave semi-empirical formulas for the distribution of the lift of biplanes. Two papers of C. Ferrari (119) deal with the theory of the biplane with infinite aspect ratio. Another paper of the same author deals with the interference between wing and propeller (120); the same subject has been treated by C. Wieselsberger (121). J. Vladea (122) investigated the interference between wing and fuselage.

Considerable work has been done on the subject of wind-tunnel

interference. H. Glauert (123), and C. N. H. Lock and F. C. Johansen (124) investigated the wind-tunnel interference on the drag of symmetrical, and especially streamlined bodies. S. Tomotika (125) and others calculated the influence of walls on the lift of a flat plate. L. Sackmann (126) investigated experimentally the flow past an obstacle between parallel plates. E. Pistolesi (127) solved the problem of a wing traversing a free jet; the same problem has been treated according to a different method by Stüper (128). The interference of the wind tunnel with rectangular cross-section was the subject of several papers—various authors obtaining partly conflicting results. The results of Th. Theodorsen (129) and L. Rosenhead (130) are partly erroneous; Toussaint (131) gave the correct calculations. The cause of the discrepancy was revealed by P. de Haller (132) in a paper presented to the International Congress for Applied Mechanics in Cambridge. A critical summary of wind-tunnel interference on wings, bodies, and air-screws was given by H. Glauert (133). C. B. Millikan (134) and E. F. Relf (135) reported on the effects of turbulence on variations in maximum-lift coefficient. E. Weinel (136), F. Numachi and J. Masuko (137), F. Weinig (138), L. Lazzarino (139), and I. Lotz (140) published theoretical investigations on the flow through lattices. K. Frey (141) investigated experimentally the reduction of energy losses in channels by a system of vanes.

IX—Compressible Fluids

F. Frankl (142) investigated theoretically the flow of compressible fluids in the case in which the velocity of the flow is of the same order as the velocity of the sound. A. Huber (143) calculated the oscillations in pressure and velocity of an ideal compressible fluid moving in an elastic pipe. The mathematical investigations of J. A. Kiebel (144) deal with the theory of the motion of compressible fluids taking into account the influence of gravity. A. F. Zahm (145) discussed the dynamics of very rare fluids with applications to the conditions in the stratosphere.

X—Experimental Methods in Fluid Mechanics

In this section some papers are collected in which the authors presented more or less new methods for flow-investigations or discussed rules for model investigations.

A. Favre (146) suggested a new method for the exploration of the velocity around obstacles, using colored fluid filaments oscillating with a given frequency; if the velocity of the fluid is variable along a streamline the wave length of the filament will be variable and the velocity can be estimated by measuring the wave length.

Several papers discussed the problem of model rules based on considerations of mechanical similarity. The papers of V. Joukovsky and P. Wolkoff (147), F. Gutsche (148), E. Engel (149), M. Lelli (150), and G. De Marchi (151) are to be mentioned.

T. B. Abell (152) used the Hele-Shaw method for photographical study of a ship's wake, U. Schmieschek (153) suggested some improvements for illuminating liquid currents for flow pictures. A. Fage (154) obtained a new kind of flow picture by means of the ultra-microscope. D. Riabouchinsky and V. Volkovisky (155) reported on their new experimental technique for visualizing air flow especially close to solid boundaries and for high, partly supersonic velocities. C. Sadron (156) showed that the velocity distribution in optically active viscous fluids can be measured by observing the double refraction of light due to the shearing stress in the liquid.

Several papers deal with improvements of the hot-wire anemometers for measuring magnitude and directions of the air velocities. M. Ziegler (157), J. Ulsamer (158), and T. C. Sen (159) tried to use the hot-wire for measuring the velocity of air and of water and found a method which is feasible at least for low velocities. L. S. Marks (160) suggested a new kind of pitot-tube suitable for the determination of the magnitude and direction of the velocity of a fluid. A. Égal (161) devised a thermoelectric method of measuring liquid flow by having one end of the thermocouple near the inside walls of a tube, the other end on the outside under a controlled temperature. When there is a fluid flow, a difference of potential arises which can be calibrated against the velocity. T. Sasaki and T. Yosida (162) designed speedometers for airplanes which indicate true air-speed independent of the altitude. A. H. Fette (163) reported on the use of a rotating chamber for a study of pressure and velocity distribution in rotating channels.

XI—Some Special Problems

In this section some special problems of technical interest are mentioned. A paper of M. Muskat (164) deals with the flow of a compressible fluid through porous media with application to the motion of natural gas through the earth. The paper of W. Hurst (165) deals with a similar problem. C. G. J. Vreedenburgh and O. Stevens (166) studied the flow of fluids through porous media by an electrodynamic analogy.

The paper of E. Tyler (167) deals with the instability of liquid jets taking into account the capillarity of the fluid. A. Weinstein (168) extended the theory of discontinuous potential motion introducing the effect of capillarity in the boundary connection of the free surface.

Several papers deal with the problem of motion of sediment in water and air. W. Barth (169) studied the motion of dust particles in pumps and ventilators. E. Kilb (170) calculated the upward speed of an air current necessary to support a hailstone. M. Biot (172) gave the equations of movement of a fluid holding particles in suspension. A. Schoklitsch (173) and M. P. O'Bryan (174) deal with the problem of bedload carried by water in channels and rivers.

A Review of Recent Papers on Plasticity

By A. NADAI,[1] EAST PITTSBURGH, PA.

AT THE International Congress for Applied Mechanics, held in Cambridge, England, in July, 1934, G. I. Taylor, Yarrow Professor of the Royal Society, reported on some further remarkable results of his own investigations on the mechanism of plastic deformation of crystals.[2] While the geometrical manner in which the permanent deformations in a single crystal occur, particularly in the metals having crystals of the regular system, is well understood and has been carefully analyzed in a number of recent investigations by Elam and Taylor, Gough, E. Schmid, Polanyi, and others, there remained much to be learned concerning the mechanical laws on which are dependent some of the fundamental strength properties of the metal crystals. It is known that certain important strength properties, such as the yield stress or the stress at rupture, could not, until recently, be quantitatively predicted from the data of the lattices. Other characteristic phenomena, such as the "strain-hardening" of a soft single crystal, could not be understood; that is, it was not clear why the stress required to produce further plastic distortion must increase quite considerably while the lattice structure apparently remains intact. Only during the last few years has more light been thrown on some of these interesting properties of metal crystals and it is only since giving up the concept of the perfect crystal that the consequences of the various effects of certain deviations from the regular arrangements of the lattice elements, and of other "imperfections" of the crystal lattice structure, have been considered.

From the investigations aforementioned, it has been found that if one plots the component of the shearing stress in the direction of slip (τ) as a function of the shear strain (γ), measured as the ratio of the relative slip of two parallel planes of slip to the distance between them, the stress-strain curve [$\tau = f(\gamma)$] thus obtained at a given temperature is a unique curve for single crystals of a given metal. The first yield stress at which the plastic deformations start is practically negligible when compared to the shearing stresses (τ) in later stages of the deformation of a single crystal. For aluminum, copper, gold, and iron single crystals, these curves resemble ordinary parabolas.

In his recent papers,[2] G. I. Taylor makes some very remarkable suggestions about the mechanism of slip, describing here for the first time a comparatively simple mechanism which not only enables him to obtain strain-hardening in a lattice structure but also enables him, from a few simple assumptions, to predict quantitatively the parabolic shape of the strain-hardening curve of a single crystal.

Until recently the phenomenon of gliding was generally regarded as a simple shift of one portion of the crystal relative to the other by the multiple of the atomic distances. It seems that the great theoretical difficulties which arise from this assumption are completely eliminated when, according to Taylor, the slipping is considered to occur not simultaneously over all the atoms of a slip plane but over a limited region. Thus he is led to introduce certain "dislocations." These are "traveling" disturbances in the regular arrangement of the elements of the lattice (of the regular spacing of the atoms) starting from a center and moving along lattice planes. It is assumed that in two adjacent layers of atoms, one layer contains, over a certain given length, one more unit cell of the lattice than the adjoining layer. Such a disturbance produces "potential hills and valleys" in the interatomic force fields and makes it possible for one atom whose connections are the weakest to jump over its potential barrier into a vacant place, its movement being actuated by the thermal agitation of the lattice structure. Thus the effect of the temperature is brought into play by allowing for "Platzwechsel" ("jumps" from one position of equilibrium of an atom to a neighboring and more stable position). This effect has also been suggested by Richard Becker and L. Prandtl in an investigation of the plasticity of amorphous materials and an investigation of elastic hysteresis, respectively. The stress distribution near a single dislocation is compared with a known case of inherent stress in an elastic body, slotted along a plane. A length L, the mean width of small subdivisions (blocks) of the crystal, is introduced. The boundaries of the crystal are supposed to be impervious to the movement of these dislocations. If τ designates the shearing-stress component, γ the plastic shear strain, G the modulus of rigidity, λ the lattice constant (distance of two atoms in the slip plane along the direction of slip), the mechanism just indicated leads to the following relation:

$$\tau = \text{const.}\, G \sqrt{\gamma} \sqrt{\frac{\lambda}{L}}$$

This expression is remarkable because of its extreme simplicity. Thus, the stress-strain curve [$\tau = f(\gamma)$] for a single crystal is a parabola.

Professor Taylor compares this formula with results of tests conducted by himself, and also by Schmid and Boas, on single aluminum crystals at various temperatures and finds that various conclusions agree very well. He also applies the theory to a non-metallic substance, namely, rock salt. For the length L, which corresponds somewhat to the free path of a dislocation, his estimates are furnishing values of the order of 10^{-4} cm for rock salt. This is the same order of magnitude as the mean dimensions of the "blocks" of the mosaic structure assumed by various recent investigators of the strength properties of crystals.

Tensile Tests Under High Velocities of Deformation[3]

The effect of the speed of deformation on the yield stress when ductile metals are stretched is becoming more and more important, especially in tests where either the temperatures are raised or where the stretching velocities increase rapidly, such as in impact tests. Brinkmann investigates the effect of the speed of deformation for copper at normal temperatures. Using a piezo-electric strain gage and an oscillograph, he compares the yield stresses in tensile impact tests made with copper bars with slow tests made under ordinary speeds of deformation. For the same amounts of elongation, the yield stresses increase as the logarithms of the speeds of deformation, when tests made under varying velocities are compared. The range of these velocities varied as 1 to 10^6.

Recent Progress in the Design of Helical Springs[4]

The law of elasticity is utilized by engineers daily in all kinds of force-measuring devices and instruments. Spring scales have been built for 300 years, since the time of Robert Hooke. It is only recently, however, that efforts to perfect the spring scales have succeeded to an extent that they become instruments with a known range of accuracy. As spring scales and helical springs are universally used as the most convenient and simplest force-measuring devices in testing materials and in scientific laboratory practice, it was thought that it is perhaps of interest to engineers to know that recent important advances have been made by mechanical analysis which have improved the accuracy of the springs and reduced their inherent defects to a negligible minimum.

M. F. Sayre,[5] A. V. de Forest,[6] R. B. Wasson,[7] in cooperation with George E. Chatillon & Sons, have developed an improved spring material which, within limits, is not sensitive to temperature changes. Inasmuch as the modulus of elasticity and of rigidity is a function of the temperature, the calibration constant of a spring depends on the temperature to which it is exposed. With the use of this spring material, complete elimination or reduction to very small amounts has been effected in defects such as elastic after-effects, hysteresis, creep, differential variation in length due to difference of the thermal-expansion coefficients of the spring and the other parts of the balance, untwisting of the helical spring causing a deviation of the straight-line characteristics, etc.

Alloys such as Invar and Elinvar (36 per cent nickel, 12 per cent chromium, 1 per cent silicon, and the rest iron) which are known to have a low thermal-expansion coefficient have other disadvantages which seem to have been overcome in the new "isoelastic alloy" recently suggested. A number of formerly disturbing secondary defects also have been eliminated successfully by a clever arrangement of the ends of the helical coils, by using flat rectangles as wire cross-sections, by combining two helical springs of equal length but wound in opposite senses, by attaching the springs to flexible arms which will correct for the non-linear characteristics of coiled springs, etc.

The details and comparative test results about the elastic properties of various materials may be found in various recent papers[8] by M. F. Sayre and in the paper by M. F. Sayre and A. V. de Forest just mentioned.

On Spiral Cracks of Fuji Volcano[9]

An interesting observation has been made by geophysicists in Japan. S. Fujiwhara finds when mapping the locations of the secondary cones situated on the slope of the great volcanic cone of the Fujiyama, that they are arranged along regular curves of spiral shape. It is known that around the impression of a stamp pressed into soft steel, logarithmical spirals become visible as slip lines on the polished surface of the specimen. The theory of the equilibrium of loose materials (sand) can be based on the properties of these surfaces of slip, which in the case where solid friction is present, will intersect each other at given angles. Systems of logarithmical spirals, as slip lines around a cavity with pressure acting within it in a radial direction, are known also to occur in loose materials. Although the mechanical conditions in the interior of a large volcano consisting partly of ejected ashes and partly of the solidified and slowly cooling magmatic materials cannot be supposed to be of a simple nature, it is remarkable enough that the secondary craters on the slope of the main cone are situated along such regular spiral lines as described by Fujiwhara, indicating that the stress field in the interior of a volcano is radially symmetrical.

Design Data

It is important that the data contained in technical papers be made readily available to designing engineers. In order to satisfy these needs of industry, this section of the Journal will include a concise presentation of data and information drawn chiefly from papers previously published by the Applied Mechanics Division of The American Society of Mechanical Engineers.

The data are prepared by a subcommittee of the Applied Mechanics Division on strength of materials (R. E. Peterson, chairman), under the general guidance of S. Timoshenko.

The first contribution, which follows, is by A. M. Wahl and treats of the subject of spring design. Future articles will cover various phases of mechanics, dealing in the first instance with questions on the strength of materials.

Helical Compression and Tension Springs

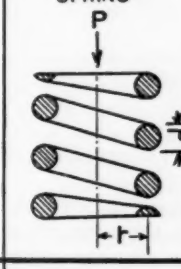
By A. M. WAHL,[1] EAST PITTSBURGH, PA.

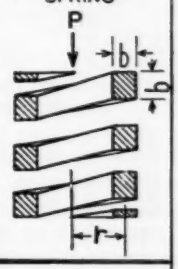
Formulas

FORMULAS for calculating load, deflection, and stress in helical compression and tension springs of round or square wire are given in Table 1. Based on recent research,[2] the stress formulas differ from those ordinarily used in that they are multiplied by a factor K (Fig. 1) dependent on the ratio c of mean coil diameter to wire diameter (or side of square cross-section). This factor takes into account the stress increase due to curvature and direct shear, and, though derived primarily for round-wire springs, also gives sufficiently accurate results for most practical purposes when applied to square-wire springs,[3] the formulas for which are based on St. Venant's theory.[4]

The formulas given in Table 1 do not apply accurately to open-wound springs when the pitch angle is in excess of 12 deg but these are not often used in practice.[5]

Inactive Turns





The number of inactive turns in springs depends on the design of the end coils. For the usual design of compression spring (Fig. 2) where the end turns are set up and ground as indicated, an approximation will be had by assuming one inactive turn at each end of the springs. The number of active turns then will equal the total number of turns (including the tapered end turns), minus two. For the shape of tension spring shown in Fig. 3 the number of active turns will be slightly greater than the nominal number in the body of the spring, due to the additional deflection of the hooks at the ends.

Unless supported laterally, compression springs should not have too great a length as otherwise undesirable buckling effects may occur.[6]

Charts for Helical Tension or Compression Springs

The charts shown in Figs. 4 and 5 are given to enable the designer to make a rapid computation of load and deflection in

TABLE 1 FORMULAS—HELICAL TENSION AND COMPRESSION SPRINGS

	ROUND WIRE SPRING	SQUARE WIRE SPRING
		
f = TOTAL DEFLECTION OF SPRING	$f = \frac{64Pr^3n}{Gd^4}$	$f = \frac{44.5Pr^3n}{Gb^4}$
S = MAXIMUM SHEARING STRESS	$S = \frac{16PrK}{\pi d^3}$	$S = \frac{4.80PrK}{b^3}$
P = LOAD ON SPRING	$P = \frac{\pi d^3 S}{16rK}$	$P = \frac{Sb^3}{4.80rK}$

IN ALL CASES $K = \frac{4C-1}{4C-4} + \frac{.615}{C}$

WHERE $C = \frac{2r}{d}$ FOR ROUND WIRE, $C = \frac{2r}{b}$ FOR SQUARE WIRE

VALUES OF K MAY BE TAKEN FROM THE CURVE OF FIG. 1
G = TORSIONAL MODULUS OF ELASTICITY IN LBS/SQ. IN.
n = NUMBER OF ACTIVE TURNS

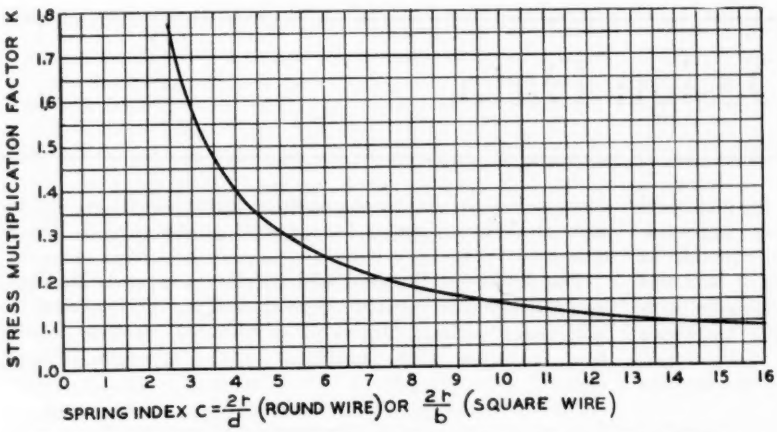

FIG. 1 CURVE FOR COMPUTING STRESS-MULTIPLICATION FACTOR K—HELICAL TENSION OR COMPRESSION SPRINGS

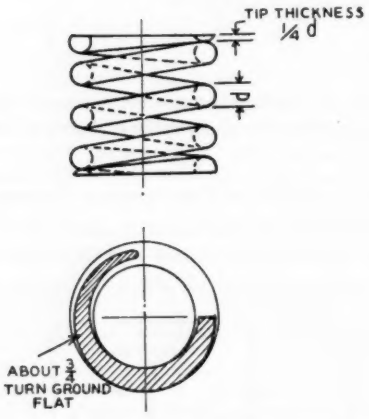

FIG. 2 COMPRESSION SPRING—ENDS SET UP AND GROUND

FIG. 3 TENSION SPRING

helical tension or compression springs of round wire when the working stress is known.

To compute the *load* on the spring, the factor C_1 is first obtained from Fig. 4 by finding the intersection of the vertical ordinate representing the wire diameter and the curve representing the outside coil diameter OD (see example and dotted line on chart). Interpolation may be necessary for intermediate dimensions. The permissible load P on the spring is found by multiplying C_1 by the ratio $\frac{S}{10{,}000}$ where S is the allowable working stress (in shear). (The load P may also be considered as that which will produce a maximum shearing stress S in the spring.)

To compute the total *deflection* of the spring, the factor C_2 is likewise obtained from Fig. 5, from the wire diameter and outside coil diameter (see example). The curves shown are based on a torsion modulus G = 11,400,000 lb per sq in., which approximates the actual value for ordinary carbon-steel springs. Hence, for such springs, to find the total deflection f, the value of C_2 thus found is multiplied by the ratio $\frac{S}{10{,}000}$ and by the number of active turns n (S being the working stress in the spring at a deflection f). The deflection *per active turn* is given by $C_2 \times \frac{S}{10{,}000}$. In cases where the torsion modulus G is different from 11,400,000 (as for alloy-steel, phosphor-bronze, or severely cold-worked springs), the value of f thus computed must be multiplied by the ratio $\frac{11{,}400{,}000}{G}$. Thus in the example given in the chart where f = 0.094 in., if the torsion modulus G is actually 10,000,000 lb per sq in., the total deflection f will be $\frac{11{,}400{,}000}{10{,}000{,}000} \times 0.094 = 0.107$ in.

It should be noted that there will always be a small inaccuracy in reading the charts, particularly if interpolations are made. Hence,

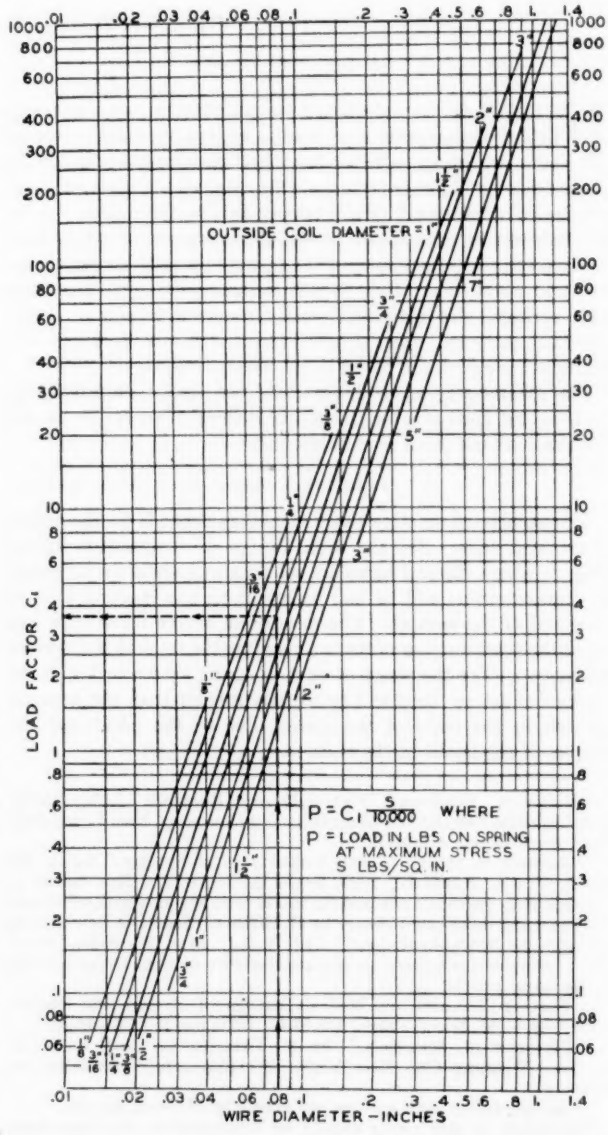

FIG. 4 (*Right*) CHART FOR VALUES OF LOAD FACTOR C_1—HELICAL COMPRESSION OR TENSION SPRINGS OF ROUND WIRE

(Example: Wire diam = 0.080 in.; S = 50,000 lb per sq in.; outside coil diam = ½ in. From chart C_1 = 3.6—see dotted line—$P = 3.6 \frac{50{,}000}{10{,}000}$ = 18 lb.)

if high accuracy is necessary, springs should be calculated by using the formulas of Table 1. It should be noted, however, that because of unavoidable commercial variations in coil diameter and wire size, the actual deflection of the spring will usually deviate by several per cent from that calculated, except where special precautions in manufacturing have been taken.

For calculating *square-wire springs*, the charts of Figs. 4 and 5 may also be used. It is merely necessary to calculate the load and deflection at the given working stress for the corresponding round-wire spring, i.e., one having the same outside coil diameter, number of turns, and a wire diameter equal to the side of the square cross-section. The loads thus found are multiplied by the factor 1.06 and the deflections by 0.738 to find those for the square-wire spring at the given stress.

Working Stresses

The choice of working stresses for springs depends on a great many factors, among which are: (1) kind and quality of material used, (2) decarburization of the surface layers which may act to reduce the fatigue strength of the material to less than one-half that with the surface layers ground off,[7] (3) condition of surface, i.e., whether rough or smooth, (4) stress range to which the spring is subjected, a smaller stress range permitting a higher working stress,[8] (5) number of repetitions of load, a considerably higher working stress being allowable if the load is applied only a few times, and (6) corrosion effects, which operate to greatly reduce spring life.

If failure of the spring is a serious matter, and the spring is under severe operating conditions, the working stress should be lower than is otherwise advisable, while special precautions in manufacturing and inspection may be necessary. In such cases it is well to consult the spring manufacturer, particularly since the fatigue strength of springs may be considerably increased by the use of recent developments in spring materials and manufacturing technique.

TABLE 2 ALLOWABLE WORKING STRESSES[6] IN SHEAR—HELICAL COMPRESSION OR TENSION SPRINGS (STEEL)

Diameter of wire, inches	Severe service	Average service	Light service
Up to 0.085	60,000	75,000	93,000
Above 0.085 to 0.185	55,000	69,000	85,000
Above 0.185 to 0.320	48,000	60,000	74,000
Above 0.320 to 0.530	42,000	52,000	65,000
Above 0.530 to 0.970	36,000	45,000	56,000
Above 0.970 to 1.5	32,000	40,000	50,000

[6] Used as a basis for design by Westinghouse Elec. & Mfg. Co.

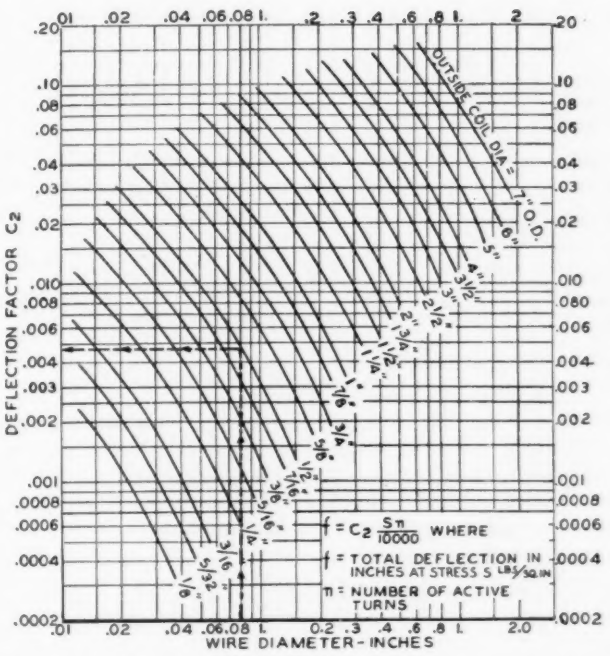

FIG. 5 CHART FOR VALUES OF DEFLECTION FACTOR C_2—HELICAL COMPRESSION OR TENSION SPRINGS OF ROUND WIRE

(Example: Wire diam = 0.080 in.; S = 50,000 lb per sq in.; G = 11,400,000 lb per sq in.; outside coil diam = ½ in.; n = 4. From chart—see dotted line—C_2 = 0.0047; $f = 0.0047 \left(\frac{50,000}{10,000}\right)$; 4 = 0.094 in. Values given are for a torsion modulus G = 11,400,000 lb per sq in. For values of G different from 11,400,000 lb per sq in., multiply f thus calculated by 11,400,000 ÷ G.)

For phosphor-bronze springs 50 per cent of these values are used. It will be noted that lower stresses are used for the larger wire sizes and for severe service, in accordance with practical experience. In most cases, these stresses will be found to be conservative, and often may be increased at the discretion of the engineer, particularly if higher grade materials and manufacturing technique are employed.

A more rational method of determining working stress in general,[9] which may be applied to spring design, will appear later.

[7] See, for example, Special Report No. 5, Department of Scientific and Industrial Research, "Endurance of Spring Steel Plates Under Repetition of Reversed Bending Stress," by G. A. Hankins, published by H. M. Stationery Office, London.

[8] Some fatigue-test data are given in "Permissible Stress Range for Small Helical Springs," by F. P. Zimmerli, Univ. of Mich., Eng. Res. Bulletin No. 26.

[9] A discussion of this is given in "General Considerations in Designing Mechanical Springs," by A. M. Wahl, *Machine Design*, May, 1930.

Book Reviews

Thermodynamics

TECHNISCHE THERMODYNAMIK. By W. Nusselt. V.D.I. Sammlung Göschen. No. 1084. Berlin/Leipzig, 1934. Walter de Gruyter and Co., G. E. Stechert and Co. Cloth, 4 × 6 in., 144 pages, 65 figs., $0.60.

REVIEWED BY JOHN A. GOFF[1]

THE author of this small book must be commended on a presentation of the elements of engineering thermodynamics which is at once singularly brief and comprehensive. A short introduction sketches the historical background of the subject. There follows a development of the First Law which is characterized by careful distinction between external work of expansion and what the author calls "technical work," that is, external work derived from steady fluid flow. An appreciation of the fundamental difference between reversible and irreversible processes is essential to a clear understanding of the laws of thermodynamics and especially of its application to such technically important processes as heat transfer, combustion, and fluid friction. The author pays careful attention to this difference throughout the book. His development of the Second Law is particularly clear and understandable.

Of special interest is the chapter on properties of vapors with, of course, special reference to the properties of steam. The more important "characteristic equations" for superheated steam that have been proposed, from that of Zeuner (1867) to that of Keyes and Smith (1934), are listed chronologically with brief comments on their salient features. In this way, the application of thermodynamics to the study of higher and higher pressures and temperatures is emphasized. The book recommends itself to readers of German—practicing engineers and students alike.

Theory of Elasticity

THEORY OF ELASTICITY. By S. Timoshenko. Engineering Societies Monograph Series. McGraw-Hill Book Company, Inc., New York, 1934. Cloth, 5¾ × 9 in., 416 pp., 203 figs., $5.

REVIEWED BY D. L. HOLL[2]

THIS is one of the series known as "Engineering Societies Monographs," published under the joint auspices of four national engineering societies whose aim ". . . is to make accessible to many users of engineering textbooks information which otherwise would be long delayed in reaching more than a few in the wide domains of engineering." In this respect the service rendered by the societies is greatly appreciated and the timely appearance of a book on elasticity by an eminent and productive author is being welcomed by an increasing number of interested readers. It provides a mine of important methods and applications of general theory to technical problems for which the elementary methods of strength of materials is inadequate. It helps bridge the gap between the common run of elementary texts on strength of materials and the more comprehensive treatises.

By introducing elementary but fundamental solutions of two-dimensional problems, the author inductively builds more complex solutions by the principle of superposition of stress systems and arrives at the disk problem under general loads (p. 107) and to the problem of a finite force or couple in an infinite plate (p. 111). Many readers would have been pleased to have the author introduce the Weighardt-Westergaard "slab-slice" analogy of Airy's stress function, and others would prefer that additional treatment be given the Fourier integral solutions of the differential equation of stress. The latter method is briefly mentioned in the von Kármán-Seewald problem where the new and interesting result is found that the deflection of the central line of a long beam is wave shaped outside of a region of high concentration of loading. An even greater technique in employing the superposition principle is given in chapter 11 where the problems of three-dimensional axially symmetrical systems furnish the solutions of Boussinesq and of thick circular plates in terms of rational integral functions of the coordinates (Legendre polynomials).

Extended expositions of photoelastic examination of stresses (with an adequate treatment of multiply connected regions, p. 115 et seq.), of soap-film determinations for the torsion and flexure problems, and for the invariant sum of principal stresses $\sigma_1 + \sigma_2$, are given in considerable detail. Important place is given to the minimizing method of Ritz to two-dimensional stress problems, to the torsion and flexure of prismatical bars. Complex function theory, curvilinear coordinates, geometrical inversion of stress systems, solid zonal harmonics, elliptic integrals (Hertz's contact pressures), Bessel's functions (circular cylinder stresses on p. 352), and the solution of differential equations by the method of successive approximations (twist of thick circular ring problem) indicate the type of analytical tools employed in the analysis. Such a formidable array of mathematics causes one to question the author's statement in the preface that . . . "The mathematical derivations . . . do not require more mathematical knowledge than is given in engineering schools." In justice to the author the reviewer hastens to add that much of the foregoing, although of practical importance, is relegated to small type and may be omitted during the first reading.

Apart from the general theory of stress and strain and the compatibility equations, the chapters on two-dimensional problems, torsion, flexure of prisms, and axially symmetrical stress problems receive the greater share of attention. The chapters on strain-energy methods, complex variable (fine print), and wave propagation are treated less extensively.

The symbolism used follows largely that of the German writers. There is an occasional use of Lame's constant λ. The author uses ν for Poisson's ratio. Among other symbols in use for this constant are μ, σ, and m. Some standard list of symbols ought to be urged upon writers of forthcoming articles to this journal and perhaps the list of notations in this book with some changes might serve the purpose. It might be well to adopt a single symbol for stresses instead of σ and τ. On pages 64 and 86 appears $\epsilon_{r\vartheta}$ for $\gamma_{r\vartheta}$. This may indicate a natural tendency to be consistent in the symbols used for strains. While it is not incorrect to use τ_{xy} and τ_{yx} interchangeably, many of the figures (e.g.,

[1] Professor of Thermodynamics, University of Illinois, Urbana, Ill., Assoc-Mem. A.S.M.E.

[2] Professor of Mathematics, Iowa State College, Ames, Iowa.

113 and 129) and equations would satisfy the meticulous reader if the defining convention of page 4 were followed more closely.

Apart from a few minor errors, such as a misspelled name, p. 134, the editing of the context material, the statement of the problems with the hypotheses, the importance given significant results (260 numbered equations), the listing of nearly 400 references, half of which are in foreign languages, and the general tenor of the book, all invoke our high esteem for the courage of the author in so ably accomplishing the purpose in presenting this difficult subject.

Mechanical Vibrations

MECHANICAL VIBRATIONS. By J. P. Den Hartog. McGraw Hill Book Co., Inc., New York, 1934. Cloth, $5^3/_4 \times 8^1/_2$ in., 390 pp., 282 figs., $5.

TORSIONAL VIBRATION. By W. A. Tuplin, M.Sc. John Wiley & Sons, Inc., New York, N. Y., 1934. Cloth, $5^1/_2 \times 8^1/_2$ in., 320 pp., 89 figs., $5.50.

REVIEWED BY C. R. SODERBERG[3]

THE literature dealing with the problem of vibrations in engineering has grown rapidly in recent years and a new contribution to the field can no longer claim the unique position it might have found a few years ago.

Professor Den Hartog's book is apparently written with a definite object of creating a textbook for a specific course on the subject. This object has somewhat limited the scope of the book but it has also furnished the incentive for an unusually clear and lucid presentation, free from obscure mathematical complexity.

As pointed out by the author in the preface, much of the subject material of this book was collected in connection with lectures presented to the Design School of the Westinghouse Company in East Pittsburgh, Pa. This has given the subject material a relevance to practical engineering problems which is not often found in textbooks of this type.

Chapter 1 deals with certain kinematic and mathematical preliminaries. In chapter 2 a discussion of problems of one degree of freedom is presented. This presentation includes many useful examples of mechanical systems and practical applications to vibration problems in engineering. A section of particular interest is the one on "vibration isolation." Chapter 3 continues with a discussion of problems with two degrees of freedom and again the application to the problem of vibration absorption forms an important part of the subject matter. Chapter 4 covers problems with many degrees of freedom and problems of vibrations of continuous bodies. Chapter 5 is devoted to problems encountered in reciprocating machinery. Chapter 6 gives a discussion of problems peculiar to rotating machinery. It covers the more common problems, such as balancing of rigid rotors and critical speeds in rotors. It also includes many special problems of outstanding interest such as the vibrations in frames of electric machines, vibrations in propeller blades, vibrations in turbine blades, and similar subjects. Chapter 7 is devoted to the subject of self-excited vibrations. This class of vibration phenomena has assumed a very important place in practical engineering work during recent years. The treatment given in this chapter is more complete than most of those available in the engineering literature, and it will be warmly welcomed by many engineers who have encountered this type of problem in their practical work. The simple and direct treatment of this rather complicated problem given in this chapter represents one of the outstanding features of the book. The last chapter is devoted to the problem of non-linear vibrations.

The book illustrates an admirable style of engineering literature and it deserves to be ranked among the valuable contributions within its field.

Mr. Tuplin's book also belongs to a field in which the literature has received many valuable contributions in recent years. However, this book cannot honestly be referred to in the superlative terms which are natural in the case of Professor Den Hartog's book. The subject is well covered, but the organization of the material and its presentation do not evoke the same praise. The book is free from the more obstruse mathematics so difficult to avoid in this subject, but in many instances the ingenuity of treatment required to compensate for this omission is lacking.

Chapter 1 covers the usual kinematical and dynamical preliminaries. Chapter 2 is headed "Equivalent Dynamical Systems" and describes the process by which actual systems with their more complicated details are reduced to abstract systems ready for the mathematical treatment. In this chapter the author has brought together a considerable amount of practical information which will be welcomed by designers working in this field. Chapters 3 and 4 present this mathematical treatment for two- and three-mass systems. Chapter 5 is inserted at this point to present the problem of the solution of high-order algebraic equations. In chapters 6, 7, and 8 the treatment is extended to problems of multi-mass systems where trial-and-error methods of computation are required. Certain aspects of the treatment in these three chapters, particularly those cases found under the heading "Special Cases of Multi-Mass Systems" are certain to be welcomed as clearing up many points which are not usually clear to the average designer. Chapter 9 discusses the subject of harmonic analysis, while chapter 10 covers the determination of vibration amplitudes and torques, without damping, for systems treated in previous chapters from the point of view of natural frequencies. Chapter 11 covers the subject of frequencies of impressed torques occurring in the usual combinations of reciprocating machinery. Chapter 12 presents a discussion of the problem of vibration amplitudes and torques at resonance under the influence of damping, while chapter 13 presents a discussion of vibration dampers and vibration absorbers. In chapter 14 a discussion is given of the problems introduced by torque fluctuations in geared systems. Chapter 15 presents a specialized treatment for cases involving vibrations of continuous bodies. Chapter 16 is devoted to a discussion of couplings. Chapter 17 presents a discussion of impact problems in torsion systems. This is a subject treated very briefly in earlier literature and embraces many problems of real importance. It is to be regretted that the author did not find it possible to enlarge further on this important subject. Chapter 18 is a brief discussion of the torsiograph and the general problem of measurement of torsional vibrations.

It is difficult to avoid a comparison of the book under review with some of the earlier contributions in this field which, more or less justifiably, may be referred to as classics. "Die Berechnung der Drehschwingungen" by Heinrich Holzer, published in 1921, which incidentally was not included in the bibliography of Mr. Tuplin's book, is perhaps the most important of these classics. The reviewer has been able to find very little material of fundamental significance in the present contribution which cannot be found in the book by Holzer. In many instances, the question may be raised whether Holzer's treatment is not to be preferred. It has been found difficult, for example, to improve upon the method for trial-and-error numerical computations given by Holzer. The method presented in the book under review does not appear to qualify as an exception to this rule.

[3] Manager, Turbine Engineering Dept., Westinghouse Electric & Manufacturing Co., South Philadelphia, Pa. Mem. A.S.M.E.

It would be unfair, on the other hand, to present Mr. Tuplin's book as entirely devoid of merit. The above criticism concerns chiefly the formal aspect of the arrangement of the material, which is after all to a large extent a matter of personal taste. The English literature on this subject is somewhat meager, and the book assumes a more important place in existing literature if books in German are excluded. The reader will find practically all of the relevant material collected in English for the first time in one treatise. It will serve as an excellent practical guide to the subject. With this purpose in mind, the book is well worthy of recommendation.

General Solution for Rectangular Plates

Eine Lösung für die Berechnung der biegsamen rechteckigen Platten. (A General Solution for Rectangular Plates.) By S. Iguchi. Hokkaido Imperial University, Sapporo, Japan. Julius Springer, Berlin, 1933. Paper, $6^1/_2 \times 9^1/_2$ in., 56 pp., 3 charts, 13 figs., 5 rm.

Reviewed by A. Nadai[4]

THIS recent contribution to literature on the bending theory of flat elastic plates deals with the case of a rectangular plate of a non-isotropic material. Investigations with regard to such plates by engineers are rather recent, although a few previous attempts have been made to find similar solutions for bodies having certain types of crystal symmetry by physicists (by Voldemar Voigt and by others). Probably the first papers devoted to the bending theory of a non-isotropic rectangular plate are those by M. T. Huber (1923), who introduced for the elastic constants a certain symmetry condition which he calls "orthotropy." This leads to the assumption that the bending rigidity of the rectangular plate is different in the two directions parallel to the sides of the rectangle. The case has some interest because of the bending of reinforced-concrete slabs when the steel bars are inserted parallel to both sides of the rectangle. The particular solutions used by Iguchi for the rectangle do not completely satisfy the partial differential equation of the anisotropic plate (this is a linear equation of the fourth order with constant coefficients); however, they are constructed so that the boundary conditions on all four sides of the rectangle can be satisfied exactly in at least nine different cases, among which are contained the practically important cases of straight-line support without constraint and fixed (built-in) edges. Mixed cases of boundary conditions also are included. The terms contain a product of a function of x with a function of y. Each function contains an algebraic portion consisting of four power terms $C_0 + C_1x + C_2x^2 + C_3x^3$ and a sine term $C_4 \sin nx$. The coefficients are first adjusted to satisfy the boundary conditions and the remaining undetermined constants are chosen so that the double sum in which they appear expresses the distribution of the given load $p = f(x,y)$ in its totality. Iguchi can thus solve practically all important cases of loading and of boundary conditions, including also those of an isotropic rectangular plate.

The detail work of determining the constants in the double series seems considerable, although Iguchi has worked out a few cases, such as those of the rectangular plate with the conditions

(w = deflection) $w = 0$ and $\frac{\partial^2 w}{\partial y^2} = 0$ along an edge x = const.

and also the case of a plate with clamped edges, and he is able to reduce the double sums by adding up one portion of the double sums into a simple series. An example of a rectangular plate on elastic foundation is also worked out. The idea of combining a few power terms in x or y with simple sine terms seems attractive, as it enables Iguchi to use one and the same general form of a certain double series in practically all cases of boundary conditions. Also partially loaded plates are treated. Tables and a few graphs are given.

Hydromechanics

Hydromechanik—Volume 2. By W. Kaufmann. Julius Springer, Berlin, 1934. Cloth, 6 × 9 in., 293 pp., 210 figs., 18 rm.

Reviewed by J. P. Den Hartog[5]

THE first volume of this work appeared some three years ago and dealt with the theoretical basis of hydro- and aerodynamics in the usual manner. The second volume is much more useful and interesting, as it gives a review of practically all applications that have been made of the theory so far, and at the same time is understandable in itself, without reference to the first volume. The topics dealt with include ship resistance, ground-water flow, and lubrication, as well as the more usual applications of hydro- and aerodynamics, so that necessarily the treatment is not exhaustive. However, the important elements of each of these subjects are discussed fully, and a large number of quotations from the literature are given which makes the book very valuable as a reference.

Volume 2 is divided into nine chapters, of which the first deals with weir and nozzle coefficients. For most of these a theoretical calculation is given by means of Helmholtz' two-dimensional free-jet method. In this manner the streamline picture as well as some of the coefficients can be found. The second chapter is on pipe flow, including the latest results on rough pipes, and the new theories of Prandtl and von Kármán on the turbulent velocity distribution. A rather complete discussion is given on the flow and pressure losses in pipe bends, elbows, and sudden expansions. Also the surges in pipe lines and penstocks are treated. The third chapter is on open channels, especially on St. Venant's theory of the distinction between "torrents" and "rivers" with the related phenomena of hydraulic jump. In the next chapter wave motion and the phenomenon of tides are discussed briefly, while the fifth chapter takes up viscous flow and bearing lubrication. The following chapter is the largest in the book, and deals with the usual applications of such a treatise as lift and drag of airplanes, including biplanes, airfoil theory and conformal mapping, propellers, fans, and hydraulic turbines. Chapter 8 gives the elements of ship resistance in a few pages, while the concluding chapter, written by O. Flachsbart, contains a discussion of wind pressure on buildings with as much experimental data as is available at the present time.

Distributed Gravity and Temperature Loading in Two-Dimensional Elasticity Replaced by Boundary Pressures and Dislocations

By M. A. BIOT,[1] CAMBRIDGE, MASS.

This paper deals with two-dimensional stresses due to an important class of body forces. Gravity stresses and temperature stresses are produced by body forces of the type investigated.

In the case of gravity stresses it is proved that these stresses may be calculated by forgetting about the action of gravity on the body and applying instead only external normal loads that are identical with a hydrostatic pressure.

This opens the possibility of applying photoelastic tests to the measurement of gravity stresses; a model loaded by these external pressures would show an isochromatic fringe pattern identical with the one that would appear in a model submitted to an intense gravity field. In Fig. 5 is shown the type of external loading to be applied to find the gravity stresses in a dam.

In the case of two-dimensional temperature stress in cylindrical bodies where the temperature distribution is stationary, it is shown that a distinction is to be made between solid and hollow cylinders. For a solid cylinder the only thermal stress component appearing is an axial stress acting perpendicularly to cross-sectional planes. In other words, the solid cylinder expands freely along the cross-sectional planes. For a hollow cylinder a general stress condition may arise which is identical with the stresses produced by cutting a longitudinal slit of a certain small width in the cylinder wall and sticking together the two sides of the slit (dislocation).

GENERAL THEORY

THE EQUATIONS of equilibrium of a rectangular element in two-dimensional elasticity with body forces are

$$\left.\begin{aligned}\frac{\partial \sigma_x}{\partial x}+\frac{\partial \tau_{xy}}{\partial y}+X=0\\ \frac{\partial \sigma_y}{\partial y}+\frac{\partial \tau_{xy}}{\partial x}+Y=0\end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [1]$$

If the body forces are derived from a function V such that

$$\left.\begin{aligned}X=-\frac{\partial V}{\partial x}\\ Y=-\frac{\partial V}{\partial y}\end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [2]$$

the equations of equilibrium become

$$\left.\begin{aligned}\frac{\partial}{\partial x}(\sigma_x-V)+\frac{\partial \tau_{xy}}{\partial y}=0\\ \frac{\partial}{\partial y}(\sigma_y-V)+\frac{\partial \tau_{xy}}{\partial x}=0\end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [3]$$

They are satisfied by introducing a "stress function" ϕ

$$\left.\begin{aligned}\sigma_x-V=\frac{\partial^2\phi}{\partial y^2}\\ \sigma_y-V=\frac{\partial^2\phi}{\partial x^2}\\ \tau_{xy}=-\frac{\partial^2\phi}{\partial x\,\partial y}\end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [4]$$

By using Hooke's law for either plane stress or plane strain distribution and the compatibility equation of the strain components, we find an equation of the type[2]

$$\frac{\partial^4\phi}{\partial x^4}+2\frac{\partial^4\phi}{\partial x^2\partial y^2}+\frac{\partial^4\phi}{\partial y^4}=C\left(\frac{\partial^2 V}{\partial x^2}+\frac{\partial^2 V}{\partial y^2}\right) \quad \ldots\ldots [5]$$

In case the function V satisfies the Laplace equation (potential function)

$$\frac{\partial^2 V}{\partial x^2}+\frac{\partial^2 V}{\partial y^2}=0 \quad \ldots\ldots\ldots\ldots [6]$$

Equation [5] reduces to

$$\frac{\partial^4\phi}{\partial x^4}+2\frac{\partial^4\phi}{\partial x^2\partial y^2}+\frac{\partial^4\phi}{\partial y^4}=0 \quad \ldots\ldots\ldots\ldots [7]$$

In this case the stress function ϕ satisfies the same equation as if there were no body forces. How will the boundary conditions be expressed?

Let l, m be the cosines of the normal direction to the boundary with the x and y directions and $\bar{X}$, $\bar{Y}$ the components of the force applied per unit length at the boundary. We have

$$\bar{X}=l\sigma_x+m\tau_{xy}$$

$$\bar{Y}=m\sigma_y+l\tau_{xy}$$

---

[1] Instructor in Applied Mechanics, Graduate School of Engineering, Harvard University. Dr. Biot received at the University of Louvain, Belgium, the degrees of Mining Engineer, 1929, Electrical Engineer, 1930, and Sc.D. in physics and mathematics, 1931. From 1931 to 1933 he was research fellow of the C.R.B. Educational Foundation at the California Institute of Technology under Prof. Th. von Kármán and at the University of Michigan under Prof. S. Timoshenko. In 1932 he received a Ph.D. from the California Institute of Technology. During 1933–1934, as a research associate of the National Research Council of Belgium, he visited the technical schools of Delft and Zürich and the Universities of Göttingen and Cambridge. He has held his present position at Harvard since September, 1934.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until August 10, 1935, for publication at a later date.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] Equation [5] is derived in "Theory of Elasticity," by S. Timoshenko, McGraw-Hill, 1934, pp. 25–26.

or from Equations [4]

$$\left.\begin{aligned}\overline{X} - lV &= l\frac{\partial^2\phi}{\partial y^2} - m\frac{\partial^2\phi}{\partial x\,\partial y}\\ \overline{Y} - mV &= m\frac{\partial^2\phi}{\partial x^2} - l\frac{\partial^2\phi}{\partial x\,\partial y}\end{aligned}\right\} \quad \ldots\ldots\ldots [8]$$

Hence the problem of finding the stresses produced by the body force loading X, Y just considered and the boundary loading

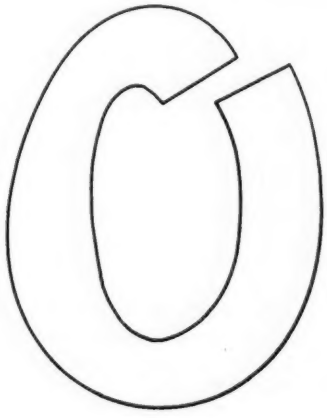

FIG. 1

$\overline{X}$ $\overline{Y}$ reduces to the solution of Equation [7] with the boundary conditions [8]. This is equivalent to finding a stress distribution

$$\left.\begin{aligned}\sigma'_x &= \frac{\partial^2\phi}{\partial y^2}\\ \sigma'_y &= \frac{\partial^2\phi}{\partial x^2}\\ \tau'_{xy} &= -\frac{\partial^2\phi}{\partial x\,\partial y}\end{aligned}\right\} \quad \ldots\ldots\ldots [9]$$

produced in the same body free from body forces but submitted to boundary forces $\overline{X} - lV$ and $\overline{Y} - mV$. This boundary load is the actual load ($\overline{X}$, $\overline{Y}$) plus a normal hydrostatic pressure equal to V.

Apparently, according to Equations [4], the actual stress in the body is the difference of the stresses σ'_x, σ'_y, τ'_{xy}, and the hydrostatic-pressure distribution represented by the potential V.

However, a very important distinction is to be made; *the statement is true only for body forces such that no singularity of the potential V occurs within the body or in any holes if the latter is hollow.*

This distinction arises from the fact that the displacements and rotations of the medium, corresponding to the hydrostatic-stress condition $p = V$ might not be single-valued, i.e., they might not take the same value when we come back to the same point after following a closed path around a singularity of the function V. In order to get single-valued displacements and rotations, we must superpose to the hydrostatic-stress condition a so-called "dislocation"-stress distribution. The meaning of a dislocation is illustrated by the following example. Take a hollow circular cylinder and cut it open by a longitudinal slit of small width (Fig. 8). We shall produce stresses in this cylinder by sticking together the two sides of the slit. This type of deformation is called a dislocation. The stress condition thus generated is not derived from the application of external forces. In our case, for instance, if the body is of hollow shape, let us cut it open so as to connect the inside with the outside. If we now assume that a stress equal to a hydrostatic pressure $p = V$ is distributed in the body, the two edges of the cut may or may not stick together (Fig. 1). If they do separate, we produce dislocation stresses by sticking them together again. As we shall see, the amount of dislocation is determined by two displacements u, v, of one face of the slit with respect to the other and by relative rotation. It can be easily calculated from the value of the potential V.

Let us call ϵ the two-dimensional linear extension of the body produced by the hydrostatic-stress distribution $p = V$. We have

$$\epsilon = -kp = -kV \quad \ldots\ldots\ldots [10]$$

The corresponding displacements of the material satisfy the equations:

$$\left.\begin{aligned}\frac{\partial u}{\partial x} &= \epsilon\\ \frac{\partial v}{\partial y} &= \epsilon\\ \frac{\partial v}{\partial x} + \frac{\partial u}{\partial y} &= 0\\ \frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} &= 2\omega\end{aligned}\right\} \quad \ldots\ldots\ldots [11]$$

where ω is the rotation.

We deduce:

$$\left.\begin{aligned}\frac{\partial u}{\partial y} &= -\omega\\ \frac{\partial v}{\partial x} &= \omega\\ \frac{\partial \epsilon}{\partial y} &= -\frac{\partial \omega}{\partial x}\\ \frac{\partial \epsilon}{\partial x} &= \frac{\partial \omega}{\partial y}\end{aligned}\right\} \quad \ldots\ldots\ldots [12]$$

From these equations we see that ϵ and ω are conjugate harmonic functions so that

$$Z(z) = \epsilon + i\omega$$

is an analytic function of $z = x + yi$. The increase of rotation on a closed circuit is

$$\omega_1 - \omega_2 = \oint -\frac{\partial \epsilon}{\partial y}\,dx + \frac{\partial \epsilon}{\partial x}\,dy \quad \ldots\ldots\ldots [13]$$

It is a quantity proportional to the flux of the body force through this closed path.

The displacement is given by

$$u + iv = \int Z dz \quad \ldots\ldots\ldots [14]$$

so that the increase in displacement on a closed circuit is given by the contour integral

$$\oint Z dz$$

This proves that the two edges of the slit show a relative displacement only when the function Z or, what amounts to the same thing, the potential V has a singularity inside the contour. Yet if the singularity is such that the flux of body force produced by it is zero and if $\oint Z dz = 0$ no dislocation stress has to be introduced.

DISTRIBUTED GRAVITY LOADING

One of the most important cases of potential field body force is the case of the gravity field acting upon a body of uniform density.

Body Resting Under Its Own Weight

Let us consider a two-dimensional elastic body B (Fig. 2) resting under its own weight on a plane surface S. Taking the vertical y axis as positive and calling δ the specific weight of the material, the body force is expressed as $X = 0$, and $Y = -\delta$, and the corresponding potential is $V = \delta y$. This potential presents no singularity whatever, hence no dislocation stress will have to be considered.

The stress condition $\sigma'_x, \sigma'_y, \tau'_{xy}$ of the above theory is produced by considering a hydrostatic boundary loading due to a pressure

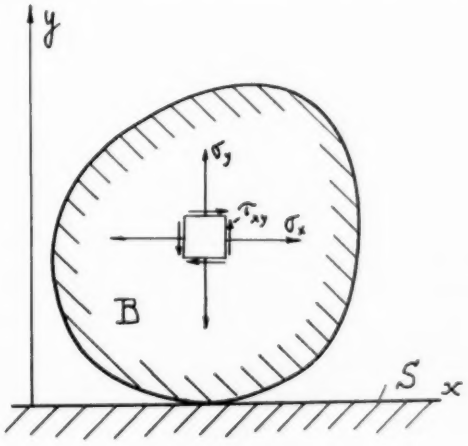

Fig. 2

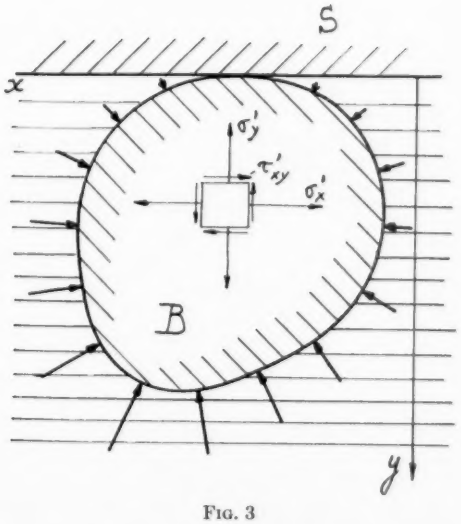

Fig. 3

$p = V = \delta y$. This loading may be applied by turning the body upside down, free from gravity, into a liquid of specific mass δ which is under the action of gravity (Fig. 3). The hydrostatic pressure $p = \delta y$ pushes it upward against the surface S with the same force as would its own weight in Fig. 2 and the contact pressures will be approximately realized. Due to this hydrostatic boundary loading a stress distribution $\sigma'_x, \sigma'_y, \tau'_{xy}$ is produced in the body B. Since no dislocation stresses have to be introduced, the value of the actual stress $\sigma_x, \sigma_y, \tau_{xy}$ due to distributed gravity loading in Fig. 2 is the difference of the stress $\sigma'_x, \sigma'_y, \tau'_{xy}$, and a pressure $p = y\delta$. Hence

$$\sigma_x = \sigma'_x + y\delta$$
$$\sigma_y = \sigma'_y + y\delta$$
$$\tau_{xy} = \tau'_{xy}$$

Gravity Stress in a Dam

Another example as shown in Fig. 4 is given by the case of a dam which is stressed under its own weight, the specific mass of which is δ.

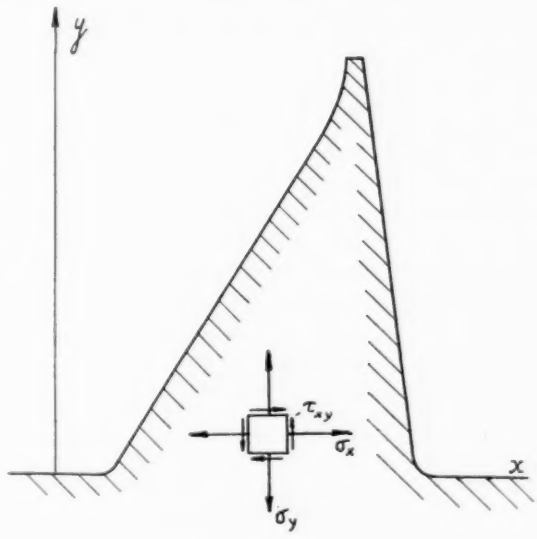

Fig. 4

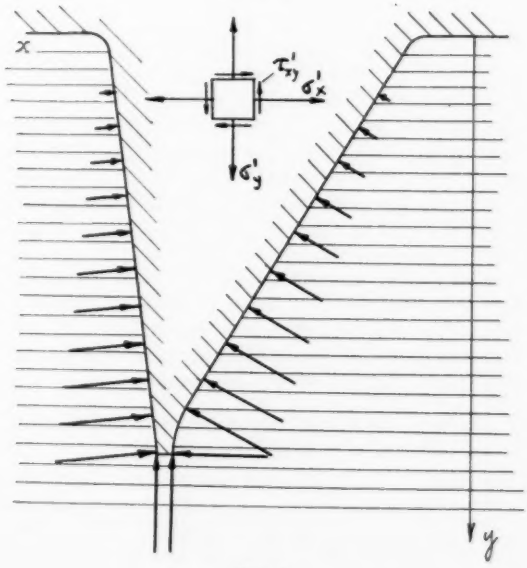

Fig. 5

The stress distribution $\sigma'_x, \sigma'_y, \tau'_{xy}$ is produced in a dam having no gravity and immersed upside down in a liquid of specific mass δ which is under the action of gravity, Fig. 5. This liquid exerts upon the dam hydrostatic boundary pressure as indicated in this figure. The actual stress $\sigma_x, \sigma_y, \tau_{xy}$ in the dam resting under its own weight as in Fig. 4, is given by the difference of the stresses $\sigma'_x, \sigma'_y, \tau'_{xy}$ and a pressure distribution $p = \delta y$. Therefore

$$\sigma_x = \sigma'_x + \delta y$$
$$\sigma_y = \sigma'_y + \delta y$$
$$\tau = \tau'_{xy}$$

Photoelastic Measurement of Gravity Stresses

The present theory shows that gravity stresses may be measured by photoelasticity by applying the proper boundary loading. The fringe pattern and the value of the maximum shear will be the same as if a magnified gravity were acting on the model.

Body With Holes

An interesting property is introduced by considering a body, with a hole, under the action of gravity. This equivalence of hydrostatic boundary loading applies provided we fill the

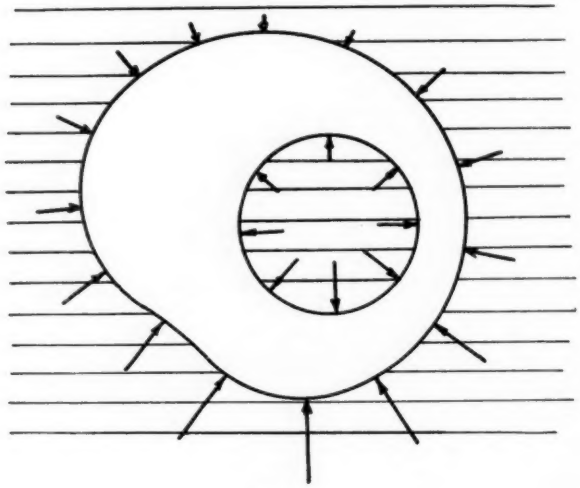

Fig. 6

hole with the weighing liquid and establish a connection between the liquid inside of the hole and the liquid outside such that both are in hydrostatic equilibrium (Fig. 6).

A theorem developed by J. H. Michell[3] shows that for a hollow two-dimensional body the stresses depend on the elasticity constants if the forces applied to the hole have a resultant different from zero. In this case the forces applied to the boundary of the hole have a resultant equal to the weight of the fluid inside. From this we conclude the following theorem:

In a solid two-dimensional homogeneous body the stresses due to gravity do not depend on the elasticity constants of the material; they do, however, in general for a body with holes.

It is important to keep this in mind when investigating gravity stresses by photoelasticity or with gelatine models.

TWO-DIMENSIONAL TEMPERATURE STRESSES RESULTING FROM STEADY HEAT FLOW

We consider a two-dimensional temperature distribution in an arbitrary cylindrical body; the temperature is supposed to be the same along any straight line parallel with the boundary. We also assume that the temperature has reached a state of equilibrium, i.e., the temperature may be different from point to point but remains constant at a given point and has any given arbitrary distribution along the boundary of the cross-section S (Fig. 7). As we know, in such a case the temperature θ in a cross-sectional plane (x, y) must satisfy the potential equation,

$$\frac{\partial^2\theta}{\partial x^2} + \frac{\partial^2\theta}{\partial y^2} = 0 \qquad [15]$$

[3] "Theory of Elasticity," by S. Timoshenko, McGraw-Hill, 1934, pp. 113–117.

Let

$$\epsilon = k\theta \qquad [16]$$

where k is the coefficient of linear thermal expansion in three dimensions. It is known that this problem of two-dimensional strain is the same as that of the deformation of the same body under the body forces

$$\left.\begin{aligned} X &= -\frac{2G(1+\nu)}{1-2\nu}\frac{\partial\epsilon}{\partial x} = -\frac{\partial V}{\partial x} \\ Y &= -\frac{2G(1+\nu)}{1-2\nu}\frac{\partial\epsilon}{\partial y} = -\frac{\partial V}{\partial y} \end{aligned}\right\} \qquad [17]$$

and a normal boundary tension

$$\frac{2G(1+\nu)}{1-2\nu}\epsilon = V \qquad [18]$$

where G is the modulus of elasticity by shear, and ν is the Poisson ratio.

Since we have a steady-state heat problem, we have, according to Equations [15], [16], and [18]

$$\frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2} = 0$$

We are thus exactly in the general case considered by the previous theory. The theory is easily applied to this case; we shall state only the conclusions.[4]

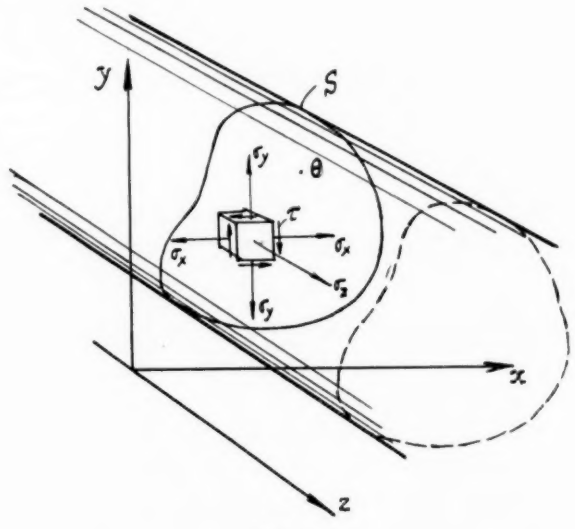

Fig. 7

We have to distinguish between the case where the cylinder is (1) solid or (2) hollow.

(1) If a solid cylinder is heated, either uniformly or not, but in such a way that a steady-state temperature distribution exists the same in every cross-section, the only stress produced is a tension or compression σ_z acting normally to the cross-section and equal to $\sigma_z = -E\epsilon = -Ek\theta$, where E is the Young modulus of the cylinder, k its coefficient of thermal expansion, and θ the

[4] It is expected that the complete analysis of this case by an independent method will be published later in the *Philosophical Magazine*: "A General Property of Two-Dimensional Thermal Stress Distribution," by M. A. Biot. See also, "Propriété generale des tensions thermiques en régime stationnaire dans les corps cylindriques," by M. A. Biot, Annales de la Sociète Scientifique de Bruxelles, vol. 54, series B, 1934.

temperature. We may say that the cylinder expands freely in the plane of its cross-section. This value $\sigma_z = -E\epsilon$ of the longitudinal stress is due to the assumption that longitudinal extension is prevented.

(2) If the cylinder is hollow, we make a longitudinal slit so as to connect the interior with the outside. When heated the two edges will in general separate. The cylinder becomes then a simply connected body without holes and we fall back on the previous case. In this slitted cylinder the temperature distribution will only produce axial stresses σ_z. But if we stick the sides of the slit together again, dislocation stresses σ'_x, σ'_y, τ'_{xy} will appear. Hence in a hollow cylinder stationary temperature

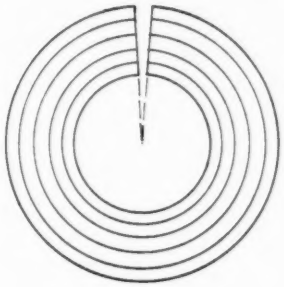

FIG. 8

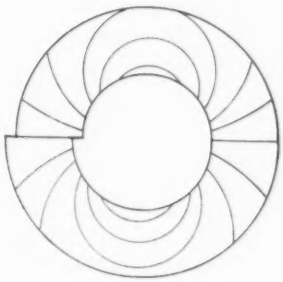

FIG. 9

distribution will generally give rise both to an axial stress σ_z and a dislocation stress system σ'_x, σ'_y, τ'_{xy}. They are the thermal stresses. In order that there should be no relative motion of the edges of the slitted cylinders, hence no stress except σ_z, the temperature distribution must satisfy three conditions, one of them being that the total flow of heat out of the hole is zero. These conditions are automatically satisfied if the temperature distribution has no singularity inside the hole (no source or sink or source-sink doublet).

Photoelastic Thermal-Stress Analysis

Thermal stresses may be measured by photoelasticity. A transient thermal-stress condition is equivalent to a boundary load and a dislocation. As previously shown, a steady-state thermal-stress condition is equivalent to a dislocation only and appears only in a hollow body. We shall have to calculate the amount of dislocation or relative motion of the two edges of a slit connecting the inside with the outside, make a model having that gap, and stick the two edges of this gap together.

Hollow Cylinder With No Heat Source Inside

In steady-state temperature distribution stresses other than σ_z may exist if the cylinder is heated from the outside. Those stresses disappear, however, if we fill the cylinder with a liquid having the same thermal conductivity as the cylinder because then all the singularities of the temperature distribution inside the hole disappear.

Circular Cylinder

For a radial heat flow we get concentric circular isothermal lines. A radial slit opens like that indicated in Fig. 8; no stress appears in the slitted cylinder. The thermal stresses in the non-slitted cylinder are those produced when bringing together the two edges of the slit. This amounts to the bending of a ring. For a doublet heat singularity (source and sink at the center) the isothermal lines are circles (Fig. 9). A radial slit as in the figure does not open up; the edges slide along each other.

Any heat-source singularity of an order higher than a doublet does not produce any heat stress in the cylinder.

On the Hydrodynamic Analogy of Torsion

By J. P. DEN HARTOG,[1] CAMBRIDGE, MASS., AND J. G. McGIVERN,[2] PULLMAN, WASH.

The authors herein describe a means for carrying out experimentally Kelvin's hydrodynamic analogy. A real liquid is used instead of the "ideal fluid" required by the analogy, the eddying flow caused thereby which violates the mathematical identity between the two cases being eliminated by taking photographs of the real liquid before eddying flow begins. The apparatus makes it possible to obtain photographs representing stress lines in shafts and also pictures of warped cross-sections.

THE first rational theory of torsion of prismatical bars, given by St. Venant in 1855, solved the problem completely for a limited number of simple cross-sections. However, a general method was lacking for the determination of the stress in any given practical section. St. Venant's solution was discussed in the first volume of Thomson and Tait's famous "Treatise of Natural Philosophy," in 1867, and it was there illustrated by a hydrodynamic interpretation, thus making it possible to visualize the general form of the solution for any kind of bar.[3]

In 1903, Prandtl disclosed an analogy employing a stretched membrane that was actually realized in experiment by Taylor and Griffith in 1916.[4] Prandtl's membrane analogy has since become so widely known that at present a large number of universities have such equipment available for instruction purposes.

Kelvin's hydrodynamic analogy is very much older than Prandtl's but we are not aware that it has ever been carried out in actual experiment. Undoubtedly the reasons for this are that an "ideal fluid" as required by the analogy cannot be obtained, and that any real liquid will show an eddying flow which violates the mathematical identity between the two cases. However, it is possible to succeed in the experiment if proper precautions are taken, and it is our purpose to describe how that may be done. Moreover, a slight modification of the experiment will give us a picture of the shape of the warped cross-section.

Kelvin's Analogy

As Thomson and Tait originally stated, the analogy employs a weightless prismatic box filled completely with "ideal fluid." This box must have the same shape as the cross-section of the elastic prism that is to be twisted and must be of unit height. If a couple is applied to the box in a plane perpendicular to its height, then the shear stress of the twisted solid will be proportional to, and have the same direction as, the velocity of the ideal fluid relative to the containing box.

Moreover, the couple or torque required to give the box a unit angular acceleration is equal to the "correction by which the torsional rigidity of the elastic prism, calculated by the false extension of Coulomb's law, must be diminished to give the true torsional rigidity."

Thus, if a flat tank having the cross-section of the twisted bar is filled with ideal fluid and rotated, a photograph of dust particles on the surface of the fluid, taken by a camera rotating with the tank, will show a set of closed curves coinciding with the stress lines in torsion.

It can also be deduced from the torsion equations that a photograph taken with the camera at rest and with the tank rotating about the "center of twist" gives a set of curves which are perpendicular to the lines of equal elevation of the warped cross-section in torsion.[5]

If a purely circular tank is rotated about its center, the ideal fluid inside will stand still, if it was initially at rest, because the ideal fluid has no friction against the tank walls. Photographed by a camera rotating with the tank, a set of concentric circles (the stress lines) will appear. A still camera, however, records no motion, expressing the well-known fact that a circular cross-section does not warp in twist. When the cross-section of the tank is not circular but roughly resembles a circle (shaft with keyway or square shaft), again the bulk of the fluid will hardly rotate, although a small part of the fluid near the corners of the edge will take part in the motion. Photographed with the rotating camera, this will give a set of closed curves (the stress lines) which are no longer circles but resemble circles at some distance from the boundary irregularities. The picture taken with the non-rotating camera will show considerable motion of the fluid near the protruding irregularities of the boundary but very little motion at some distance away.

Description of Apparatus

Difficulties from eddy formation and other frictional effects, which will occur in the non-ideal fluid used in the actual experiment, were avoided by taking the photograph immediately after starting the vessel from rest. It is known that any hydrodynamic system starting from rest exhibits a potential motion at the beginning and it is only after some time that eddies develop as a result of the friction in the fluid layers near the boundaries. To be sure, the time during which this potential motion occurs is very short, so that special precautions have to be taken in making the photograph. The apparatus consisted of a heavy horizontal disk rotatable on a large conical bearing about a vertical axis. The camera, facing downward, was solidly mounted at some height above the disk by means of vertical posts attached to the disk. The vessel containing water could be either clamped to the disk or mounted on it by means of another bearing so that it was rotatable with respect to the disk. Small aluminum particles were scattered on the water as is usual in hydrodynamic experiments. The ordinary precautions were taken of mixing india

ink or potassium permanganese with the water in order to make the bottom invisible and of waxing the sides of the vessel to insure a proper meniscus.[6]

The vessel was photographed during the first 10 deg of its rotation, approximately, while a tripper mechanism opened and closed the lens of the camera at the right instants. In this manner pictures could be obtained of the ideal flow before the boundary layer had time to upset its pattern.

Discussion of Results

Figs. 1*a* and 1*b* pertain to a square shaft and represent the stress conditions and cross-sectional warping, respectively. Fig. 1*a*

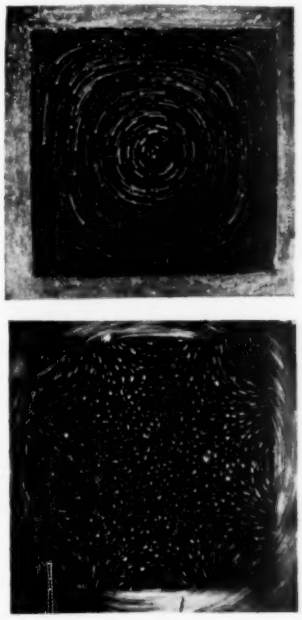

Fig. 1*a* (top) Stress Lines of a Square Shaft

Fig. 1*b* Warped Cross-Section of a Square Shaft

was taken with a camera rotating with the tank, resulting in a picture in which a sharp outline of the tank appears. The lines follow the direction of the shear stresses while the lengths of the individual streaks are proportional to these stresses. When photographing Fig. 1*b*, the camera was held still while the tank was rotated, the resulting picture being one in which a sharp outline of the tank does not appear. The lines photographed follow the direction of maximum slope of the warped cross-section and are perpendicular to the lines of equal height of that section. The lengths of the individual streaks are proportional to the slope. Since the square is a symmetrical cross-section, the center of twist coincides with its center of symmetry.

Figs. 2*a* and 2*b* depict a shaft with a keyway. Fig. 2*a*, illustrating a sharp keyway, is self-explanatory. Because of the sharp edge of the keyway, it is particularly difficult to avoid eddy formation. On the right or upstream side of the illustration no trouble occurs, but on the left or downstream side of the keyway the beginning of any eddy can be seen. This, of course, has to be discounted in interpreting the picture.

The non-symmetry of the keyway shaft is not very pronounced so that its center of twist is not far removed from the geometrical center. When photographing Fig. 2*b*, the tank was rotated about its geometrical center with the camera at rest and, therefore, shows an approximation of the lines of maximum slope of the cross-section. It is seen that the distortion is limited to the neighborhood of the keyway.

Fig. 3 illustrates the stress lines of an elongated rectangular section.

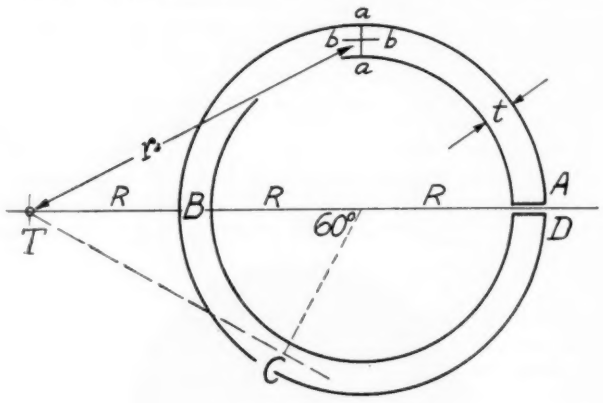
For sections made up of very thin parts, such as structural beams and split tubes, it is necessary to turn the tank through a very large angle (30 or 45 deg) in order to obtain sufficient relative motion. This, however, sets up a wave motion in the tank and makes it very difficult to secure a good picture. However, even in such cases the hydrodynamic analogy is very useful as it enables us to visualize the shape of the warped cross-section.

As an example, consider the split thin-walled tube shown in Fig. 4*a*. The center of twist T of this section lies at a distance R to the left if the wall is very thin. Imagine a tank of this shape rotated about T through an angle α. It can readily be seen that the displacement of any point of the tank walls is very great in comparison to the relative motion of the liquid with respect to the walls. The absolute motion of the liquid is non-rotational,

Fig. 2*a* (top) Stress Lines of a Shaft With a Keyway

Fig. 2*b* Warped Cross-Section of a Shaft With a Keyway

Fig. 3 Stress Lines of a Rectangular Shaft



and since the line *bb* in Fig. 4*a* is at rest relative to the tank, *bb* turns through an angle α with the tank. For non-rotational (potential) flow it is then necessary for the perpendicular *aa* to turn through an angle $-\alpha$, so that the 45-deg dashed cross in Fig. 4*b*[7] retains its direction in space. With a wall-thickness t,

[6] "Applied Hydro- and Aeromechanics," by Prandtl-Tietjens, McGraw-Hill Book Co., New York, N. Y., 1934, p. 270.

[7] "Fundamentals of Hydro- and Aeromechanics," by Prandtl-Tietjens, McGraw-Hill Book Co., New York, N. Y., 1934, p. 154.

this leads to a relative displacement of the liquid at the walls of αt. The displacement of that point of the tank wall is αr, so that the ratio of the relative to the tank displacements is t/r, which is negligible for thin walls.

Thus, the warped cross-section picture is practically the same as that of the tank motion alone, or in other words, the water may be considered frozen. *The lines of maximum slope of the warped shape of a thin-walled section are circles about the center of twist, and the lines of equal elevation are radii through the center of twist,*

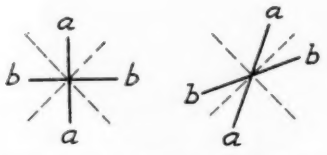


FIG. 4a (ABOVE) SPLIT THIN TUBE WITH ITS CENTER OF TWIST T

FIG. 4b (BELOW) THE DASHED CROSS RETAINS ITS DIRECTION IN SPACE WHEN THE PERPENDICULAR aa IN FIG. 4a TURNS THROUGH AN ANGLE HAVING A VALUE OF $-\alpha$

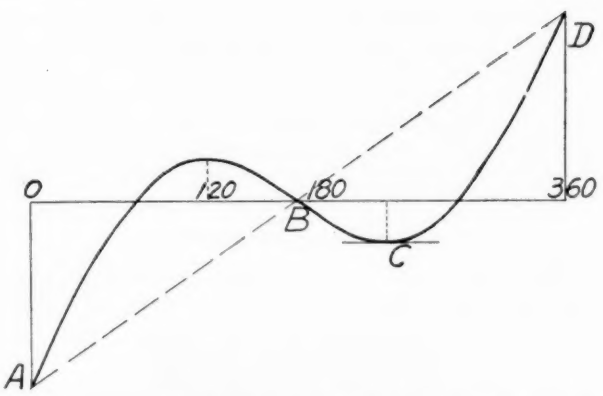

FIG. 5 DISTORTED CROSS-SECTION OF THE TUBE OF FIG. 4a DEVELOPED ON THE CIRCUMFERENCE

provided we consider only regions which are many wall thicknesses away from the center of twist.

For the split tube in particular it can be verified that the tank velocity at the slit is three times greater than at a point 180 deg away from the slit, so that the slope of the warped section is also three times as great. From the fact that the velocity is proportional to the slope, the shape of the warped section can easily be found to be

$$h = \theta - \pi + 2 \sin \theta$$

where h is the elevation and θ the angular distance from the slit. Fig. 5 shows this shape developed on the circumference, the points A, B, C, and D corresponding to those in Fig. 4a. This result so easily obtained shows the value of the warping analogy, because from casual observation of split tubes one is inclined to believe that Fig. 5 should have the shape of an inclined straight line, and the warped section that of a helix. In reality, however, the slope of the warped surface 180 deg from the slit is opposite in sign to what it would be in the case of a helix.

Pitting Due to Rolling Contact

By STEWART WAY,[1] EAST PITTSBURGH, PA.

Pitting, as the term is used in this paper, means a form of failure which occurs on gear teeth near the pitch circle, on rollers, in anti-friction bearings, and on other machine parts where cylindrical surfaces come in rolling contact under heavy loads. The purpose of the investigation described in this paper is to study the manner in which pits develop, to discover the reason for their development, and to find what conditions must be fulfilled to prevent their occurrence.

A testing machine was used in which steel rollers approximately 1.5 in. in diameter, rolling together and loaded as shown in Fig. 2, could be tested. More than eighty tests have been made with rollers of different materials, with different lubricants, and with various loads.

Pits are found to have a definitely characteristic shape and orientation with respect to the direction of rolling. They were observed to develop from minute cracks in the roller surfaces which appear after about 500,000 revolutions. Photographs were taken tracing the growth of these pitting cracks from their earliest observed stage. The cracks from the very beginning have a characteristic shape and orientation.

The principal findings in the tests on the steel rollers were: (1) That a lubricant must be present if pitting is to take place; (2) that if the lubricant is of a viscosity above a certain critical value which depends on the load, pitting can be prevented; (3) that the nature of the surface finish on the rollers greatly influences the tendency to pit, pitting being prevented on a highly polished surface and accelerated on a rough-machined surface; (4) that nitrided rollers will not pit under conditions that would result in severe pitting of quenched and tempered mild carbon-steel rollers, also that pits are smaller on harder surfaces, in general.

In the theoretical section of the paper, the load-carrying capacity for the oil film between two rollers having a common peripheral velocity is calculated, and it is shown that the critical viscosity necessary to prevent pitting is far below that necessary to prevent metal-to-metal contact, a fact also checked experimentally. The normal and tangential oil forces on the rollers after metal-to-metal contact are also calculated, and the tangential component is found to be small compared with the normal component. Calculation showed that no tensile stress would exist at the surface, where pitting cracks appear to start, due to contact pressure or oil forces. However, it is found by analysis that a small crack in the surface, if filled with oil, will tend to grow, provided it has a certain initial direction. This direction is the same as that of the cracks which precede pitting. This strongly suggests that oil penetration of very small surface cracks with a certain initial direction is the reason for the growth of these cracks until a particle is separated from the main body of material, leaving a pit. The experimental results harmonize, also, with this theory.

WHEN two cylindrical metallic surfaces engage in rolling contact, a form of failure known as "pitting" often occurs. This mode of failure is particularly troublesome on gear teeth in the vicinity of the pitch circle, where the teeth roll on each other without sliding. To give a clear idea as to what is meant by "pitting," a photograph, Fig. 1, of pits produced in the laboratory on steel rollers is shown.

Several features will be noted in Fig. 1: (*a*) The pit is bounded roughly by two straight lines and a curved line, and may be said to be fan-shaped; (*b*) at the vertex, there is a nipple-shaped extension to the cavity; (*c*) the pit is symmetrical about a line *AB* parallel to the direction of rolling; (*d*) the bottom of the pit is characterized by a series of curved steps, indicating a progressive fracture. Though it is not apparent in the figure, the direction of rolling, by which is meant the direction of motion of the contact area, is from *A* toward *B*. All pits that have been observed exhibit, with minor deviations, the four features just mentioned, and also have the previously mentioned orientation with respect to the direction of rolling.

In spite of the economic importance of preventing pitting, practically nothing has been done to discover the fundamental cause of this type of failure. Several theories have been proposed, however. The one most commonly advanced is that a fatigue crack begins as a result of repetition of the contact stresses, and that it probably begins near the region of maximum

shearing stress a short distance below the surface.[2] Lanchester[3] suggests that pitting is due to the welding of material of one body to that of the other in a small region, which results in a particle's being torn away. Still another theory, obviously incomplete, is that pitting is due to initial inaccuracies in machining, leading to stress concentration at high spots and destruction of the surface at those places. To evaluate these several theories, to arrive at a better theory of the cause of pitting, and, if possible, to find a way to prevent such failure, the following experiments with steel rollers, were carried out.

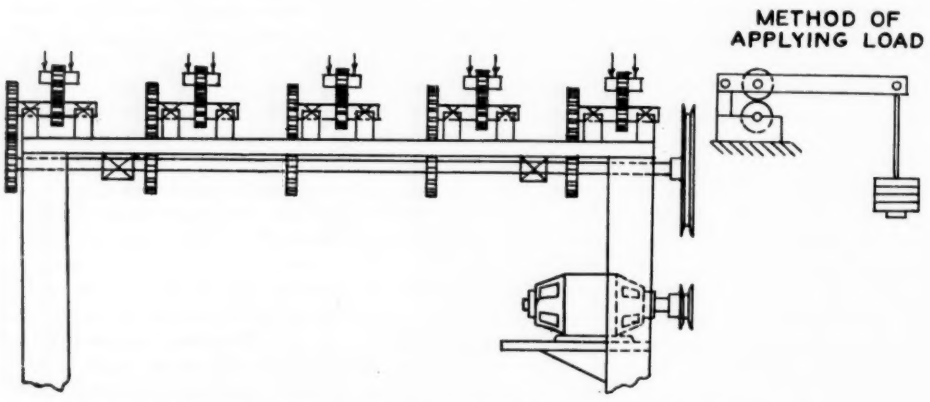

FIG. 2 SCHEMATIC DIAGRAM OF MACHINE FOR TESTING FIVE PAIRS OF ROLLERS

FIG. 3 PHOTOGRAPH OF THE TESTING MACHINE SHOWN IN FIG. 2

TESTS OF STEEL ROLLERS

The testing apparatus is shown schematically in Fig. 2, and by photograph, Fig. 3. The rollers have a face width of 1/2 in.; and the lower one is 1.576 in. in diameter while the upper has a diameter of 1.500 in. The difference in diameters insures that any point on one roller shall come in contact with a different point on the other roller with each revolution. The lower roller is driven at 400 rpm from a lineshaft by gears, and it in turn drives the upper by traction in the contact area.

There is good reason to believe that there is no relative sliding between the rollers.[4] The lower roller dips into an oil bath, the same lubricant being used for the bearings as for the rollers. Shock loads are minimized by spring suspension for the weights on the lever arms.

The main variables which can be controlled and studied with the present equipment are material, lubricant, and load. Speed may also be varied by changing gears or pulleys. The material variable must be understood to include not only all manner of metals and alloys, but also various treatments of these materials and various types of surface finish. In this paper the results of tests on three materials are discussed. The composition and properties of these materials are given in Table 1.

Steels Nos. 1 and 2 are of the same composition but have different treatments. Except where otherwise noted, all tests were made with rollers having a ground-surface finish.

About 80 pairs of rollers have been tested so far. Space does not permit a description of each test. The outstanding results are as follows:

Pitting Will Not Occur With-

out Lubricant. In all investigations of the wear and pitting of gear teeth that have come to the author's attention, the tests were carried out with lubrication. A. H. Burr,[5] however, made a large number of tests on steel rollers similar to those tested by the author, but running without lubricant. In no case was pitting obtained. Rollers running dry have also been tested by the author, with no pitting resulting. When oil is used to lubricate the rollers, pitting sometimes results and sometimes does not, depending on the load used, the viscosity of the oil, and other factors. One fact, however, was consistently borne out in tests by both Mr. Burr and the author, i.e., that pitting could not be produced without lubrication, regardless of the load used. The duration of these tests was, in most cases, in excess of five million cycles, and in one case twelve million and in another eighteen million. In 54 tests with lubricated rollers which pitted, pitting occurred in 50 per cent of the cases between 670,000 and 1,450,000 cycles, while the longest run was 4,867,000 cycles.

When steel rollers were run without lubricant, oxides formed on the surfaces. These oxides form very soon after the start of the test, and flake off. The composition of the oxide flakes was found to be 1.1 per cent Fe, 44.6 per cent FeO, and 54.2 per cent Fe_2O_3.

One pair of rollers was run without lubricant for 5,400,000 cycles. Oil was then added. At 5,560,000 cycles several pits had formed.

Pits Develop From Cracks That Start at the Surface. It was concluded at an early stage that the most satisfactory way to find the cause of pitting was to study pits while they were being formed. It was discovered, first, that a pit does not result from the gradual enlargement of a small cavity, but results from the growth of a crack which eventually separates a particle from the main body of material. In Fig. 4, *a* and *b* are the top view of a pre-pitting crack and the pit which formed shortly after. In *c* and *d* another crack and its eventual pit are shown. It will be noted that there is as definite a characteristic shape and orientation for the cracks as for the pits.

In Fig. 4 *e*, *f*, *g*, *h*, and *i* are shown various stages in the growth of a particular crack, at 13 × magnification. When first observed, cracks usually appear as in Fig. 4*e*. The shape is that of a V with the point toward the contact region as the crack approaches this area.

The cracks have also been studied by cutting the rollers perpendicularly to the axis. A crack in the stage of development of 4*e*, or perhaps slightly earlier, is shown in section at *a* in Fig. 5, at 100 × magnification. A crack a little further along is shown in top view and in vertical section in Figs. 5*b* and 5*c*. The top view was photographed after the sectional cut had been made.

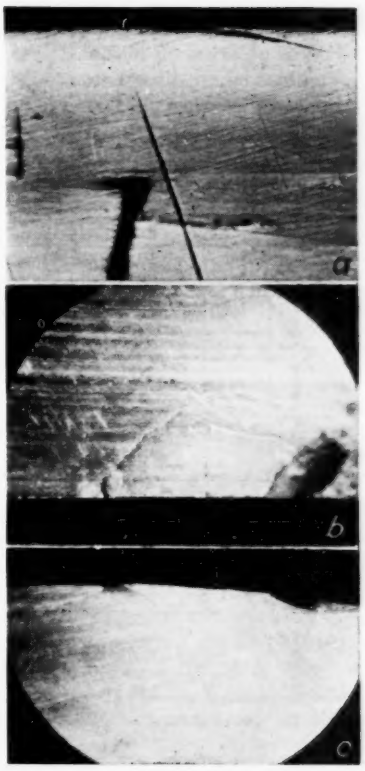

FIG. 5 ENLARGEMENTS OF PITTING CRACKS

[*a*, Section cut perpendicularly to the axis showing crack (×100); *b*, top view of a crack (×13); *c*, section through the roller and crack shown in *b* (×13).]

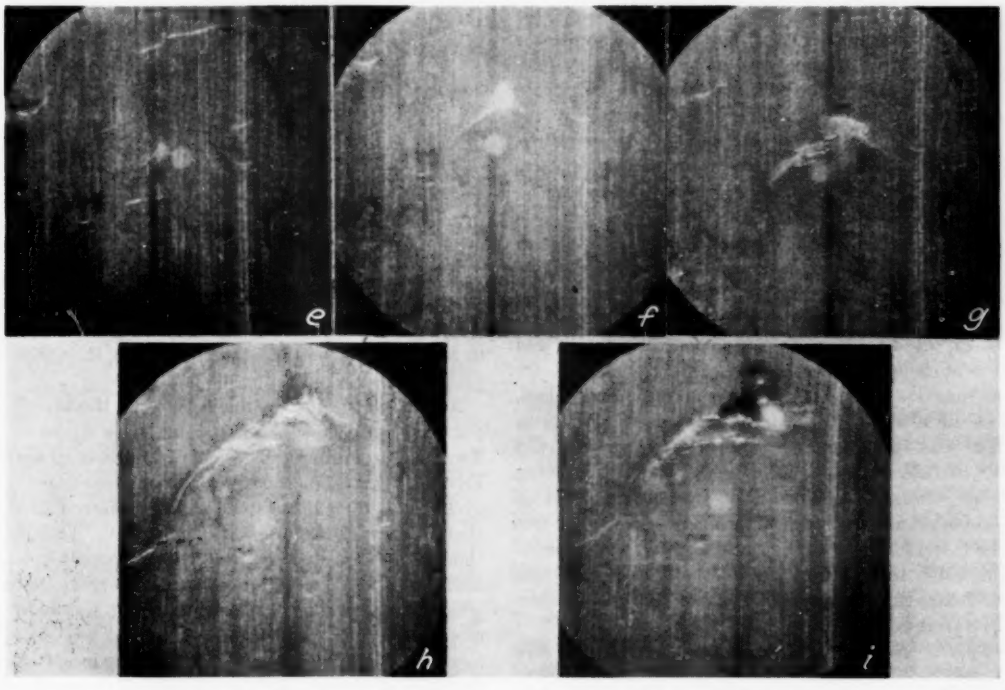

FIG. 4 *e–i* VARIOUS STAGES IN THE GROWTH OF A CRACK (×13)

The cracks show every evidence of having started at the surface. No cracks bearing any resemblance to pre-pitting cracks could be observed on rollers not yet tested. These cracks were found to start usually between 500,000 and 1,500,000 cycles. In most cases less than 100,000 cycles were required from the time a crack first appeared to the time when a pit was formed. The cracks extend into the roller at an acute angle to the direction of motion of the contact region along the surface.

M. Ulrich[6] says that in case-hardened gear teeth, cracks were observed starting beneath the surface. The author questions

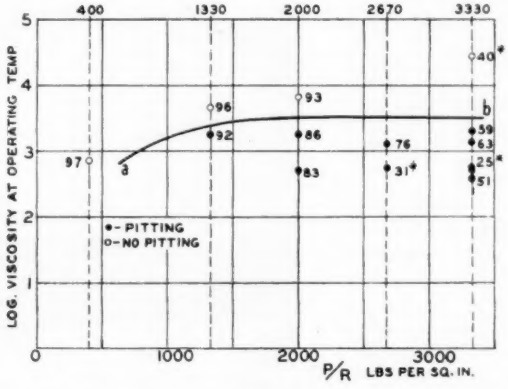

FIG. 6 LOAD-VISCOSITY RELATION IN PITTING TESTS
(0.40 per cent carbon steel rollers of 250 VPN hardness; speed 400 rpm; *speed 700 rpm.)

whether these cracks are related to the cracks which precede pitting.

Pitting Can Be Prevented by Using Oil of Sufficiently High Viscosity. It would seem reasonable to believe that if an oil of viscosity sufficiently high to prevent metal-to-metal contact of the rollers were used, no pitting would result. The interesting fact is, however, that even with metal-to-metal contact, pitting can be prevented by increasing the viscosity of the oil above a certain critical value. This critical value will depend on the load carried by the rollers. In Fig. 6, points are plotted for a number of pitting tests in a viscosity-load coordinate system. The load is measured by P/R, the pounds per inch of roller face width per inch of radius, and the viscosity is measured by the logarithm of the Saybolt viscosity at the operating temperature. Points indicated by dots represent tests where pitting took place, while points indicated by small circles represent tests where no pitting took place. All tests represented in this figure were made with steel No. 1. A curve *ab* of indefinite shape and position can be drawn so that the no-pitting points lie above it and the pitting points lie below it. Additional tests would more definitely determine the position of this curve. The location of the curve would be expected to depend on the speed of rotation and on the properties of the material.

To settle the question of whether or not the oil film is broken, in tests with an oil of viscosity high enough to prevent pitting, the upper roller was insulated from the lower except for the contact region. An electromotive force was introduced between upper and lower rollers. Running at no-load, no measurable current was conducted across the oil film, but as soon as the test load was applied, the film was broken and considerable current passed from one roller to the other. That the oil film is broken at much lower loads than necessary to cause pitting is shown theoretically in a later portion of this paper.

Hard and Smooth Surfaces Better Resist Pitting. In five tests with steel No. 1; a mineral oil of viscosity 87 sec Saybolt at 210 F and 900 sec at 100 F; and a load P/R = 3330 lb per sq in., the average number of cycles that elapsed until pitting was first observed was 1,555,000. In three tests with steel No. 2, the same oil, and the same load, the average number of cycles until pitting began was 1,416,000. It seems that the number of cycles necessary for pitting is practically independent of the hardness. However, an extremely hard surface, as that on the nitrided rollers of steel No. 3, was found not pitted at all after 6,000,000 cycles. In the test made with nitrided rollers, the load was 2670 lb per sq in. and the oil was the same as that already mentioned. Referring to Fig. 6, at P/R = 2670 the viscosity necessary to prevent pitting would have to be about 2000 sec Saybolt for steel No. 1. The oil used had a viscosity at the operating temperature of about 700 sec. Both steel No. 1 and steel No. 2 were found to pit badly with oils even heavier and a load of 2670 lb per sq in.

In the case of steel No. 2, although pitting began as soon as it did on rollers of steel No. 1, the pits were much smaller. The average diameter of the ten largest pits on a roller of steel No. 1 was 0.070 in., while that of the ten largest pits on a roller of steel No. 2 was only 0.036 in.

The degree of roughness of the surface is another factor that influences pitting. The rollers of steel No. 1 in the five tests previously mentioned had ground finishes. Two tests were made similar to these five except that the surfaces were polished. In one case, a test made by Mr. Burr, the rollers ran 12,600,000 cycles without pitting, and in the other case pitting began after 4,267,000 cycles. It is believed that the polish on the latter rollers was not as fine as on the former. But the point that should be emphasized is that polishing decidedly reduces the likelihood of pitting. In three tests with rough-machined surfaces, pitting began on an average at 430,000 cycles.

Significance of Experimental Results. A satisfactory explanation of pitting must take account of the part played by the lubricant. It must explain also why lubricants of a sufficiently high viscosity prevent pitting, even though they do not prevent metal-to-metal contact. It must account for the effects of surface roughness. Finally, it must explain why pits and the cracks which precede them have a certain characteristic shape and orientation.

The theory that pitting comes as a result of repetitions of the Hertzian system of contact stresses, discussed later, fails to explain why pitting does not take place without oil and why an extremely high polish on the surface will greatly retard or even prevent such failure. The theory that there is a welding together of the rollers in a small region, resulting in the tearing away of a particle, does not seem to be substantiated by observations of the pitting cracks.

It was found that the pits tend to form in planes perpendicular to the roller axis. This implies that the rollers do not have a truly cylindrical surface, and that the diameter is slightly larger in some planes than in others, resulting in higher loads in those planes.

A distinction must be made between the primary cause of the pitting cracks shown in Fig. 4 and the cause of their growth. Two results of importance should be mentioned in this connection. First, in the test of the rollers which were run dry for 5,400,000 cycles, and then lubricated, pitting occurred in the remarkably short span of 160,000 additional cycles. This implies that, although oil is necessary for pitting, some form of destruction leading to the formation of pitting cracks takes place independently of the oil. Secondly, a test was made in the usual manner with oil until several pits and ten pitting cracks had formed. The rollers were then cleaned and dried. On continuation of the test without oil none of the cracks developed into a pit. This indicates that oil is necessary for crack growth.

[6] "Zur Frage der Grübchenbildung bei Zahnrädern," M. Ulrich, *Zeit. V.D.I.*, 1934, vol. 28, no. 2.

The theory was advanced that steel particles, torn from the roller surfaces, would adhere to the rollers because of the oil, and would be carried into the contact region, causing high tensile stresses at the surface and possibly starting cracks. But it was found that oil was not essential to bring particles into the contact region; dry rollers were seen to be dented by particles, as were those tested with lubricant. Also, the fact pointed out in the last paragraph, that oil is probably not responsible for the beginning of the destructive process, leads to the conclusion that though particles may play an important part in this stage of the process, the oil is not a necessary aid in their action.

In support of the assumption that particles are a powerful contributing factor in the initial formation of pitting cracks stands the result of a test with polished rollers and oil filled with steel particles. In this test pitting began at 537,000 cycles. Also in tests in which felt wipers or a compressed-air jet were used in an effort to remove all steel particles, pitting was decidedly retarded. In opposition to the particle-action theory are numerous observations of pitting cracks at a very early stage, though perhaps not early enough, which showed no signs that a particle had been responsible for their origin. Also, the introduction of steel particles, MgO powder, or rouge powder into the oil did not materially accelerate pitting on rollers with ground surfaces.

Before going further into the discussion of the cause of pitting, some conclusions arrived at theoretically will be reviewed.

Theoretical Considerations[7]

Two problems present themselves, one to determine the loading on the rollers and the other to find the stresses caused by this loading. The loading consists of the forces due to metallic contact and the forces applied by the oil.

If the oil were not present, it would probably be justifiable to assume that the loading would be an elliptical distribution of contact pressure over a narrow rectangular contact area, in accordance with the Hertz theory of the contact of elastic bodies. If the cylinders are lubricated with oil, but are not in contact, the oil pressure can be calculated in the oil film in the same manner that the pressure in oil films in bearings is calculated. If the cylinders are in contact and also are lubricated with oil, the problem becomes extremely difficult unless the assumption is made that the deformation of the surface in front of the contact area is that due to contact pressures alone. The oil pressure at any point in front of the contact area can then be calculated. Also the tangential oil forces can be found. Within the contact area the loading will be the elliptically distributed contact pressure.

In calculating the oil forces, the amount of oil that passes between the rollers must be considered. This quantity will depend on the height of irregularities on the roller surfaces. For the pitting-test rollers with ground surfaces, the irregularities were found to have a maximum height of about $2\delta = 0.0002$ in.[8]

When loads are given, the problem of finding the stresses in the rollers at any particular point presents little analytical difficulty. The contact stress system has to be superimposed on the stress system due to the oil forces.

Without going into the calculations, the results of the theoretical study of loads and stresses will now be briefly reviewed.

A study of the contact stresses for parallel elastic cylinders as determined by the Hertz theory and further calculations by Belajef[9] show definitely that there is no tensile stress near the region of contact. Analysis of the oil forces before the rollers are in contact shows that at loads high enough to produce contact the oil pressure is so low, for usual viscosities and speeds, that the effect of pressure upon viscosity can be neglected. Equation [18], Appendix 2, arrived at for the load-carrying capacity of the oil film, indicates that in the pitting tests the oil film is broken at loads very much lower than those necessary for pitting. Investigation of oil forces after the rollers are in contact shows that as long as the influence of pressure on viscosity can be neglected the oil tangential traction will be quite small compared with the normal oil pressure. Normal oil pressures are found to be quite small compared with contact pressures that exist in the pitting tests, which tends to justify the assumption that the shape of the roller surfaces in front of the contact area is determined mainly by the contact forces. The tensile stresses at the surface due to the tangential oil forces are found to be quite small compared with the compressive stresses due to normal oil pressure, so that the net effect of the oil forces is to produce only compressive stresses.

Neglecting the stresses due to tangential oil forces, the resultant stress at any point will consist of the stress due to the distributed oil pressure as shown at p_2, Fig. 13, and the distributed contact pressure p_1. Referring to Fig. 14, the stress due to these loads at a point, A, a short distance below the surface and in front of the contact area can be calculated. The stress at a point, B, at the surface but closer to the contact area than A can also be calculated. A plane passing through A and B will then make an acute angle with the roller surfaces. If this acute angle falls in a certain range, it can be shown that the normal stress on plane AB at A is less than at B. If the angle θ, Fig. 14, is negative, it can be shown that the normal stress on plane AB is greater at A than at B, for A sufficiently close to the surface. This has a certain significance. For if we imagine that a very small crack exists, extending along the plane BA, and if BA is so oriented that the normal stress at A is less than at B, oil penetration of that crack would cause a high tensile stress at A. The oil that penetrates the crack will be under a pressure equal to the value of p_2 at B, which is also the value of the compressive stress on plane AB at B. The entrance of the oil into the crack would raise the pressure on the walls of the crack from some value less than the value of p_2 at B to this value. The stress system resulting from these added forces on the walls of the crack would give a concentrated tensile stress at the end of the crack. Thus, if a fine crack exists at the surface, inclined at an acute angle to the surface in the direction of rolling, and if the oil is of a viscosity sufficiently low to permit it to enter the crack, it is probable that the crack will grow.

Since we find that contact pressure and oil forces do not produce any tensile stress when the tangential oil forces are small compared with the normal oil forces, it would seem very improbable that repetitions of these loads could result in a fatigue crack.

General Conclusions

The two questions regarding pitting that puzzle the engineer are: What causes pitting? and How can pitting be prevented?

Although the author is not prepared to say definitely what causes pitting, he has arrived at some conclusions which can guide future investigation. Explanations of pitting advanced in the past are shown by the test results to be unsatisfactory or incomplete. The development of pitting cracks from a minute crack at the surface to a pit has repeatedly been carefully traced. The reason for the growth of these cracks, no matter how small they are to start with, seems to be adequately explained by the theory of oil penetration for the following reasons:

(1) The theory requires that oil be present for pitting.

[7] A more detailed theoretical treatment is given in the appendixes.

[8] A gelatine cast was made of the surface of the roller and examined in section under high magnification. The technique of such observations is described by W. Norman Thomas, *Engineering*, October 12, 1923.

[9] Institute of Ways and Communications, Leningrad, U.S.S.R.

(2) The theory requires that the oil be of viscosity low enough to permit penetration of fine cracks, if the cracks are to grow.

(3) The theory shows that cracks will grow only if they have a certain initial direction. This direction is the same as that of pitting cracks observed at a very early stage, as shown in Fig. 5.

(4) The theory explains why the critical viscosity for pitting does not increase appreciably with the load at high loads; for the oil pressure p_2 is practically independent of the total load carried, once there is metal-to-metal contact. p_2 will depend on the load only as δ is reduced by increasing the load.

(5) The theory is consistent with the finding that the rougher the surface finish the greater the likelihood of pitting. It is natural to expect more and larger cracks initially in the surface of a rough-machined roller than in that of a polished roller.

Possible methods of preventing pitting found so far are as follows: (1) Using no oil; (2) using highly polished surfaces; (3) increasing the viscosity of the oil; (4) using a very hard surface and tough interior as are obtained by nitriding.

The first method is obviously not practical and the second is quite expensive. The third method in many cases can be successfully applied. The fourth method deserves much further study.

Future investigation should be mainly along two lines, one aiming definitely to determine the primary cause of pitting cracks starting (as distinguished from the cause of their growth) at the surface, and the other aiming to find materials and heat treatments which show superior resistance to the formation and growth of pitting cracks. The effects of different grain sizes deserve special attention.

Acknowledgment

The author wishes to emphasize the importance of the work done by A. H. Burr in the Westinghouse Laboratories, who, to the author's knowledge, was the first to find substantial evidence that rollers run dry will never pit. Mr. Burr also succeeded in preventing pitting by the use of polished rollers. He suggested that pitting might be due to oil penetration of fine cracks, which theory is substantiated by the experimental and theoretical work of the author.

The work could not have been carried out without the cooperation of R. S. Marthens of the Nuttall Works, Westinghouse Electric and Manufacturing Company, which concern supplied the test rollers. The author is also indebted to Howard Scott, Miss M. Ferguson, and J. G. Hoop for assistance and advice on the metallurgical side of the investigation, and to J. G. Ford for his cooperation in the lubrication field.

Appendix 1

Contact Stresses

The Hertz[10] theory is based on the assumptions that the contacting bodies are perfectly elastic, that there are no shearing stresses in the contact area, and that the radii of curvature are large in comparison with the dimensions of the area of contact. The results of this theory are well verified by experiment[11] if reasonable precautions are taken to fulfil the assumptions, but if the assumptions are not fulfilled, as is the case if there is a large tangential stress between the bodies, the results of the Hertz theory may be considerably in error.[12]

[10] "Miscellaneous Papers," by H. Hertz, 1896, p. 146. "Theory of Elasticity," by S. Timoshenko, McGraw-Hill Co., 1934, p. 344.

[12] Hans Fromm, *Zeit. f. Tech. Physik*, 1928, pp. 229–311.

For cylinders of radii R_1 and R_2, the Hertz theory gives the following expressions for width of contact area and load distribution

$$2b = \sqrt{\frac{32\,P\,(1-\mu^2)}{\pi E\left(\frac{1}{R_1}+\frac{1}{R_2}\right)}} \quad \ldots\ldots [1]$$

$$p = p_{\max}\sqrt{1-\frac{y^2}{b^2}} \quad \ldots\ldots [2]$$

$$p_{\max} = \frac{2P}{\pi b} \quad \ldots\ldots [3]$$

The maximum shearing stress occurs at the point $y = 0$, $z = 0.786b$, axes being located as shown in Fig. 7. The magnitude of

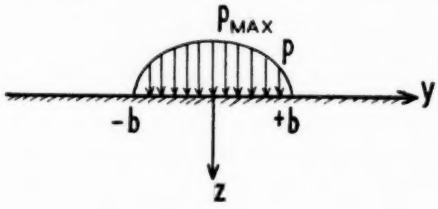

Fig. 7

the maximum shearing stress is 0.300 $p_{\max}$. The general expressions of Hertz for the stresses have been evaluated for this case by Belajef,[9] who finds the principal stresses are given by

$$\sigma_{1,2} = -\,p_{\max}\,e^{-\alpha}\sin\beta\left\{1 \mp \frac{\sin h\,\alpha}{\sqrt{\sin^2\beta+\sin h^2\,\alpha}}\right\} \quad \ldots [4]$$

where α and β are elliptical coordinates which specify the position

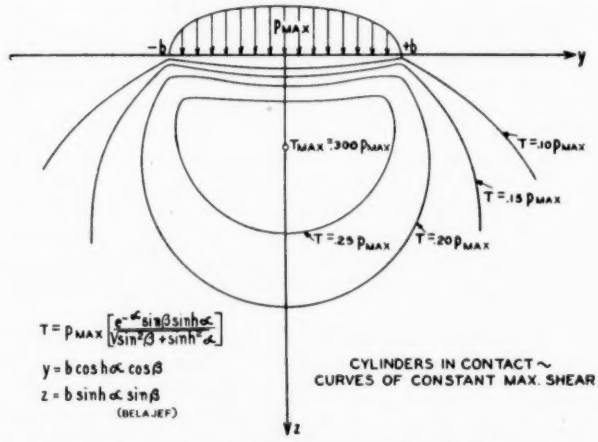

Fig. 8*a* Curves of Constant Principal Shearing Stress

of any point in the body. We see that σ_1 and σ_2 are always compressive stresses, since α and β are positive. Belajef gives for the principal shearing stress at any point

$$T = p_{\max}\left\{\frac{e^{-\alpha}\sin\beta\,\sin h\,\alpha}{\sqrt{\sin^2\beta+\sin h^2\,\alpha}}\right\} \quad \ldots\ldots [5]$$

Curves of constant principal shearing stress based on Equation [5] are plotted in Fig. 8*a*. In Fig. 8*b* the photoelastic picture of bakelite cylinders in contact shows good confirmation, qualitatively, of the theory.

For the rollers used in the pitting tests we have the following data:

$$\frac{1}{R_1} + \frac{1}{R_2} = \frac{1}{0.75} + \frac{1}{0.788} = 2.603$$

$$E = 30 \times 10^6 \text{ (lb per sq in.)}$$

$$\mu = 0.3$$

$$\frac{1 - \mu^2}{\pi E} = 0.965 \times 10^{-8}$$

The width of contact area, maximum compressive stress, depth of the point of maximum shearing stress, and magnitude of the maximum shearing stress are found to be, respectively

$$2b = 3.44 \times 10^{-4} \sqrt{P} \text{ (in.)}$$

$$p_{max} = 3695 \sqrt{P} \text{ (lb per sq in.)}$$

$$0.786b = 1.352 \times 10^{-4} \sqrt{P} \text{ (in.)}$$

$$Y_{z\,max} = 1110 \sqrt{P} \text{ (lb per sq in.)}$$

where P is the load per inch of roller-face width. Values of these quantities for a number of loads are given in Table 2.

TABLE 2

FIG. 8b PHOTOELASTIC TEST OF CYLINDERS IN CONTACT
(Compare shape of constant-shear curve with Fig. 8a.)

Appendix 2

OIL FORCES BEFORE METALLIC CONTACT

The rollers are assumed to be cylindrical and separated a distance 2δ as shown in Fig. 9. The y-axis is chosen mid-way between the rollers. Neglecting inertia forces and considering only the region where the distance between the rollers is small compared with the roller radii, the equation of equilibrium in the y-direction takes the form[13]

$$-\frac{dp}{dy} + \lambda \frac{\partial^2 v}{\partial z^2} = 0 \quad \ldots\ldots [6]$$

where p is the pressure, v the y-component of velocity and λ the viscosity. If the velocity is $-\alpha$ at the bounding surfaces $z = z_1$, $z = -z_2$, Equation [6] gives, after integration

$$v = \frac{1}{2}(z + z_2)(z - z_1)\frac{1}{\lambda}\frac{dp}{dy} - \alpha \quad \ldots\ldots [7]$$

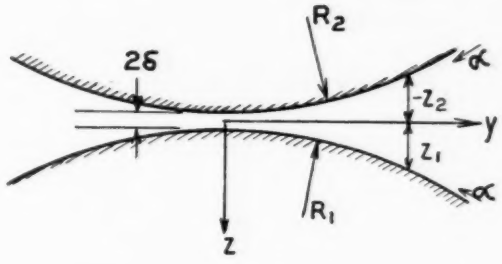

FIG. 9

The total quantity of oil passing between the rollers per unit time is

$$Q = -\int_{-z_2}^{z_1} v\,dz \quad \ldots\ldots [8]$$

and if we substitute Equation [7], integrate, and rearrange the terms, we obtain

$$\frac{1}{\lambda}\frac{dp}{dy} = \frac{3Q - 6\alpha\zeta}{2\zeta^3}; \quad \zeta = \frac{z_1 + z_2}{2} \quad \ldots\ldots [9]$$

If we assume for ζ and λ the expressions

$$\zeta = \delta + \frac{y^2}{2R}; \quad \frac{1}{R} = \frac{1}{2}\left(\frac{1}{R_1} + \frac{1}{R_2}\right) \quad \ldots\ldots [10]$$

$$\lambda = \lambda_0 (1 + \gamma p^2) \quad \ldots\ldots [11]$$

where λ_0 is the viscosity at zero pressure and γ is a constant to be determined experimentally, Equation [8] may be integrated, with the result

$$\frac{1}{\sqrt{\gamma}} \tan^{-1} p\sqrt{\gamma} = \frac{3\lambda_0'}{\delta'^{3/2}} f(y', \beta) \quad \ldots\ldots [12]$$

in which

$$\lambda_0' = \lambda_0\alpha/R;\ \delta' = \delta/R;\ y' = y/\sqrt{R\delta};\ \beta = Q/2\alpha\delta$$

$$f(y',\beta) = \frac{\beta}{4}\left\{\frac{y'}{\left(1 + \frac{y'^2}{2}\right)^2} + \frac{^3/_2\, y'}{1 + \frac{y'^2}{2}} + \frac{3}{\sqrt{2}}\left(\tan^{-1}\frac{y'}{\sqrt{2}} - \frac{\pi}{2}\right)\right\} - \frac{y'}{1 + \frac{y'^2}{2}} - \frac{1}{\sqrt{2}}\left(\tan^{-1}\frac{y'}{\sqrt{2}} - \frac{\pi}{2}\right) \quad \ldots\ldots [13]$$

The condition that $p = 0$ when $y = \infty$ has been used. To determine β, it is assumed that on the out-flow side p and dp/dy become zero together, or that p is zero when the velocity is uniform and equal to $-\alpha$. Equations [9] and [12] then give the value

[13] See "Mechanical Properties of Fluids," Blackie & Son, Ltd., London, p. 115.

1.225 for β, and we find that dp/dy is zero at $y' = \pm 0.671$. When $y' = -0.671$ p is zero, and when $y' = 0.671$ p is maximum, p_{max} is given by

$$\frac{1}{\sqrt{\gamma}} \tan^{-1} p_{max} \sqrt{\gamma} = \frac{3\lambda_0'}{\delta'^{3/2}} (0.1793) \quad [14]$$

The total load carried by the oil film is

$$\frac{P}{R} = \sqrt{\delta'} \int_{-0.671}^{\infty} p dy' \quad [15]$$

Assuming that γp^2_{max} is small compared with unity we shall have, instead of Equations [12], [14], and [15] for $\beta = 1.225$

$$p = \frac{3\lambda'_0}{\delta'^{3/2}} f(y', \beta)_{\beta=1.225} \quad [16]$$

$$p_{max} = \frac{3\lambda_0'}{\delta'^{3/2}} (0.1793) \quad [17]$$

$$\frac{P}{R} = 1.227 \frac{\lambda'_0}{\delta'} \quad [18]$$

To show the distribution of oil pressure, p has been plotted against y' in Fig. 10.

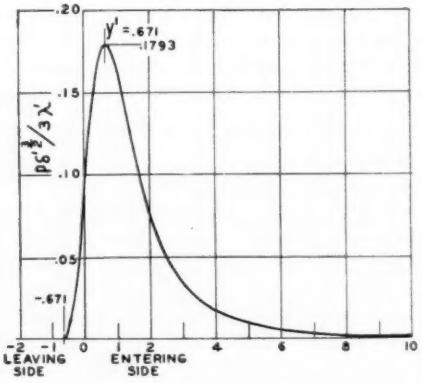

FIG. 10 PRESSURE VARIATION IN OIL FILM BETWEEN ROLLERS SEPARATED BY A DISTANCE 2δ; $\left(\delta' = \frac{\delta}{R}\right)$

Since 2δ is the average thickness of the oil film when $y = 0$, the condition for the rollers to come into contact is that 2δ shall equal the height of the surface irregularities. As previously mentioned, the irregularities on the surfaces of the pitting-test rollers had a height $2\delta = 0.0002$ in., so that $\delta' = 0.000133$. The maximum oil pressures have been computed for this value of δ' and for various values of λ_0', by Equations [14] and [17], with the results as given in Table 3.

TABLE 3 VALUES OF p_{max} IN LB PER SQ IN.

λ'_0, dynes per sq cm.....	20	50	100	200	400
p_{max} Eq. [14].....	101	254	509	1030	2150
p_{max} Eq. [17].....	101	254	509	1015	2030

In Equation [14] the value 0.285×10^{-8} cm²/dyne was taken[14] for $\sqrt{\gamma}$. Values for λ_0' correspond to the range of viscosities of the oils used in the pitting tests and the mean angular velocity of 42 radians per sec. We see that p_{max} by Equation [17] is only slightly less than p_{max} by Equation [14], indicating that the influence of pressure on viscosity can usually be neglected. From Equation [18], if $\lambda_0' = 400$ and $\delta' = 0.000133$, $P/R = 53.5$ lb per sq in. We conclude that the load-carrying capacity of the oil film will in general be much less than the loads applied to the rollers in the pitting tests.

[14] Viscosity pressure tables for several mineral oils are given by J. H. Hyde, Proc. Royal Society of London, 1920, 97A, p. 240.

Appendix 3

OIL FORCES AFTER METALLIC CONTACT

When the rollers are in contact there will be a flattened area of width $2b$, as shown in Fig. 11. We shall assume that the

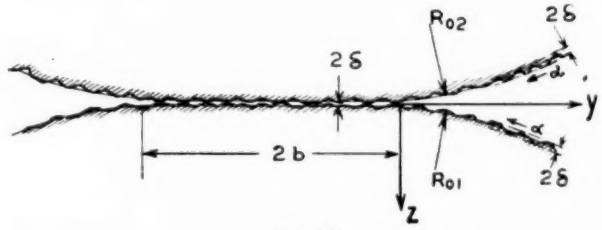

FIG. 11

deformation of the surface is that due to the contact pressure alone. This leads to the conclusion that the contact pressure distribution is elliptical, in accordance with Hertz's law, Equation [2]. The contact pressure will be denoted by p_1 and the oil pressure by p_2, shown in Fig. 13, and the y and z axes will be located as shown in Fig. 11.

The radii of the roller surfaces for small values of y will be reduced because of elastic deformation by the p_1 forces to R_{01}, R_{02}. Equation [12] for the pressure distribution holds true for the case at hand when $1/R$ is replaced by $1/R_0$, where $\frac{1}{R_0} = \frac{1}{2}\left(\frac{1}{R_{01}} + \frac{1}{R_{02}}\right)$. In this case we make β unity, since the discharge Q is $2\alpha\delta$.

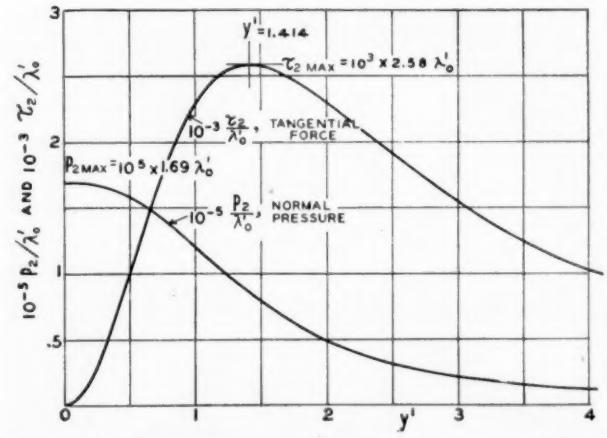

FIG. 12 NORMAL AND TANGENTIAL OIL FORCES FOR $\delta' = 0.00029$ (Rollers in contact.)

In addition to the normal oil pressure p_2, we can say something about the tangential oil traction τ_2. Since the shearing stress in the oil is $\lambda \frac{dv}{dz}$, we have, for $z = z_1$, by Equation [7]

$$\tau_2 = \lambda \left(\frac{z_1 + z_2}{2}\right) \frac{1}{\lambda} \frac{dp}{dy} \quad [19]$$

Using the relations $\frac{z_1 + z_2}{2} = \zeta$, $\zeta = \delta + \frac{y^2}{2R_0}$, and $y' = y/\sqrt{R_0\delta}$

and also Equation [9], the tangential oil traction becomes, for $\beta = 1$

$$\tau_2 = -\frac{3\lambda_0'}{\delta'}(1+\gamma p^2)\frac{y'^2/2}{\left(1+\frac{y'^2}{2}\right)^2} \quad \ldots\ldots [20]$$

For small values of γp^2, the pressure- and tangential-stress distributions due to the oil are given by

$$p_2 = \frac{3\lambda_0'}{4\delta'^{3/2}}\left\{\frac{y'}{\left(1+\frac{y'^2}{2}\right)^2} - \frac{y'/2}{1+\frac{y'^2}{2}} - \frac{1}{\sqrt{2}}\left(\tan^{-1}\frac{y'}{\sqrt{2}} - \frac{\pi}{2}\right)\right\} \quad \ldots\ldots [21]$$

$$\tau_2 = -\frac{3\lambda_0'}{\delta'}\frac{\frac{y'^2}{2}}{\left(1+\frac{y'^2}{2}\right)^2} \quad \ldots\ldots [22]$$

From these expressions curves have been plotted in Fig. 12, for unit λ'_0 and for $\delta' = 0.00029$;[15] p_2 and τ_2 have maximum values at different points

$$p_{2\max} = (p_2)_{y'=0} = \frac{3\lambda'_0\pi}{8\sqrt{2}\,\delta'^{3/2}} \quad \ldots\ldots [23]$$

$$\tau_{2\max} = (\tau_2)_{y'=\sqrt{2}} = -\frac{3\lambda_0'}{4\delta'} \quad \ldots\ldots [24]$$

Stresses Due to Oil and Contact Forces. Axes are chosen in the same position as in the discussion of contact stresses. We

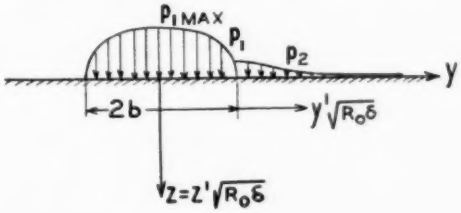

FIG. 13

use the additional coordinates y' and z' to aid in defining the oil forces. y' and z' are defined by

$$y' = \frac{y-b}{\sqrt{R_0\delta}}; \quad z' = \frac{z}{\sqrt{R_0\delta}}$$

The loads applied to the roller surfaces are the oil forces given by Equations [21] and [22] and the contact pressure

$$p_1 = p_{1\max}\sqrt{1-\frac{y^2}{b^2}} \quad \ldots\ldots [25]$$

The stress at some point in the interior may be expressed by

$$Y_y = Y_{y1} + Y_{y2};\ Z_z = Z_{z1} + Z_{z2};\ Y_z = Y_{z1} + Y_{z2} \ldots [26]$$

where Y_{y1}, Z_{z1}, and Y_{z1} are contact stresses and Y_{y2}, Z_{z2}, and Y_{z2} are stresses due to loads p_2 and τ_2, as follows:

$$\left.\begin{aligned} Y_{y2} &= -\frac{2}{\pi}\int_v^\infty \frac{z'(y'-v)^2 p_2 dv}{((y'-v)^2+z'^2)^2} - \frac{2}{\pi}\int_0^\infty \frac{(y'-v)^2\tau_2 dv}{((y'-v)^2+z'^2)^2} \\ Z_{z2} &= -\frac{2}{\pi}\int_0^\infty \frac{z'^3 p_2 dv}{((y'-v)^2+z'^2)^2} - \frac{2}{\pi}\int_0^\infty \frac{(y'-v)z'^2\tau_2 dv}{((y'-v)^2+z'^2)^2} \\ Y_{z2} &= -\frac{2}{\pi}\int_0^\infty \frac{z'^2(y'-v)p_2 dv}{((y'-v)^2+z'^2)^2} - \frac{2}{\pi}\int_0^\infty \frac{(y'-v)^2 z'\tau_2 dv}{((y'-v)^2+z'^2)^2} \end{aligned}\right\} . [27]$$

$$\left.\begin{aligned} Y_{y1} &= p_{\max}\left\{-e^{-\alpha}\sin\beta + \sin\beta\sinh\alpha\left(1-\frac{\sin h\,2\alpha}{\cos h\,2\alpha - \cos 2\beta}\right)\right\} \\ Z_{z1} &= p_{\max}\left\{-e^{-\alpha}\sin\beta - \sin\beta\sinh\alpha\left(1-\frac{\sin h\,2\alpha}{\cos h\,2\alpha - \cos 2\beta}\right)\right\} \\ Y_{z1} &= p_{\max}\left\{-\sin h\,\alpha\sin\beta\,\frac{\sin 2\beta}{\cos h\,2\alpha - \cos 2\beta}\right\} \end{aligned}\right\} . [28]$$

$$y = b\cos h\,\alpha\cos\beta;\ z = b\sin h\,\alpha\sin\beta \ldots\ldots [29]$$

in Equation [27] p_2 and τ_2 are load intensities at the point $y' = v$.

In Equation [4] it is clear that Y_{y1}, Z_{z1}, and Y_{z1} cannot give rise to any tensile stress. If Y_{y2}, Z_{z2}, and Y_{z2} are to give rise to a tensile stress, it is natural to look for that tensile stress at the surface. At the surface, the contact pressure p_1 contributes nothing to the stress system outside the contact area. The p_2 forces contribute the compressive stress $-p_2$ in both the y' and z' directions, and the τ_2 loading contributes the second integrals in Equation [27]. These latter stresses, due to τ_2 are

$$\left.\begin{aligned} (Y_y\tau_2)_{z'=0} &= \frac{3\lambda_0'}{\pi\delta'}\left\{\frac{\frac{y'^2}{2}}{\left(1+\frac{y'^2}{2}\right)^2}\log\frac{y'^2}{2} + \frac{\left(\frac{y'^2}{2}-1\right)\left(\frac{\pi\sqrt{2}}{4}y'-1\right)}{\left(1+\frac{y'^2}{2}\right)^2}\right\} \\ (Z_z\tau_2)_{z'=0} &= 0 \\ (Y_z\tau_2)_{z'=0} &= \tau_2 \end{aligned}\right\} .. [30]$$

The stress $(Y_y\tau_2)_{z'=0}$ is tension for small values of y', but with increasing y' changes to compression. For there to be a tensile stress at the surface, the tension $(Y_y\tau_2)_{z'=0}$ must be greater at some point than p_2. The ratio of $(Y_y\tau_2)_{z'=0}$ to p_2 is greatest at $y' = 0$ and has the value $8\sqrt{2\delta'}/\pi^2$. Unless $\sqrt{\delta'}$ is greater than $\pi^2/8\sqrt{2}$, $(Y_y\tau_2)_{z'=0}$ cannot be greater than p_2 and there can be no tension at the surface. But for $\sqrt{\delta'}$ to be of the order of $\pi^2/8\sqrt{2}$ is absurd. We conclude that the oil forces p_2 and τ_2 together cannot produce tension at the surface.

The stresses will now be calculated at a point under the surface and in front of the contact area. Referring to Fig. 12, the tan-

[15] A consideration of the elastic deformation of the roller surfaces leads to the approximate value $0.46R$ for R_0. If δ/R is 0.000133, then δ/R_0 is 0.00029.

gential forces are quite small compared with the normal oil forces. In the present calculation, therefore, the stresses due to τ_2 will be neglected. We assume the following numerical data:

$$R_0 = 0.46R;\ b/R = 0.00588;\ \delta/R_0 = \delta' = 0.0001$$

$$E = 30 \times 10^6 \text{ lb per sq in.};\ \mu = 0.3$$

and calculate stresses at the point $y' = 0.8; z' = 0.1$

Since

$$\frac{y}{b} = 1 + \frac{R_0}{b} y'\sqrt{\delta'};\quad \frac{z}{b} = \frac{R_0}{b} z'\sqrt{\delta'}$$

the coordinates of the selected point are $y/b = 1.626$; $z/b = 0.0783$.

Evaluating the first integrals in Equation [27], making use of

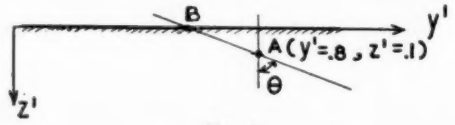

FIG. 14

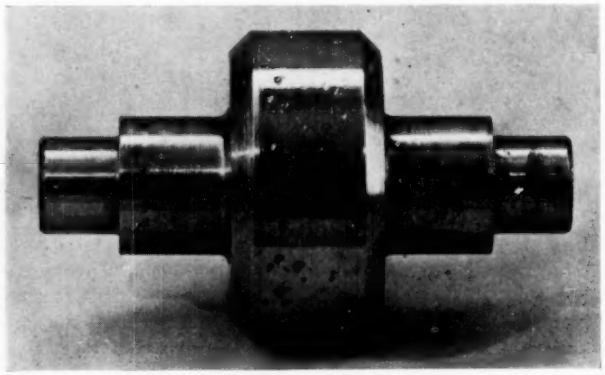

FIG. 15 PITTED TEST ROLLER

Equation [21], the stresses due to the oil pressure p_2 at the selected point are

$$Y_{y2} = -0.570 \times 10^6\lambda'_0;\quad Z_{z2} = -0.703 \times 10^6\lambda'_0;$$

$$Y_{z2} = -0.032 \times 10^6\lambda'_0$$

The contact stresses in pounds per square inch at the point $y = 1.626b$, $z = 0.0783b$ which is the same as $\alpha = 1.0705$, $\beta = 0.0609$ are found from Equation [28] to be

$$Y_{y1} = -4050;\ Z_{z1} = -9.7;\ Y_{z1} = -278$$

Assuming values of 100, 200, and 300 dynes per sq cm for λ'_0 (0.145×10^{-2}, 0.290×10^{-2}, 0.435×10^{-2} lb per sq in.) the stresses at $y' = 0.8$, $z' = 0.1$ due to the p_2 loading are found to be as given in Table 4.

TABLE 4 STRESSES DUE TO OIL PRESSURE

(Lb per sq in.)

Viscosity × ω	Y_{y2}	Z_{z2}	Y_{z2}
$\lambda_0' = 0.00145$	−826	−1020	−46
$\lambda_0' = 0.00290$	−1650	−2040	−93
$\lambda_0' = 0.00435$	−2480	−3060	−139

Combination of oil pressure stresses and contact stresses gives resultant values as in Table 5.

TABLE 5 RESULTANT STRESSES

(Lb per sq in.)

Viscosity × ω	Y_y	Z_z	Y_z
$\lambda_0' = 0.00145$	−4870	−1030	−324
$\lambda_0' = 0.00290$	−5700	−2050	−371
$\lambda_0' = 0.00435$	−6530	−3070	−417

For $\delta' = 0.0001$ and the above values for λ_0' the intensity of load p_2 at several points on the surface between $y' = 0$ and $y' = 0.8$ is given in Table 6.

TABLE 6 p_2 AT VARIOUS POINTS

(Lb per sq in.)

Viscosity × ω	$y' = 0.4$	$y' = 0.5$	$y' = 0.6$	$y' = 0.7$
$\lambda_0' = 0.00145$	1167	1135	1094	1043
$\lambda_0' = 0.00290$	2330	2270	2190	2090
$\lambda_0' = 0.00435$	3500	3400	3280	3130

Let A be the point $y' = 0.8, z' = 0.1$ and let B be a point on the surface between $y' = 0$ and $y' = 0.8$, as shown in Fig. 14. Let a plane pass through A and B perpendicular to the $y' = z'$ plane. Let θ be the angle between the z'-axis and plane AB. We shall calculate the normal stresses on plane AB at points A and B.

The normal stress at B is the compressive stress $-p_2$. The normal stress at A is calculated from the values in Table 5 and the relation

$$N = Y_y \cos^2\theta + Z_z \sin^2\theta - 2Y_z \sin\theta\cos\theta$$

In Table 7 the normal stresses on plane AB at A and B are given for various values of θ and for λ_0' equal to 300 dynes per sq cm (0.00435 lb per sq in.).

TABLE 7 NORMAL STRESSES AT A AND B

Angle θ	B	Stress at A lb per sq in.	Stress at B lb per sq in.
$\tan^{-1} 4$	$y' = 0.4$	−3070	−3500
$\tan^{-1} 3$	$y' = 0.5$	−3160	−3400
$\tan^{-1} 2$	$y' = 0.6$	−3430	−3280
$\tan^{-1} 1$	$y' = 0.7$	−4370	−3130

In this particular case, if θ is between 66 and 83 deg the normal stress at A is less than at B. If other data had been assumed for λ_0', δ', and b/R it would be possible by taking the point A close enough to the surface to again find a range of values of θ between 0 and 90 deg for which the normal stress at A would be less than that at B. When θ is negative and when A is very close to the surface, the normal stress at A will in general be greater than at B.

Film Lubrication in Sleeve Bearings

By M. STONE,[1] PITTSBURGH, PA.

The author discusses the design of bearings as based on fluid friction in hydrodynamic films and investigates the limiting design factors in such bearings. He points out that the thickness of the oil film is dependent on the viscosity of the lubricant alone and that this thickness may be controlled, thus making it possible to base the design of a bearing on a minimum thickness of the oil film. Two appendixes conclude the report, one which presents simplified theoretical considerations for the design of film-lubricated bearings while the other explains the highly accurate electromagnetic micrometer used for determining shaft positions in the bearing.

IN THE early days of rotating shafts, when an iron shaft was rotated in a wooden bearing shell, a reduction in friction was obtained by rubbing the surface with suet or smearing it with asphalt. Such a bearing, from the point of view of modern engineering, is hardly a bearing, the design now being approached from the background of fluid friction in hydrodynamic films. Sleeve bearings, designed on this principle, vary widely in their efficiencies, the extent of their friction losses and length of life depending on the magnitude of the load being carried, the speed of rotation, the viscosity and oiliness of the lubricant, temperature, running clearance, bearing metals, and fineness of machine finish. The problem is to determine the proper design of a bearing for a given load and speed requirements. The purpose of this paper, therefore, is to present briefly the limiting factors which must be considered in the design of a fluid-film bearing and to show how the thickness of the oil film, which in the final analysis determines the success of the bearing, may be controlled in design.

A ready means of differentiating between the various types of sleeve bearings is given in Fig. 1, in which ZN/P is plotted against μ, where Z is absolute viscosity in centipoises, N is speed of the shaft in rpm, P is the projected-area pressure in lb per sq in., and μ is the equivalent coefficient of friction. The justification for drawing such a curve goes back to the theory of film lubrication which is presented briefly in Appendix 1. As seen from the curve, Fig. 1, two, and perhaps three, regions of bearing friction are recognized. In the region to the right of the point marked "breakdown," the friction in the bearing is entirely made up of fluid friction within the lubricant itself, and the friction coefficient is very small, becoming as little as 0.001, and under, for carefully machined surfaces. The curve as shown is for a fixed value of bearing clearance, i.e., a fixed ratio of sleeve to shaft diameter. The region referred to already may be termed the region of perfect lubrication. To the left of the breakdown point, the friction coefficient increases very rapidly which, as will be discussed, is due to a combination of fluid and metal-to-metal friction. In this region, where μ has a value of between 0.010 and 0.100, there is an imperfect hydrodynamic film and it is therefore termed the region of partial lubrication. For values of μ between 0.100 and 0.300, a condition of practically solid friction exists and we have no bearing in the ordinary sense.

On the basis of Tower's (1)[2] investigation of the pressure distribution in sleeve bearings, Reynolds (2) developed the hydrodynamic theory of film lubrication which has formed the basis of modern sleeve-bearing design. In Reynolds' considerations, the viscosity at the operating temperature of the bearing was the only property of the lubricant involved. Since the promulgation of the theory, there has been considerable experimentation to substantiate or disprove the original contentions, confusion resulting when it was found that there is considerable difference in bearing losses and temperatures in two cases of exactly similar bearings using two oils of exactly the same vis-

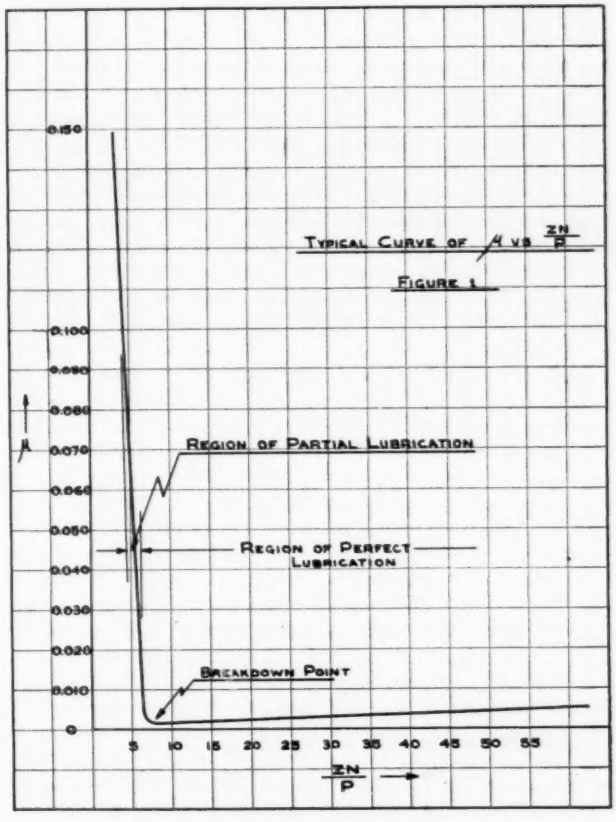

FIG. 1 TYPICAL CURVE OF μ VS. ZN/P

[1] United Engineering and Foundry Company, Pittsburgh, Pa. Mr. Stone was graduated from the Harvard Engineering School in mechanical engineering in 1923, and received the degree M.S. in 1925. He later, in 1933, obtained the doctor's degree from the University of Pittsburgh for advanced engineering work. The years 1924–1925 were spent in work on the A.S.M.E. high-pressure steam program at Harvard. From 1925 to 1934, Mr. Stone was associated with the Westinghouse Electric & Manufacturing Company, first on mechanical research, and later as supervisory design engineer on large power apparatus, petroleum equipment, air-conditioning apparatus, etc. During 1930–1931, he was in Germany and England as Lamme Fellow on advanced study and liaison engineering work. His present work is on the design of steel-mill machinery, particularly large strip mills.

Presented at the Annual Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, New York, N. Y., December 3 to 7, 1934.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until August 10, 1935, for publication at a later date.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] Numbers in parentheses refer to similarly numbered references listed at the end of the paper.

cosity. As a result, a question was raised as to the limitations of the theory, or more exactly, as to the nature of the physical conditions within the bearing. It was found, in general, that as the speed or viscosity decreased, or as the pressure increased, the friction torque decreased for a time, and then suddenly increased, being accompanied by bearing wipe. The thought occurred that the thickness of the film was influenced by the changing conditions, and that some quantitative ideas concerning the latter would clarify the picture. It was soon appreciated that as ZN/P decreased, a breakdown point was reached. Considerable work has been done of late, principally by the McKees (3), to determine the lowest safe value of ZN/P.

The work of Karelitz (4), as referred to in Appendix 1, resulted in a curve relation between h_{min} and ZN/P which is shown in Fig. 3. Thus, from the curves in Fig. 3, we see that as ZN/P decreases, both h_{min} and μ decrease down to the breakdown point. In these curves, m represents the ratio between the mean radial clearance and the journal radius. This forcefully presents the argument that as the bearing friction decreases, the minimum oil film also decreases until a sudden collapse of conditions takes place.

Satisfactory results have been obtained from tests on bearings where 5 is the assigned value of ZN/P. From the upper graph in Fig. 3, the value of h_{min} corresponding to ZN/P is 0.0002 in. for a 10-in. diam bearing with a 120-deg bearing arc. For usual turbine-bearing practice, a value of 0.0006 in. for h_{min} is usually used, since load and speed conditions do not demand a smaller figure. However, for heavy loads and low speeds, considerably lower values are necessary if successful bearings are to be made. This, of course, emphasizes the necessity for accurate grinding of shafts and absence of bearing-sleeve distortion. We come then to the ultimate criterion of a satisfactory bearing, i.e., a lower limit on minimum oil-film thickness. In this connection, reference should be made to G. B. Karelitz' discussion of oil-ring bearings (5).

The tests herein discussed were made to measure these oil-film thicknesses, in order to test the validity and accuracy of curves such as shown in the upper graph in Fig. 3. Using an oil with a viscosity of 110 S.S.U. (16 centipoises, absolute), tests were made at speeds varying from 0 to 900 rpm on a full-size power bearing with 90-deg support angle, 9 in. diam, 0.012 in. diametral clearance, and a projected-area pressure of 100 lb per sq in. A very accurate micrometric electromagnetic measuring arrangement, as described in Appendix 2 and illustrated in Fig. 4, was employed, which allowed the simultaneous recording of the vertical and horizontal instantaneous positions of the shaft with respect to the bearing. A typical oscillograph record is shown in Fig. 7, where the modulations of the carrier frequency are the measures of the shaft position. Tests were conducted for a series of speeds, and the results obtained are shown in Fig. 8, where the instantaneous positions of the shaft are shown plotted within the clearance circle, i.e., a circle of radius δ within which the center is physically confined. If, for the moment, we pass over the fact that the shaft executes cyclical motions at rpm frequency about a mean position, and plot h_{min} against ZN/P as obtained from both these results and calculations based on Karelitz' work, we get the comparison between test results and calculated values as shown in Fig. 9. The agreement between the two is indeed good, especially when we realize that such effects as side and leakage, variable viscosity within the film necessarily are introduced incompletely into an already involved calculation. This, then, can be taken as definite support for the general correctness of values based on pure calculation. Although earlier measurements of oil-film thickness were made by Vieweg (6), Wolff (7), and Hummel (8), it is felt that the aforementioned tests on full-size bearings of commercial design, employing recording apparatus of requisite accuracy, provide a final touch to this phase of fluid-film bearing design. The work of Wolff, particularly, utilizing interferometric means, must have been seriously interfered with by the cyclical motion of the shaft, and probably accounts for its failure to confirm the present results.

The fact that the shaft may not necessarily assume a fixed equilibrium position relative to the sleeve was first investigated analytically and experimentally by Stodola (9) and Hummel (8) in small test bearings, and it was their contention that the film provided a definite elastic force field, which could under circumstances be made to vibrate violently at resonance. While it is not within the scope of this paper to develop this phase of shaft behavior, suffice it to say that simultaneous pedestal vibration readings were taken by means of a Geiger vibrograph, and that whereas a definite critical speed was observed at 700 rpm, the amplitude of motion of the shaft relative to the bearing was still increasing up to 900 rpm and over. Tests were repeated with the machine perfectly balanced and with the rotor as badly unbalanced as personal safety would permit, with no remarkable change in the film records; the pedestal vibration, however, was proportional to the unbalance. All these facts point to a much more complex condition than Stodola assumed, and might well merit a more thorough investigation. The fact, however, that a sustained cyclical motion may take place, suggests a mechanism for supplying energy for the vibration along the general lines of self-induced phenomena, which have been discussed in recent literature. The fact, however, that such shaft motions may exist, presents another possible limitation on the permissible minimum oil-film thickness.

As ZN/P decreases, the rate of lubricant shear becomes higher and higher, and it might well be that the force necessary to tear the oil free from the metal surfaces is reached at a critical shear rate, even if perfect shaft and sleeve surfaces were attainable. As is generally the case, however, the film thins down to the dimensions of the machining irregularities, and actual metal-to-metal contact begins to take place in spots, resulting in an increase of friction. In this region of lubrication, where true film conditions no longer exist, new properties of the lubricant begin to assume greater importance, and oiliness, as it is conveniently termed, begins to be a factor. For such bearings, and they still inevitably exist, as the water-lubricated metal, wood, and fiber types of roll-neck bearings, plane-slide bearings, and rocker bearings, there are different contentions as to what are the proper and best types of lubricant. For this class of bearings, wear is inevitable, while for the fluid-film bearing, bearing life should be indefinite, as long as sufficient lubricant is provided, and frequent stopping and starting is not necessary.

In summary, then, it has been demonstrated that it is tenable and further that a quantitative basis exists, to base bearing design on a minimum oil-film thickness. Further, that for carefully constructed bearings a value of 0.0001 in. may well form the lower limit for h_{min}, compatible with fine machining and absence of distortion. Finally, that viscosity alone, as concerns the lubricant, determines the film thicknesses and bearing losses.

Appendix 1

Simplified Theoretical Considerations in Film-Lubricated Bearings

As a result of Tower's early experiments, and at the suggestion of Lord Rayleigh, Osborne Reynolds developed the modern hydrodynamic theory of film lubrication, and established the important fundamental fact that real bearing capacity is only

developed when a wedge-shaped film can be formed, the wedge narrowing in the direction of the sliding surface.

Modern expositions of journal-bearing theory have been given by Howarth (10), Kingsbury (11), and Karelitz (4), but the following presentation gives the salient relations in a simple general form. Beginning with Reynolds' simplified fluid-flow equations

$$\frac{d}{dx}\left(h^3\frac{dp}{dx}\right) = -6ZU\frac{dh}{dx} \quad \ldots\ldots [1]$$

$$f = \frac{ZU}{h} + \frac{h}{2}\frac{dp}{dx} \quad \ldots\ldots [2]$$

where h is the film thickness, p is the oil-film pressure, and f is the shearing stress in the oil.

Integrating Equation [1], and calling $h = h'$ at the point of maximum pressure, i.e., at $dp/dx = 0$ or $p = p_{max}$, we get

$$\frac{dp}{dx} = -6ZU\frac{h - h'}{h^3} \quad \ldots\ldots [3]$$

Now for the case of a clearance type of sleeve bearing, such as shown in Fig. 2, let

$$x = r\theta$$
$$e = c\delta, \text{ where } \delta = mr(c < 1)$$
$$h = mr(1 + c\cos\theta), \text{ and}$$
$$h_{min} = mr(1 - c);\quad h' = mr(1 + c\cos\theta')$$

By substituting these values in Equation [3]

$$\frac{dp}{d\theta} = \frac{6ZU}{m^2r}f(\theta, \theta', c) \quad \ldots\ldots [4]$$

where $f(\theta, \theta', c)$ is a definite function, the form of which we are not concerned with for the time being.

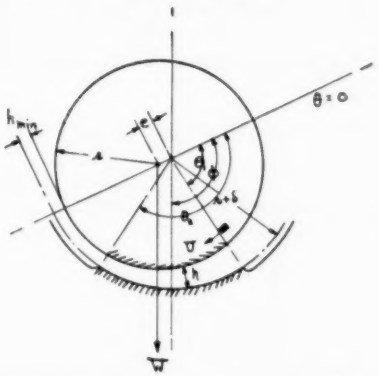

FIG. 2 CLEARANCE TYPE OF SLEEVE BEARING USED IN THE TESTS

Integrating Equation [4]

$$p = \frac{6ZU}{m^2r}F(\theta, \theta', \theta_1, c) \quad \ldots\ldots [5]$$

Now since $p = 0$ for $\theta = \theta_1$, and $\theta = \theta_2$, we see that the second of the two conditions fixes a relation between θ and c for a given bearing arc (θ_1, θ_2), i.e., Equation [5] may be modified to

$$p = \frac{6ZU}{m^2r}F'(\theta, \theta_1, \theta_2, c) \quad \ldots\ldots [6]$$

Now since the vertical component of the bearing pressure must equal the load, W, then, too, the component of W along and perpendicular to the line $\theta = 0$ must equal the sum of the p components along the same directions, i.e.,

$$\left.\begin{aligned} W\cos\phi &= r\int_{\theta_1}^{\theta_2} p\cos\theta\, d\theta \\ W\sin\phi &= r\int_{\theta_1}^{\theta_2} p\sin\theta\, d\theta \end{aligned}\right\} \quad \ldots\ldots [7]$$

Integrating by parts:

$$\left.\begin{aligned} W\cos\phi &= r(p\sin\theta)\Big|_{\theta_1}^{\theta_2} - r\int_{\theta_1}^{\theta_2}\frac{dp}{d\theta}\sin\theta\, d\theta \\ &\quad\Big\|\ 0 \\ W\sin\phi &= -r(p\cos\theta)\Big|_{\theta_1}^{\theta_2} + r\int_{\theta_1}^{\theta_2}\frac{dp}{d\theta}\cos\theta\, d\theta \end{aligned}\right\} \quad \ldots\ldots [8]$$

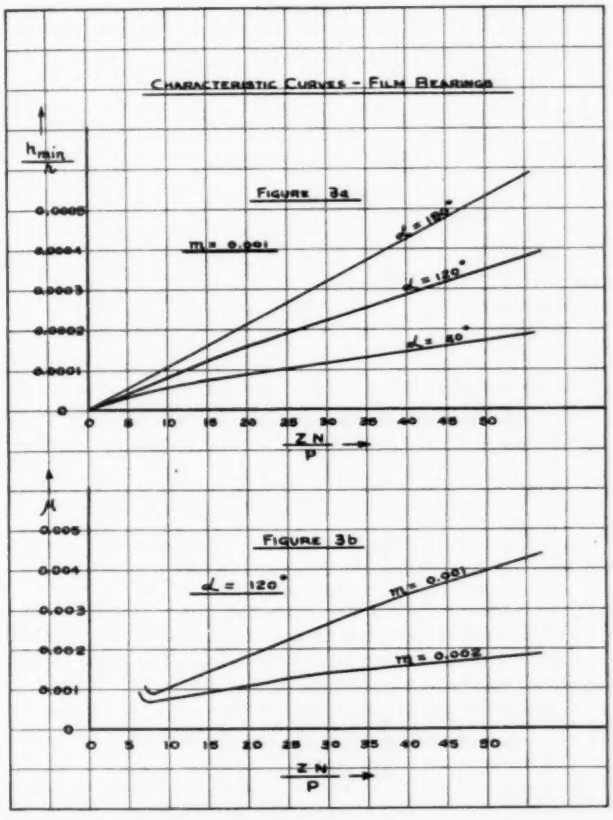

FIG. 3 CHARACTERISTIC CURVES OF FLUID-FILM BEARINGS

Combining Equations [4] and [8]

$$W\cos\phi = \frac{6ZU}{m^2}g_1(\theta_1, \theta_2, c)$$

$$W\sin\phi = \frac{6ZU}{m^2}g_2(\theta_1, \theta_2, c)$$

or $$W = \frac{6ZU}{m^2}\sqrt{g_1^2 + g_2^2} = \frac{6ZU}{m^2}G(\theta_1, \theta_2, c) \quad \ldots\ldots [9]$$

Since $U = 2\pi rN$ and $W = 2rP$, where P is the projected area pressure, we may write

$$c = G'\left(\theta_1, \theta_2, m, \frac{ZN}{P}\right) \quad \ldots\ldots [10]$$

and since $h_{min} = mr(1 - c)$, then finally

$$\frac{h_{min}}{r} = H\left(\theta_1, \theta_2, m, \frac{ZN}{P}\right) \quad \ldots\ldots [11]$$

Thus for a given bearing design—θ_1, θ_2, m, and r—h_{min} and ZN/P are definitely related, as worked out numerically by Karelitz. The quantitative relations are given in the upper graph in Fig. 3, for $m = 0.001$ and $\alpha = \theta_2 - \theta_1$, symmetrical with respect to the vertical.

Proceeding further, from Equations [2] and [4], we get directly

$$f = \frac{ZU}{mr} k(\theta, \theta', c) \quad \ldots\ldots\ldots\ldots\ldots\ldots [12]$$

Without going too far into all the considerations involved, the equivalent force, F, which multiplied by the radius produces the frictional torque, may be defined as

$$F = \int_{\theta_1}^{\theta_2} f\, r\, d\theta = \frac{ZU}{m} K(\theta_1, \theta_2, c) \ldots\ldots\ldots [13]$$

and the equivalent coefficient of friction defined as $\mu = F/W$ is obtained from Equations [9] and [13] to be

$$\mu = \frac{m}{6} \frac{K(\theta_1, \theta_2, c)}{G(\theta_1, \theta_2, c)}$$

But since c is a function of ZN/P as seen from Equation [10], we may also write

$$\mu = Q(\theta_1, \theta_2, m, ZN/P) \ldots\ldots\ldots\ldots\ldots\ldots [14]$$

Relations between μ and ZN/P have been experimentally determined and checked analytically by several men, including McKee, and are of the general nature of the lower graph in Fig. 3.

Appendix 2

Electromagnetic Micrometer for Determining Shaft Positions

The experimental apparatus employed in this investigation is extremely accurate, accuracy to less than $^1/_{100,000}$ in. being readily obtained. The apparatus also provided at the same time a means of recording the motion of the shaft. The schematic arrangement of the apparatus is shown in Fig. 4. Its fundamental principle is illustrated in Figs. 6*a* and 6*b*. An oscillographic record obtained by its use is shown in Fig. 7.

Referring to Fig. 6*a*, it will be seen that the electromagnetic micrometer is in reality two coupled variable-reluctance transformers, indicated by the two flux paths ϕ_1 and ϕ_2. The primaries

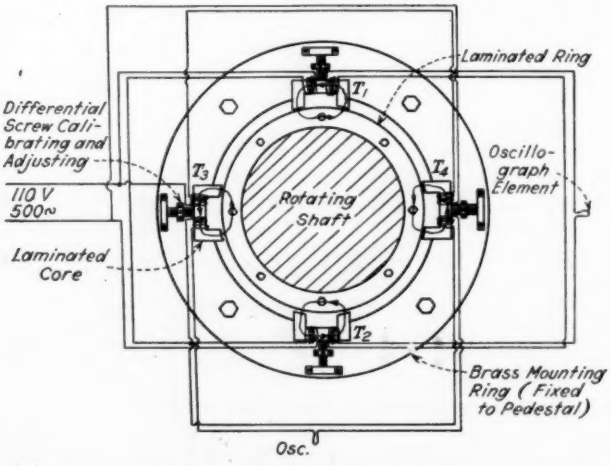

Fig. 4 Principle of the Electromagnetic Micrometer

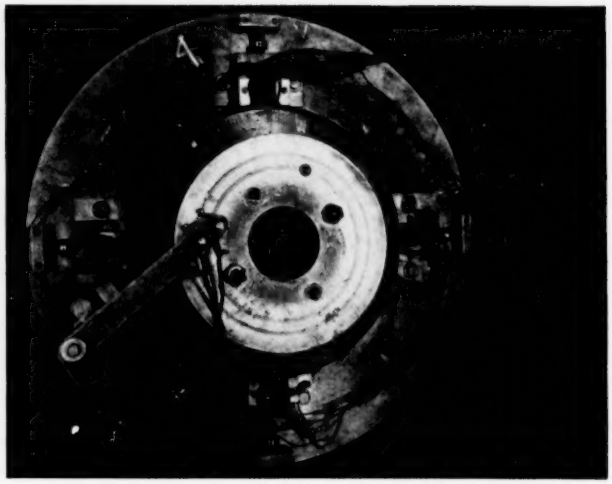

Fig. 5 Experimental Set-Up for Determining Thickness of the Oil Film

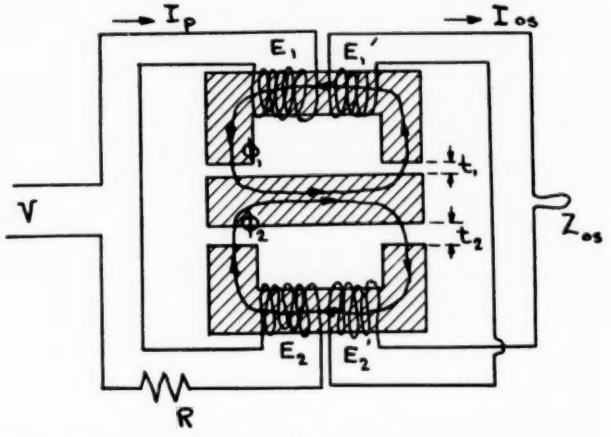

Fig. 6*a* Circuit Diagram of Electromagnetic Micrometer

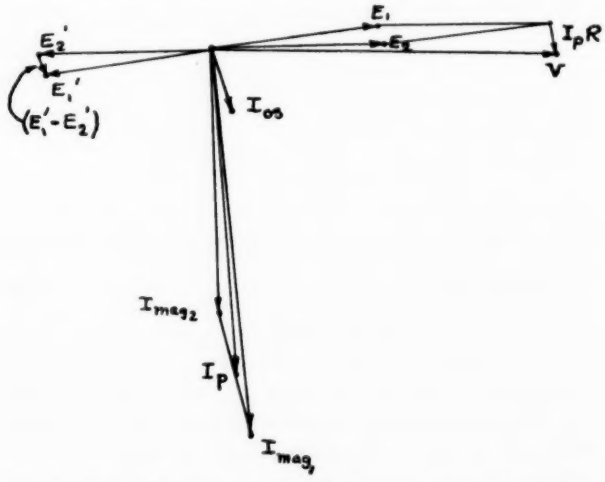

Fig. 6*b* Vector Diagram of the Electromagnetic Micrometer

are connected in series, and the secondaries in series opposed. For a central position of the armature ($t_1 = t_2$), $E_1 = E_2$ and so $E'_2 - E'_1 = 0$. For a slight movement of the armature, an appreciable value of $E'_2 - E'_1$ is obtained which is a direct measure of the movement.

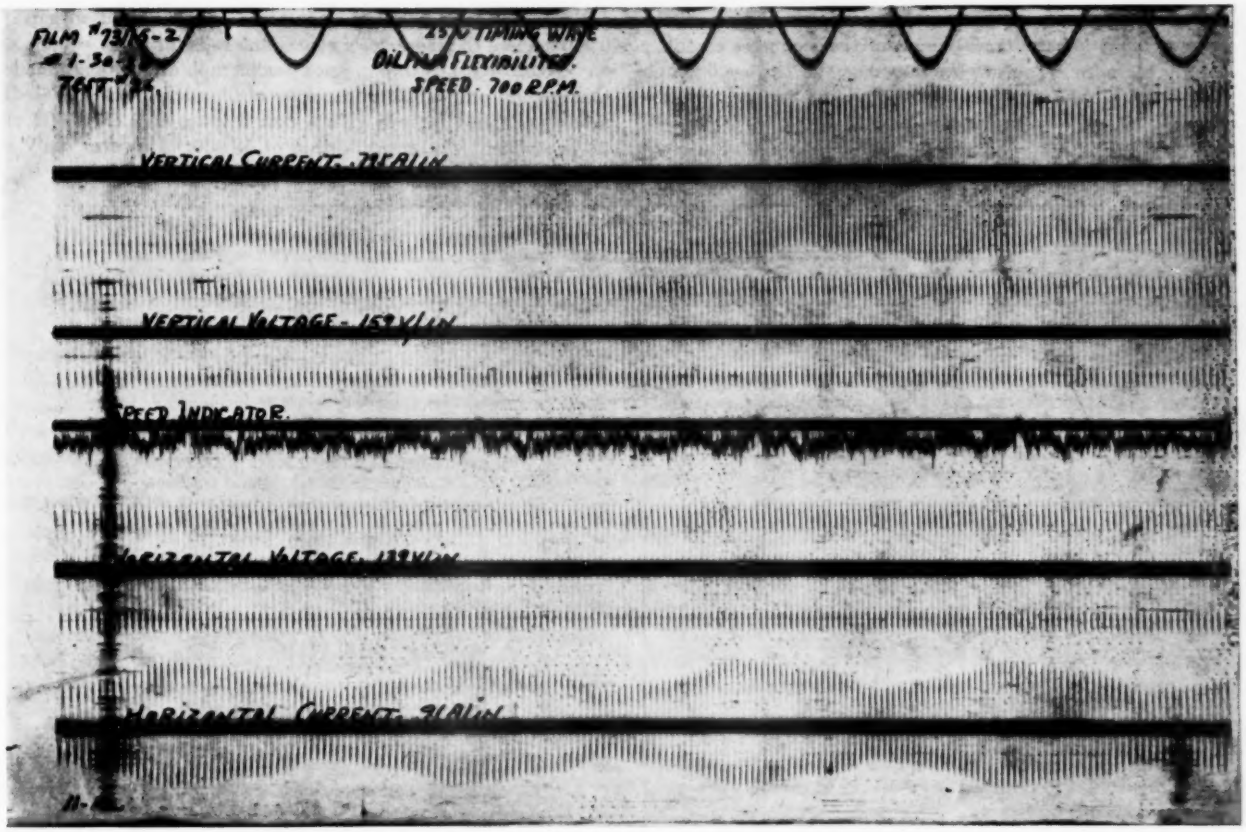

FIG. 7 OSCILLOGRAPHIC RECORD OBTAINED WITH THE ELECTROMAGNETIC MEASURING ARRANGEMENT. THE MODULATIONS OF THE CARRIER FREQUENCY ARE THE MEASURES OF SHAFT POSITION WITH RESPECT TO THE BEARING SURFACE

To determine the sensitivity of the instruments quantitatively, the simple vectorial-circuit equations can be written

$$E'_1 - E'_2 = I_{os}Z_{os}$$

or

$$\left.\begin{aligned} E_2 - E_1 &= I_{os}Z_{os} \\ V &= E_1 + E_2 + I_pR \\ I_{mag1} &= K_1E_1 \\ I_{mag2} &= K_2E_2 \\ I_p &= K_1E_1 - I_{os} \\ I_p &= K_2E_2 + I_{os} \end{aligned}\right\} \quad \ldots\ldots [15]$$

By elimination and combination among Equations [15], the final expression for the oscillograph current becomes

$$I_{os} = V\left[\frac{K_1 - K_2}{(K_1 + K_2)Z_{os} + 4 + R(K_1 + K_2 + K_1K_2Z_{os})}\right] \ldots [16]$$

Now K is the reciprocal of the inductive reactance of the coils. For the central position of the armature, $K_1 = K_2 = K_0$ and for a displaced position of the armature, the increase and decrease in the K's is the same, i.e.

$$\left.\begin{aligned} K_1 &= K_0(1 + \epsilon) \\ K_2 &= K_0(1 - \epsilon) \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots [17]$$

which influences Equation [16] to become

$$I_{os} = V\left[\frac{\epsilon}{Z_{os} + \frac{2}{K_0} + R\left(1 + \frac{K_0}{2}Z_{os} - \frac{K_0}{2}Z_{os}\,\epsilon^2\right)}\right] \ldots [18]$$

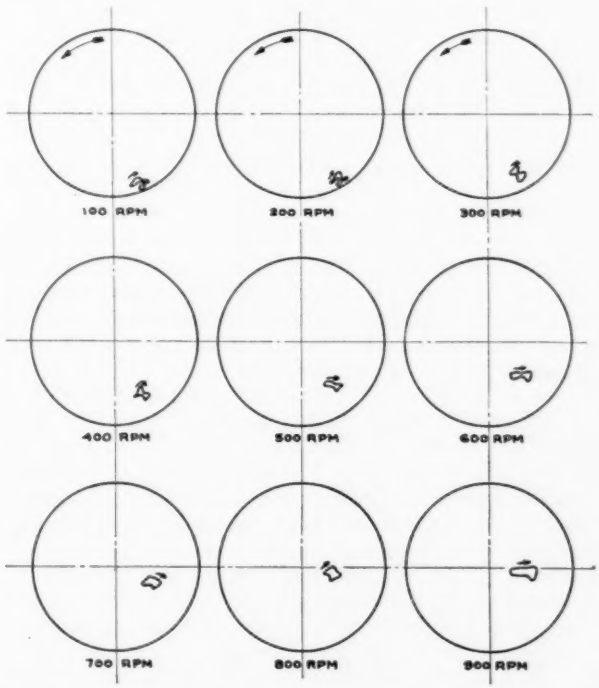

FIG. 8 SHAFT MOTIONS AND POSITIONS PLOTTED WITHIN THE CLEARANCE CIRCLE

For the instrument as built, there are 150 turns per coil, an air gap of 0.050 in., the cross-section of the magnetic circuit is $^1/_2$ in. by $^1/_2$ in. or $^1/_4$ sq in., the impedance of the oscillograph circuit is 1.5 ohms (pure resistance), and the primary coil resistance is 0.90 ohm. Thus $K_0 = 0.176$, where the carrier frequency was picked equal to 500 cycles, and hence vectorially:

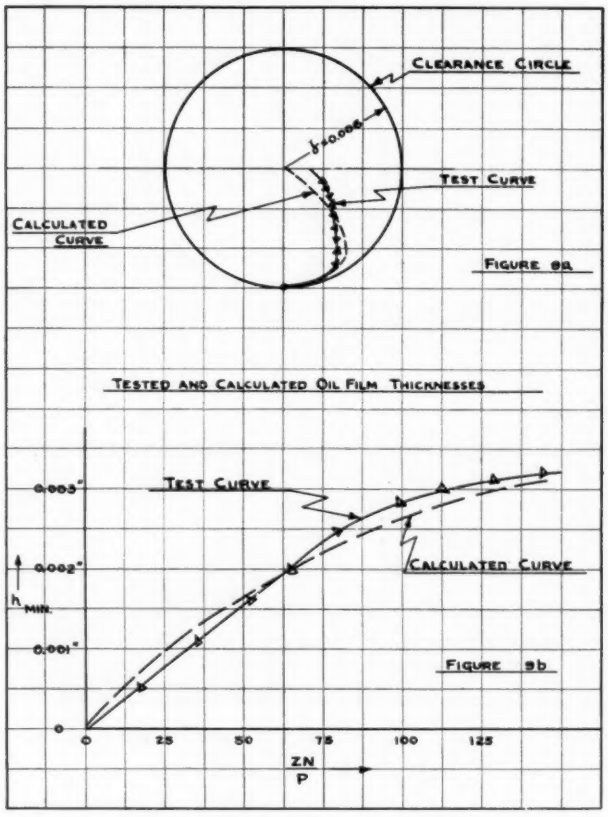

FIG. 9 A COMPARISON BETWEEN TEST RESULTS AND CALCULATED VALUES OF OIL-FILM THICKNESS

$$\left.\begin{aligned} V &= 65 + j\,0 \\ R &= 0.9 + j\,0 \\ Z_{os} &= 1.5 + j\,0 \\ K_0 &= 0 - j\,0.176 \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots [19]$$

Substituting Equation [19] in the various expressions for E_1, E_2, I_{mag1}, I_{mag2}, I_p, I_{os}, etc., we get the vector diagram as shown in Fig. 6*b*, which illustrates the theory of the micrometer. For the purpose of rapid calculation, however, a simplified interpretation of Equation [19] shows that

$$I_{os} = \frac{K_0 V \epsilon}{2} = 0.09\, V\epsilon$$

For a motion of 0.001 in., $\epsilon = 0.02$ since the initial air gap is 0.050 in., and therefore, for a value of 65 volts for V, $I_{os} = 0.09 \times 65 \times 0.02 = 0.117$ amp. Since oscillograph elements are made that require only 0.002 amp per in. of film deflection, this shaft motion of 0.001 in. will give a film reading of 0.117/0.002 or 58 in., which is a magnification of 58,000. However, only a magnification of 1000/1 was actually utilized during the tests.

LIST OF SYMBOLS

Z = absolute viscosity (centipoises)
N = rpm of shaft
P = projected area pressure (lb per sq in.)
μ = equivalent coefficient of friction
U = rubbing speed (ft per min)
h = film thickness
h_{min} = minimum oil-film thickness
h' = film thickness at point of maximum pressure
p = oil-film pressure (lb per sq in.)
f = shearing stress in oil
x, θ = general linear and angular coordinates
θ_1, θ_2 = angles defining bearing arc with respect to location of minimum oil-film thickness (radians)
ϕ = angle defining position of load with respect to location of minimum oil-film thickness (radians)
r = journal radius (inches)
δ = radial clearance (inches)
e = eccentricity of bearing (inches)
m = ratio = δ/r
c = ratio = e/δ
V = applied potential (volts)
E_1, E_2 = back emf in primary windings (volts)
E'_1, E'_2 = induced voltages in secondary windings (volts)
I_p = primary current (amperes)
I_{os} = oscillograph current (amperes)
I_{mag1}, I_{mag2} = magnetizing current for the two transformers (amperes)
R = primary resistance (ohms)
Z_{os} = oscillograph impedance (ohms)
K_0, K_1, K_2 = permittance values (ohms)
ϵ = ratio of armature movement, with reference to normal air gap

Review of Recent Research in Thermodynamics

By JOHN A. GOFF,[1] URBANA, ILL.

ACTIVITY in steam research still deserves prominence in a report of progress in thermodynamics. In the United States, Keyes, Smith, and Gerry (1)[2] present an interesting formulation of p-v-t data for superheated steam obtained at Massachusetts Institute of Technology. In the first place, it is noted that extrapolation to the saturation limit appears to give reliable values of the saturation volumes. From the formulation, three different relations are deduced by application of the general equations of thermodynamics: The first gives $c_{p=0}$, the isobaric specific heat of the limiting zero-pressure or perfect-gas state which is a function of temperature only, in terms of h'', the enthalpy at saturation; the second gives $c_{p=0}$ in terms of c_p; the third gives $c_{p=0}$ in terms of μ, the Joule-Thomson coefficient. Using the experimental data of Osborne, Stimson, and Fiock for h'', those of Koch for c_p, and those of Davis and Kleinschmidt for μ, an ensemble of $c_{p=0}$ values is obtained from which an empirical equation is deduced by the method of least squares after excluding c_p values of Koch near saturation. The reason for excluding these values is that they exhibit a sharply increasing trend becoming quite pronounced at high pressures, and, in the opinion of the authors, indicate that the Koch c_p data near saturation are in error.

Since this report was written, Keyes, Smith, and Gerry (13) have revised their formulation, taking account of new low-pressure data by S. C. Collins obtained with the new calorimeter which measures $(dh/dp)_T$ and $(dT/dp)_h$ in the same apparatus and correcting an error of computation of the p^{12} term in the p-v-t formulation previously referred to. Moreover, the indirect determination of $c_{p=0}$ as already described has been abandoned and values taken directly from measurements of the band spectrum of water vapor have been used instead. The results of these changes are better agreement with the Joule-Thomson data of Davis and Kleinschmidt and satisfactory accord with the c_p values of Koch near saturation.

Smith and Keyes (2) present a formulation of the M.I.T. liquid-volume data which also appears to give reliable values of saturation volumes by extrapolation. Using experimental data of Osborne, Stimson, and Fiock on h', the enthalpy of saturated liquid, values of the isobaric specific heat of the liquid at saturation are deduced by application of the general thermodynamic equations. Osborne, Stimson, and Ginnings (3) present a report of progress in calorimetric determinations of the enthalpies of saturated liquid and vapor at the United States Bureau of Standards. To date, the results for the liquid thoroughly cover the range up to 370 C (3050 lb per sq in.); for the vapor, the results are not so complete, but include measurements at 325 C (1750 lb per sq in.) and 350 C (2400 lb per sq in.). Osborne, Stimson, and Ginnings (14) have, since this report was written, communicated additional measurements on the enthalpies of saturated liquid and vapor as prepared for presentation at the International Steam Tables Conference of 1934. Completion of a detailed report has been postponed pending further experiments near the critical region. A valuable contribution to the knowledge of the pressure-temperature relation at saturation is a formula constructed by Osborne and Meyers (4) based on all available trustworthy data and covering the whole range from 0 to 374 C. The formula gives what are considered best values not only of the pressure-temperature relation itself, but also of the pressure-temperature derivative. The authors offer their formula as suitable for adoption in the International Skeleton Steam Table at its next revision.

In Germany, Jakob and Fritz (5) have extended their measurements of heat of vaporization r from 310 C (101 kg per sq cm) to 340 C (149 kg per sq cm). Koch (6) presents measurements of the isobaric specific heat c_p of liquid water from 0 to 350 C and from saturation to pressures as high as 260 kg per sq cm; each isobar on the c_p t-plane exhibits the well-known minimum value above 0 C and a rapid rise at higher temperatures.

Of importance especially to the thermodynamics of combustion, is a critical study by E. Justi (7) of available high-temperature specific-heat data for water vapor and other so-called technical gases. The author judges it proper to disregard values obtained by the explosion method as being generally too high, also those obtained by the sound-velocity method as being generally too low; only values obtained by the Lummer-Pringsheim and flow methods are considered reliable. These latter are shown to be in good agreement with values deduced from spectroscopic measurements which are therefore used as a basis for the construction of $c_{p=0}$ t-tables extending up to 3000 C. Equilibrium constants and their variation with temperature as deduced from the specific-heat data are also given for use in calculation of dissociation.

Under the heading of dynamical properties, may be mentioned determinations of the viscosity of superheated steam presented by Schiller (8). The flow-velocity at which the discharge coefficient of a suitable nozzle executes an abrupt rise was observed for water as a reference medium and for steam. Equating the two Reynolds numbers gives a relation from which the viscosity of steam in terms of that of water can be calculated. The results show a characteristic dependence of viscosity upon pressure as well as temperature which appears to admit of reasonable extrapolation to the critical point. Of importance to the subject of heat transfer are measurements by E. Schmidt (9) of the relative radiation constants of water and ice forming wetted and frosted surfaces. Thin layers of frost appear to emit as much as 98.5 per cent of black-body radiation, this figure being the highest yet measured.

Supersaturation of steam is the subject of a paper by Yellott (10). By means of a search tube, the variation of static pressure along the axis of a nozzle of rectangular cross-section with one glass side plate was measured. Under illumination along the nozzle axis, condensation in very small drops—as evidenced by the fact that the incident light was scattered rather than reflected and that the scattered light was blue in color—was seen to occur suddenly at a point where the static pressure executed an abrupt rise. In a written discussion of the paper, Keenan (11) presented an interesting analysis of the phenomena involved.

An experimental investigation of the changes of state occurring in the uniflow engine has been reported by Ulsamer (12). Temperature measurements in the clearance space and at various points on the cylinder walls disclose the fact that the main portion

[2] Numbers in parentheses refer to bibliography at the end of the paper.

of the cylinder steam never crosses the saturation curve but remains superheated even though the initial superheat is quite small. On the basis of this fact, simultaneous measurements of temperature and pressure suffice to follow the course of evaporation and condensation on the cylinder walls.

Design Data

It is important that the data contained in technical papers be made readily available to designing engineers. In order to satisfy these needs of industry, this section of the Journal will include a concise presentation of data and information drawn chiefly from papers previously published by the Applied Mechanics Division of The American Society of Mechanical Engineers.

The data are prepared by a subcommittee of the Applied Mechanics Division on strength of materials (R. E. Peterson, chairman), under the guidance of S. Timoshenko.

Factors of Stress Concentration Photoelastically Determined[1]

By MAX M. FROCHT,[2] PITTSBURGH, PA.

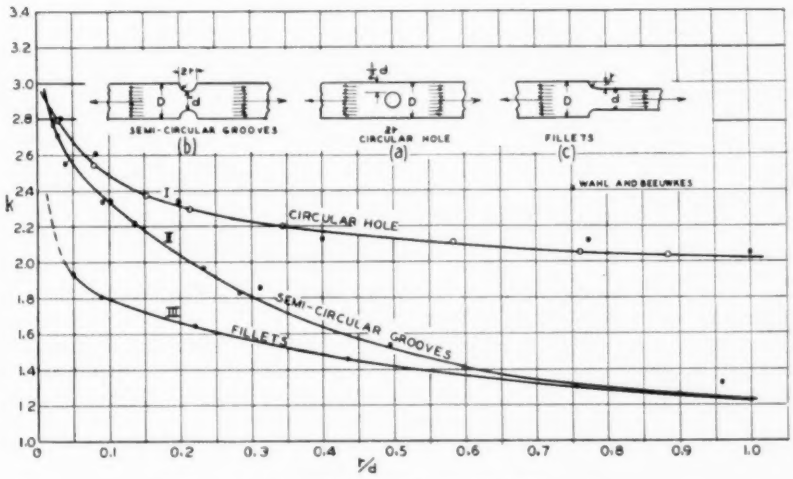

FIG. 1 INVARIANT CASES IN TENSION OR COMPRESSION

THE factor of stress concentration is defined as the ratio of the maximum to the minimum stress in the section, or $k = s_m/s$, where

k = factor of stress concentration
s_m = maximum stress in section
s = average stress in section = P/A
P = axial load
A = cross-sectional area of minimum section

Experiments show that the factor of stress concentration is a function of the ratio r/d, Fig. 1, and of the stress distribution on both sides of the discontinuity. The special cases in which the factors of stress concentration can be expressed as a function of r/d only are here defined as invariant cases. Three basic invariant cases are shown in Fig. 1. Curves I, II, and III, Fig. 1, give k as a function of r/d, respectively, for circular holes, semi-circular grooves, and fillets between fields of uniform tension or compression.[3]

Pure bending as used here refers to that in which the bending moment is constant and the longitudinal stresses are linear on each side of the discontinuity, Fig. 2.

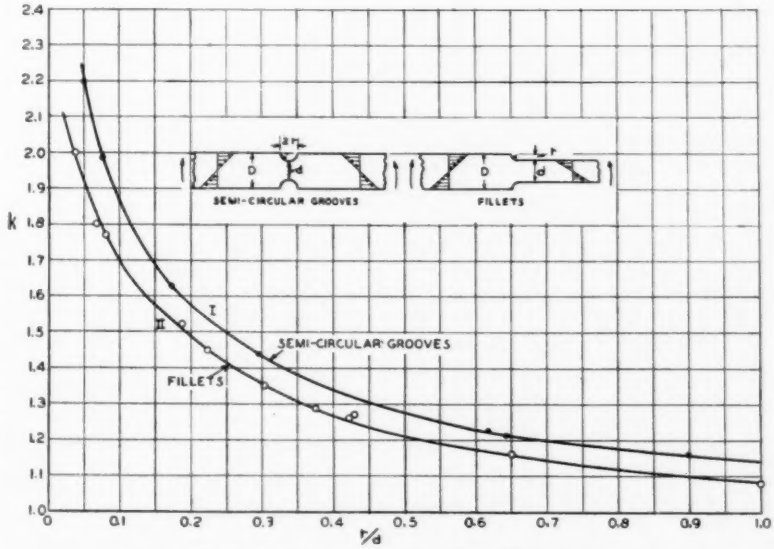

FIG. 2 INVARIANT CASES IN PURE BENDING

[1] Special cases from a paper by the author entitled "Photoelastic Studies in Stress Concentrations," to be presented at the National Meeting, Ann Arbor, Mich., June 18 and 19, 1935, of the Applied Mechanics Division of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS. Other nonvariant cases and related aspects of stress concentrations are included in the paper.

[2] Associate Professor of Mechanics, Carnegie Institute of Technology.

[3] Present results are in good agreement with those from comparable tests by other investigators.

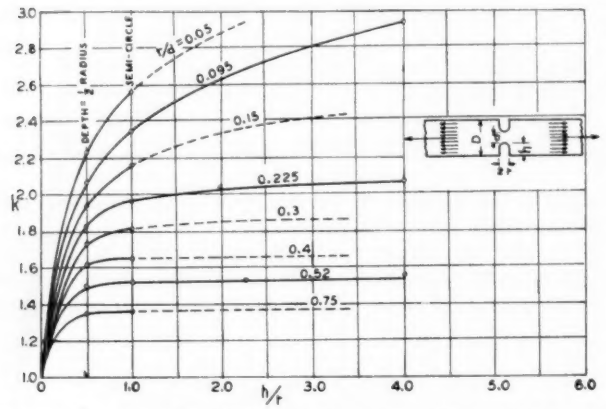

FIG. 3 FACTORS OF STRESS CONCENTRATION FOR GROOVES OF VARYING DEPTHS IN TENSION OR COMPRESSION

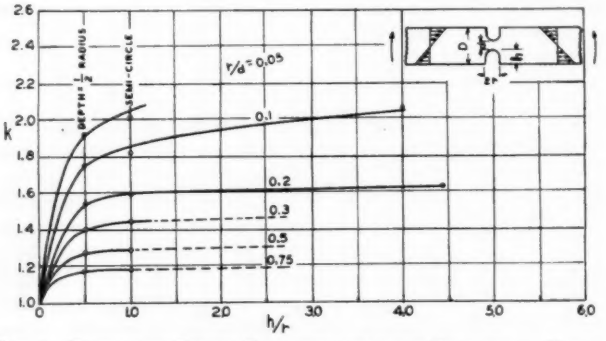

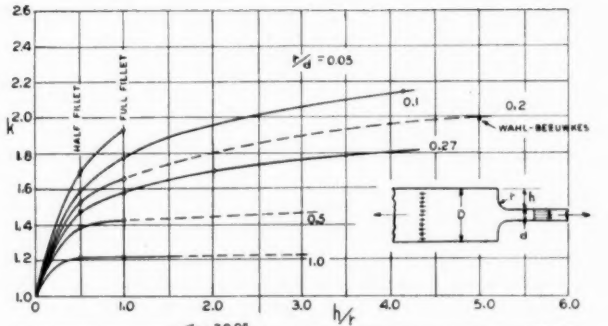

FIG. 4 FACTORS OF STRESS CONCENTRATION FOR GROOVES OF VARYING DEPTHS IN PURE BENDING

Curves I and II, Fig. 2, give k as a function of r/d for two basic invariant cases—semi-circular grooves and fillets.

Referring to Fig. 3 a deep groove is one in which h/r is greater than unity and a shallow groove one in which h/r is less than unity.

The effect of deep grooves depends on the ratio r/d. For small values of r/d such as 0.2 or less there is a pronounced increase

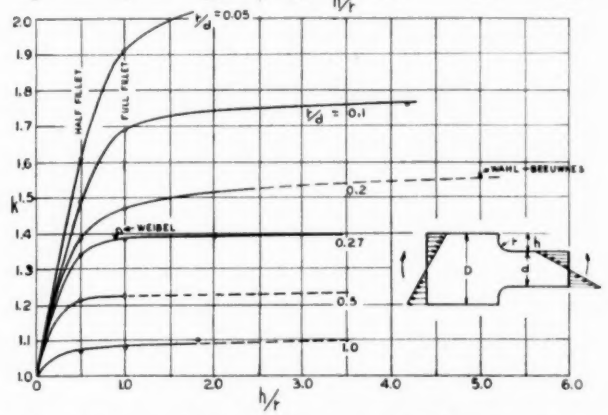

FIG. 5 FACTORS OF STRESS CONCENTRATION FOR FILLETS OF VARYING DEPTHS IN TENSION OR COMPRESSION

FIG. 6 FACTORS OF STRESS CONCENTRATION FOR FILLETS OF VARYING DEPTHS IN PURE BENDING

in the value of k as h/r increases. This increase is more noticeable in tension than in bending.

Shallow grooves reduce the factors of stress concentration, k approaching unity as h/r approaches zero. The curves in Figs. 3 and 4 show k as a function of h/r in pure tension and pure bending, respectively.

The curves in Figs. 5 and 6 show k as a function of h/r for fillets in pure tension, compression, and bending.

Discussion

Fatigue of Shafts at Fitted Members, With a Related Photoelastic Analysis[1]

CHARLES S. BARRETT.[2] The surface-rolling treatment that is so effectively used by the authors offers some worth-while problems to those interested in the practical applications of X-rays. We should like to be able to settle by X-rays whether or not the rolling is effective through the action of the internal stresses it produces. The fact that the diameter of the specimen is always decreased by the rolling seems to me to point to such stresses. There could scarcely be enough voids in the metal, closed up by the rolling, to account for the decrease in diameter; it more probably occurs through an increase in length, which would put the core of the specimens in tension and the outer fibers in compression. Perhaps the decrease in density of the outer layer, which results from the cold-working process, is an important factor in building up these stresses. It has recently been shown by Buchholtz and Buehler that compressive stresses in the outer fibers can materially increase the endurance limit, and it remains only to prove their existence in surface-rolled specimens. While X-rays have been used for stress measurement, they are at a disadvantage when dealing with cold-worked metal such as this, and the problem can better be attacked by the usual mechanical methods.

There is another item in the rolling technique, however, that can be studied effectively by X-rays; namely, the depth to which the metal is cold worked. There is an X-ray method available for measuring this depth simply and directly which I have used on one of the authors' specimens. It involves the principle that the Debye rings in a diffraction pattern from a metal are made up of spots which lose their sharpness and distinctness when the metal is cold worked. The penetration of the cold-worked layer may be determined by taking a series of photograms at different depths and observing the amount of fuzziness and overlapping of the diffraction spots on each photogram.

This method was applied to one of the authors' cantilever specimens of 0.42 per cent carbon whose surface had been cold worked by rollers of 2-in. diam and $1^1/_2$-in. contour radius under a radial force of 400 lb. The specimen was studied at a point along its length where its diameter was $1^5/_8$ in. It was mounted in a back-reflection X-ray camera in which cobalt radiation was used so that the penetration of the X-rays into the specimen was negligible. The diffraction pattern of the surface of the specimen showed a continuous ring of completely overlapping spots. A layer 0.014 in. thick was etched away with 50 per cent nitric acid and another photogram prepared of the metal thus exposed. The effects of the cold work was less severe at this depth. Photograms after etching to depths of 0.035 in., 0.040 in., 0.044 in., and 0.049 in. showed a steadily decreasing amount of cold work, and when a depth of 0.059 in. was reached, the photograms consisted of spots as sharp as those from the center of the specimen. From the evidence of these photograms we may conclude that to a depth of perhaps 0.030 in. all the grains were plastically deformed, that between 0.030 in. and 0.055 in. certain grains were deformed and others were not, and that below 0.055 in., ± 0.005 in., there was no plastic deformation. Mr. Peterson tells me that if one calculates the stress intensities under the rolls by the formula of Thomas and Hoersch, the penetration can be estimated, and that for this specimen it is in the neighborhood of 0.067 in., slightly greater than was found by the X-rays.

S. WAY.[3] In this paper the subject of increasing fatigue strength by surface rolling is introduced. In this connection, it is desirable to know approximately the depth of cold worked material when a shaft is rolled with rollers of a certain form under a certain load.

If an elastic body has another brought into contact with it, the greatest principal shearing stress along a line normal to the surface and extending inward from the center of the contact area will vary as shown in Fig. 1 of this discussion. The shear

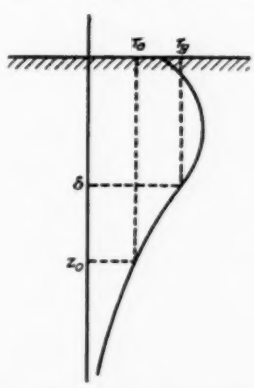

FIG. 1 VARIATION OF PRINCIPAL SHEARING STRESS ALONG A LINE NORMAL TO THE SURFACE OF AN ELASTIC BODY WHEN ANOTHER BODY IS BROUGHT INTO CONTACT WITH IT

stress τ_0 occurs at depth z_0. When a shaft is rolled, a layer of material of thickness δ will have experienced plastic deformation. Assume that the stress system under the roller at a depth greater than δ is negligibly different from that which would exist were the body perfectly elastic. The depth δ can then be determined as the place where the shear stress is equal to the yield strength, τ_y. The yield strength in shear should be taken equal to one-half that in pure tension. This can be demonstrated by the energy of distortion theory of strength when two of the principal stresses are equal, as is very nearly the case in the problem at hand.

In calculating the depth, z, of the point where the shear stress is τ, three relations will be of interest. The first is the Boussinesq formula for the case of a load applied at a point:

$$\tau = \frac{P}{8\pi}\left[\frac{7-2\mu}{z^2}\right] \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

For a circular contact area we have

$$\tau = \frac{aE}{2R(1-\mu^2)}\left[\frac{3}{\pi}\frac{a^2}{a^2+z^2} + \frac{2}{\pi}(1+\mu)\left(\frac{z}{a}\cot^{-1}\frac{z}{a} - 1\right)\right] \quad \ldots\ldots\ldots [2]$$

[1] By R. E. Peterson and A. M. Wahl. Published in the March, 1935, issue of the JOURNAL OF APPLIED MECHANICS (A.S.M.E. Transactions).

[3] Westinghouse Research Laboratories, East Pittsburgh, Pa.

where a is the radius of the circle of contact and $\frac{1}{R}$ is the average of the four principal curvatures of the two bodies. For the general case[4] of an elliptical contact area of major semi-axis, a, and minor semi-axis, b

$$\tau = \frac{aE}{R(1-\mu^2)} \cdot f\left(k, \mu, \frac{z}{a}\right); \quad k = \frac{b}{a} \ldots\ldots\ldots [3]$$

The semi-axis, a, is given by

$$a = \sqrt[3]{\left(\frac{3PR(1-\mu^2)E(k')}{2\pi k^2 E}\right)}; \quad k'^2 = 1 - k^2 \ldots\ldots [4]$$

which, for the case of the circular contact area, reduces to

$$a = \sqrt[3]{\left(\frac{3PR(1-\mu^2)}{4E}\right)} \ldots\ldots\ldots\ldots [5]$$

Using relations expressed in Equations [3] and [4], τ was calculated as a function of z for $R = 1$ in., $P = 1000$ lb, $\mu = {}^3/_{10}$ and $E = 30 \times 10^6$ lb per sq in., and for various values of k. The results are plotted in Fig. 2, showing the effect of the manner

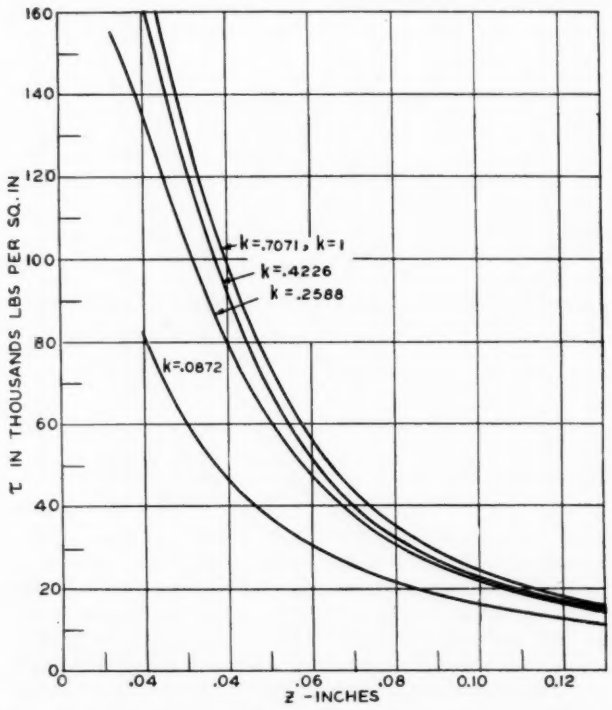

FIG. 2 SHEAR STRESS AT VARIOUS DEPTHS WHEN $P = 1000$ LB, $R = 1$, AND $K = b/a$

of distribution of the contact pressure on the shearing stress beneath the surface. For values of k greater than 0.5 we see it is justifiable to assume we have a circular contact area.

Using relations [2] and [5], τ was plotted in Fig. 3 as a function of z for $P = 1000$ lb, $\mu = {}^3/_{10}$, $E = 30 \times 10^6$ lb per sq in. and for various values of R. These curves can be used when k is greater than 0.5 as well as for the special case $k = 1$. The curve $R = 0$ is obtained from the Boussinesq solution, Equation [1]. If we have a load $P_1 = 1000\,m$, the stress $\tau_1 = \tau\sqrt[3]{m}$ will exist at depth $z_1 = z\sqrt[3]{m}$, where τ is the stress at depth z with 1000 lb load. This can easily be verified by inspection of Equations [2] and [5].

Example. Radius of shaft = 1.5 in.; radius of roller = 1.02 in.; radius of roller in plane of shaft axis = 1.5 in.; $\tau_y = 30{,}000$ lb per sq in. Required the load on the rollers necessary to cause cold working to a depth of 0.2 in.

$$\frac{1}{R} = \frac{1}{4}\left(\frac{1}{1.5} + \frac{1}{1.5} + \frac{1}{1.02} + \frac{1}{\infty}\right) = \frac{1}{1.728}$$

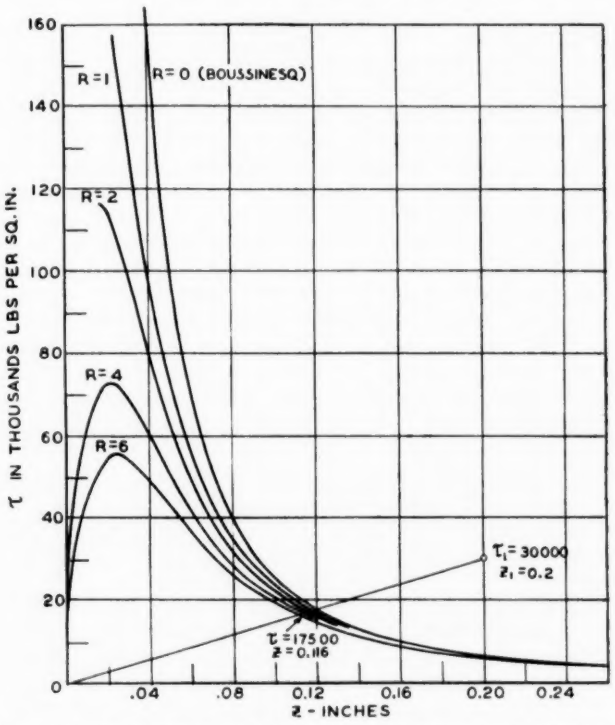

FIG. 3 SHEAR STRESS AT VARIOUS DEPTHS WHEN $P = 1000$ LB, AND $k = 1$

Calculation[4] shows that $k = 0.55$, so we use the curves in Fig. 3. In Fig. 3 let a radial line be drawn from the origin to the point $\tau_1 = 30{,}000$, $z_1 = 0.2$. This line would meet the curve for $R = 1.728$ at the point $\tau = 17{,}400$, $z = 0.116$. m is now determined, for

$$\sqrt[3]{m} = \frac{2}{0.116} = \frac{30{,}000}{17{,}400} = 1.724$$

$$m = 5.12$$

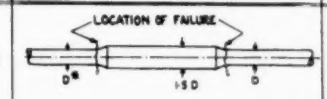
The required load is therefore 5120 lb. The Boussinesq relation, Equation [1] gives $P_1 = 4730$ lb. If a load of 4730 lb. were used, the penetration by the relation expressed in Equation [2] would be 0.194 in., instead of 0.2 in., so the Boussinesq formula is only slightly in error. The range of values over which the Boussinesq solution should be applied can be estimated from Fig. 3.

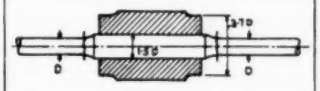
For k less than 0.5 the curves in Fig. 2 should be used. If $P_1 = 1000\,m$, $R_1 = n \times 1 = n$ the stress $\tau_1 = \tau\sqrt[3]{(m/n^2)}$ will be at the point $z_1 = z\sqrt[3]{(mn)}$, where τ is the stress at the point z with $P = 1000$ lb and $R = 1$.

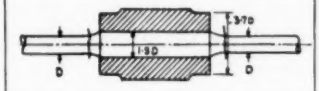
The condition[4] for k to be greater than 0.5 is that

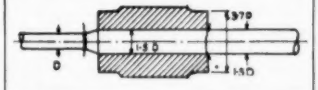
$$\frac{(1/R_1' + 1/R_2')}{(1/R_1 + 1/R_2)} < 2.85 \ldots\ldots\ldots\ldots [6]$$

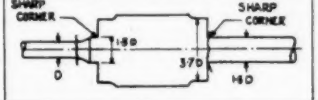
[4] See Thomas and Hoersch, Bulletin 212, Engineering Exp. Station, University of Illinois.

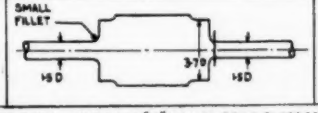












where R_1 and R_1' are the principal radii of one body and R_2 and R_2' principal radii of the other. R_1 and R_2 sweep arcs in the same plane, as do also R_1' and R_2'. The radii of the bodies should be assigned symbols R_1, R_2, R_1', R_2' in such a manner that the fraction in the expression [6] is greater than unity.

O. J. Horger[5] and J. L. Maulbetsch.[6] Although engineers are accustomed to using stress-concentration factors where fillets are involted in designed parts, too little consideration has been given to the greatly reduced strength of press-fitted members.

Kühnel was only partially quoted in the authors' Table 2, but it is believed that the importance of this problem warrants the submission of his further findings. They would appear to have considerable bearing on a possible means of improving the strength of press-fit assemblies. For this reason the entire tests of Kühnel are quoted in Table 1.

TABLE 1 FATIGUE-TEST DATA ON THE PRESS-FIT PROBLEM

(Kühnel-German State Railways)

	TYPE OF SPECIMEN		ENDURANCE STRENGTH LBS./SQ. IN.	% ORDINARY ENDURANCE LIMIT	STRESS CONCENTRATION FACTOR
1			33000	≈100	1.00
2			34000	≈100	1.00
3			31000	94	1.06
4 5		L R	30000 19000	91 61	1.10 1.74
6 7		L R	30000 19000	91 61	1.10 1.74
8			23000	70	1.44

*NOTE THAT ALL RATIOS OF "D" SCALED FROM PHOTOGRAPHS OF TEST SPECIMENS FROM KUHNEL

An examination of Table 1 indicates the decided reduction (from 2.0 to 1.1) in stress concentration when the axle is designed with a raised wheel seat or pad for the outer press-fitted member. While no dimensions of the test specimen are given by Kühnel it would appear from scaling the photographs that the pad diameter is about 1.5 times that of the adjoining section. Such a pad-diameter ratio is difficult to attain in practice, but the effect is promising enough to justify further tests on ratios more feasible in the design of machine parts.

In this connection the writers have made a photoelastic study of the pad construction just outlined, as shown in Fig. 4. The determination of σ_1 and σ_2 have not yet been made, so that the principal stresses are unknown. It would appear, however, that the $\sigma_1 - \sigma_2$ fringes indicate less stress concentration. This may be expected because a more gradual transition in section from the axle into the sleeve is obtained, the ends of the pad provide less lateral restraint with a consequent reduction in peak

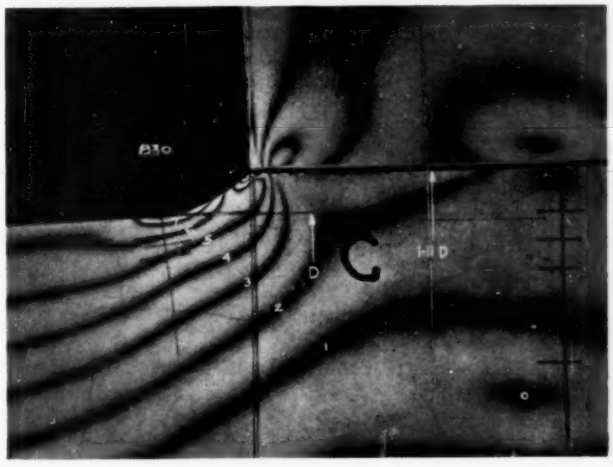


Fig. 4 Stress-Concentration at the Raised Wheel Seat of an Axle

[6] Timken Roller Bearing Company, Canton, Ohio.

press-fit pressure at the end of the sleeve, and the bending stresses finally disappear at the ends of the pad.

In connection with the testing of grooved sleeves, the authors mention the possible effect of groove shape on stress concentration. The writers have investigated different types of grooves by photoelastic studies, a number of the better types of which are shown in Figs. 5 and 6. Here again no separate values of σ_1 and σ_2 are yet available, but the point is being made that groove shape appears to have some influence on the final strength of the press-fit assembly. Only fatigue tests of press-fit assemblies with different types of groove designs can tell what improvement in strength is to be expected.

Regarding the stress-concentration factors, the authors state that the fatigue stress-concentration factors are in general closer to the photoelastic stress-concentration factors than is ordinarily the case, and a comparison is made between the numerical values of stress-concentration factors obtained by photoelasticity and from fatigue tests.

The writers believe that a direct comparison of these numerical values is misleading. As long as only a comparison between two different designs is desired, as for instance between the plain press fit and the grooved construction, it is reasonable to assume if one construction shows in the photoelastic tests a smaller stress-concentration factor than some other design, that the superiority of the first design over the other will also be found by fatigue tests, but not necessarily by the same difference in stress concentration.

The numerical values cited by the authors seem to indicate a close agreement between the fatigue and photoelastic stress-concentration factors. However, in the Darmstadt tests 11 and 12 (Table 3) the stress-concentration factors are 2.2 and 2.6 although the photoelastic test gives 1.95 for the plain press fit. The objection may be raised that in these two tests the material of the shaft does not have the same physical properties as the material of the collar while in the photoelastic study the same material is used for both parts. In test 12 the shaft is of Cr-Ni steel, and the collar is of low-carbon steel; this combination gives the stress-concentration factor of 2.6. If tests were made with a collar of the same material as the one of the shaft, i.e., Cr-Ni steel, it would be found that the stress-concentration factor would be still higher, probably near 3 or higher. This increase in stress concentration when a material of higher physical properties is used for the collar is shown by tests 2, 10, and 11 (Table 3).

The photoelastic studies show only the stress concentration due to the shape of the construction. In fatigue tests, as mentioned by the authors, the stress concentration is due to the weakening action of the rubbing corrosion superimposed on the stress concentration due to shape, and as known will be a function of the sensitivity of the material and size of the specimens. For a material with low sensitivity to stress concentration it may happen that the fatigue stress concentration due to shape plus the effect of rubbing corrosion will give an apparent fatigue stress-concentration factor of the same magnitude as the photoelastic factor. If the material has a high sensitivity this equivalence of numerical values will not hold unless the effect of rubbing corrosion should be small for this material.

The reduction of the size effect noted by the authors may be due to the fact that only the stress concentration due to shape is subject to the size effect, while the weakening action due to rubbing corrosion may be little affected by the size of the specimen.

It is noted that no reaction is taken through the pressed-on sleeve in the fatigue tests, while in the photoelastic tests the reaction of the loads used to produce bending is taken through the lower sleeve which acts as a support. For this reason the resultant of the pressure forces acting on the tension side of the Bakelite beam will not equal the resultant of the pressure forces acting on the compression side. In the fatigue tests described by the authors the resultants for the tension and the compression sides must be equal. In practical applications both cases may be found and it would be of interest to know the opinion of the authors on the effect of the reaction taken through the press fit on the stress-concentration factor.

The authors indicate the use of the term "fatigue stress concentration" in variance with the strict interpretation of the term, for lack of a better one. Eventually the factors which introduce an increase in stresses and those which decrease the strength of the material should be segregated.

Authors' Closure

The X-ray reflection method of determining the depth of the plastic layer due to rolling as presented by Dr. Barrett in his discussion seems to offer considerable promise. It should be mentioned that microscopic examination did not prove effective in this connection for the material used (0.42 per cent C steel). This is in agreement with German experience with medium carbon steel, although for 0.10 per cent C iron, micrographs show considerable grain flattening near the surface.

Dr. Way's discussion forms a valuable contribution to our knowledge of the rolling process. For the 1⅝-in.-diameter fatigue specimen and 800-lb rolling load, the computed depth of plastic penetration is approximately 0.1 in. Since practically full endurance strength of such a shaft with a press-fitted collar was obtained, it was decided to attempt to roll larger shafts of the same material, keeping the ratio of depth of plastic penetration to shaft diameter constant. From the results shown in Table 2, it will be noticed that good agreement was obtained between the computed depths of penetration and the X-ray determinations of Dr. Barrett. Vickers hardness measurements also gave good agreement for the larger shaft diameters.

TABLE 2 COMPARISON OF METHODS FOR OBTAINING PLASTIC PENETRATION ON VARIOUS-DIAMETER SHAFTS

Shaft diam, in.	Rolling load, lb	Roller diam, in.	Roller contour radius, in.	Depth of plastic layer, in.		
				Computed	X-Ray	Hardness
1⅝	400	2	1½	0.067	0.055	.....
1⅝	800	2	1½	0.100	.....	.....
3 3/16	3000	2	1½	0.200	.....	0.21–0.23
5	7000	2	1½	0.300	.....	.....
7¼	12000	6	3	0.450	0.41–0.47	0.42–0.52

Messrs. Horger and Maulbetsch present Kühnel's complete results as having considerable bearing on the development of the pad construction which appears to have possibilities as a method of strengthening press fits. It seems to the writers that the ideas connected with the pad construction as presented by the discussers are essentially new and not to be derived from Kühnel's test results. From Table 1 it would appear that the fillet end (4) carrying 30,000 lb per sq in. nominal stress is better than the plain press fit (5) carrying 19,000 lb per sq in. in nominal stress. However, the section modulus of (5) is over three times that of (4) so that (5) can actually carry twice as much moment as (4). If the smaller diameter is limited and the press-fit diameter can be increased considerably, the press-fit strength can obviously be increased by virtue of increased section modulus. The new idea introduced by the discussers is that the pad construction provides more gradual transition of section, less lateral restraint and consequently reduced peak pressure. This means that with *a given press-fit diameter* (d_2), it is possible by decreasing the diameter a *small* amount outside the fit and using a generous transition radius to actually increase the *moment carrying capacity*, as compared to a shaft of constant diameter (d_2). The discussers' Fig. 4 shows that the above possibility exists. It is hoped that

the discussers will extend this interesting possibility to find optimum conditions of variables d_2/d_1 and fillet radius.

As mentioned in the paper, the authors believe that the press-fit fatigue problem involves essentially a high stress concentration acting on a material weakened by rubbing corrosion. Some fatigue tests have been made with the idea of isolating the rubbing-corrosion effect by use of special clamps. Although this work is not completed, it appears that a reduction due to corrosion alone of about 25–30 per cent will be obtained for the same material as used in the press-fit tests. In Table 2, column (5) is obtained by dividing the values of column (4) by 1.4 which is intended to give a fatigue value due to stress alone for comparison with photoelastic values.

Additional photoelastic tests were also made on plain press-fit models to determine the effect (on the stress-concentration factor) of the ratio l/d of the length of collar to diameter of shaft, as well as that of the ratio p/σ of nominal press-fit pressure to nominal bending stress. These tests were made by using an arrangement to give a pure bending moment on the bar representing the shaft, since the cantilever apparatus described in the paper (Fig. 8) did not lend itself to the study of light press fits because of the compressive load on the lower block representing the collar. The photoelastic stress-concentration factors K_p thus obtained are represented by the experimental points of Fig. 7 from which it may be seen that within limits the relation

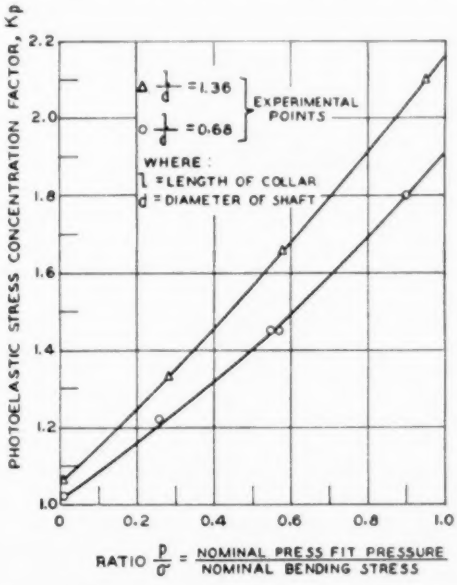

FIG. 7 PHOTOELASTIC STRESS-CONCENTRATION FACTORS
(Press-fit tests.)

between the factor K_p and the ratio p/σ is roughly linear for given values of l/d. Using the curves of Fig. 7, a plot showing the relation between K_p and l/d for various values of p/σ was drawn (Fig. 8). Since it is reasonable to assume that the stress-concentration factor will approach unity for small values of l/d, the curves have been so drawn as to approach this value. Because of the small number of experimental points available, these curves should be considered as rough approximations only. The photoelastic factors K_p shown on Table 3 were taken from Fig. 8.

An examination of Table 3 shows that the photoelastic stress-concentration factors are greater than the fatigue stress-concentration factors (corrected for corrosion). This is in agreement with experience, as in most cases photoelastic factors are lower than the corresponding fatigue factors, and in no case does the latter exceed the former.

In order to explain the results of series 4 and 5 (Table 5) obtained on solid specimens having the same contour as the

TABLE 3 COMPARISON OF FATIGUE AND PHOTOELASTIC STRESS-CONCENTRATION FACTORS
(PRESS FITS)

Fatigue series No. (Table 5)	Ratio l/d	Ratio p/σ at endurance limit	Fatigue stress-concentration factor K	Fatigue stress-concentration factor corrected for corrosion K_c	Photoelastic stress-concentration factor K_p
1 (Plain press-fit)	0.60	0.23[a]	1.47	1.05	1.18
2 (Plain press-fit)	0.92	1.01	2.00	1.43	2.02
3 (Plain press-fit)	0.92	0.01	1.44	1.03	1.10
6 (Grooved construction)	0.92	0.64	1.70	1.21	1.34[b]

[a] Estimated value of p taken as 5000 lb per sq in.
[b] In this case, because of lack of test data no correction was made to take into account the difference in l/d obtaining in the fatigue test and in the corresponding photoelastic test. This correction should be small, however.

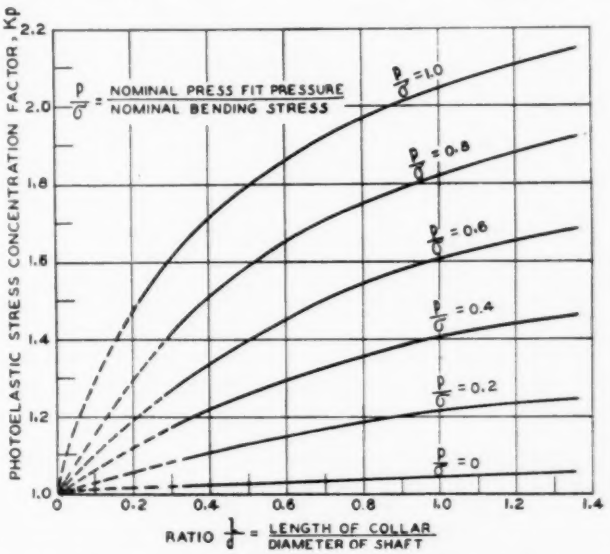

FIG. 8 PLOT OF PHOTOELASTIC STRESS-CONCENTRATION FACTORS—PRESS-FIT TESTS
(Curves obtained from data of Fig. 7.)

press-fit specimens, some photoelastic tests were also made on flat bars with enlargements having sharp corners, to simulate the conditions occurring in the fatigue test. When the ratio of the width of the enlarged portion to the width of the bar proper was 3.7 (corresponding to the ratio D/d) a value of $K_p = 2.62$ (average of four tests) was obtained. Although the stress-concentration factor is theoretically infinite for a sharp corner, yet actually a small radius always exists and in the photoelastic tests when the fringe order curve was extrapolated to the edge, a finite value of stress was found. In a similar test where the ratio of the widths of the enlarged part of the bar to that of the narrow part was 1.2, corresponding to the proportions obtaining in test 5 (Table 5), an average photoelastic factor $K_p = 2.07$ was found. These photoelastic values compare with corresponding fatigue factors of 2.3 and 1.9, respectively, and thus explain why the results of series 5 show lower stress-concentration values than those of series 4.

The discussers state that by using a high-grade alloy-steel shaft and collar, a fatigue stress-concentration factor of 3 may be found (referring to Thum's tests). High factors may be due to the following: (1) High ratio l/d of collar length to shaft

diameter. (2) A high-strength steel collar would allow the use of higher press-fit pressures without yielding at the collar edge. (3) The rubbing-corrosion effect may be greater with a higher-strength shaft material. If all these factors are taken into account it is believed that the fatigue values will not exceed the photoelastic stress-concentration factors.

The question concerning the size effect, mentioned by the discussers in connection with the fatigue tests of series 1 and 2, is answered by the subsequent photoelastic tests which show a considerable decrease in K_p with decreasing values of the ratios l/d and p/σ. These tests thus confirm the opinion expressed in the paper that the lower value of K found in series 1 is caused primarily by the relatively short collar and low press-fit pressures used.

Regarding the question on the effect of the collar reaction raised by Messrs. Horger and Maulbetsch, a comparison of the results obtained with the bending-moment apparatus and those obtained with the cantilever apparatus (Fig. 8) shows only a small difference (of the order of 5 per cent at the most) for ratios of p/σ around 0.7 to 0.8. This would be expected since, in the case of the present tests, the reaction increases the total press-fit pressure by only about 7 per cent on the compression side.

Assuming a like increase in peak stress on the compression side, the effect on the stress range (which determines the factor K_p) would only be around $3^1/_2$ per cent. For these reasons the authors believe that the effect of the reaction is of minor importance, except possibly for extremely short shafts.

Book Reviews

Steel Structures Research

SECOND REPORT OF THE STEEL STRUCTURES RESEARCH COMMITTEE. Department of Scientific and Industrial Research. His Majesty's Stationery Office, London, 1934. Cloth, 6 × 9½ in., 369 pp., 164 figs., 7s 6d.

REVIEWED BY L. C. MAUGH[1]

THE Steel Structures Research Committee is composed of a distinguished group of engineers who represent the British Steelwork Association, the Institution of Civil Engineers, and the Government of Great Britain. Its establishment was primarily due to the desire of the members of the British Steelwork Association to encourage a more efficient, economic, and extended use of steel, and a willingness on their part to contribute financially toward such an undertaking. In collaboration with the Institution of Civil Engineers, a committee was formed in August, 1929, under the direction of the Department of Scientific and Industrial Research. The aims and purposes of this Committee were clearly stated in the first report, published in 1931, namely:

(a) "To review present methods and regulations for the design of steel structures, including bridges.

(b) To investigate the application of modern theory of structures to the design of structures, including bridges, and to make recommendations for the translation to practice of such of the results as would appear to lead to more efficient and economical design."

In accordance with these objectives the first report was devoted largely to a compilation and comparison of representative specifications and research data relating to structural-steel design. Much attention was also given to the development of more accurate methods of determining the allowable capacities of riveted, bolted, and welded connections. A recommended code of practice, which has been widely used in Great Britain, was included for temporary use.

The second and latest report presents the progress of the committee for the period March, 1931, to March, 1933. The contents of this bulletin treats, in general, the problem of stress analysis of building frames. More specifically, information and results of analytical and experimental research on the following subjects has been recorded:

(a) The effective length of continuous columns in structural-steel frames.

(b) Observed stresses in a number of structural-steel frames, mainly with seat-angle connections.

(c) Experimental investigation of the elastic properties of various types of beam and column connections, particularly the relation between moment and angular deformation in riveted and bolted connections.

(d) The analysis of the moments in the members of a frame having rigid or semi-rigid connections under vertical load by means of modified slope-deflection equations and the method of moment distribution.

(e) Welding of steel structures.

The results presented in this report have considerable value in showing what bending stresses are produced in columns by ordinary riveted beam connections, when the beams are subjected to vertical loads. Various methods of analysis are suggested in which the elastic properties of the various types of connections can be introduced. Although these methods are not likely to be of immediate practical use, nevertheless they give a start toward removing that glaring inconsistency which is so common in the design of steel buildings, namely, that of assuming no restraint at the ends of beams when subjected to vertical loads and full restraint at the connections when the building is subjected to horizontal loads. There seems to be opportunity for more economical design if this problem can be satisfactorily solved.

Welded Structures

FABRICATED WELDED STEEL CONSTRUCTION. By J. Collinson, M.I.W.E. Draughtsman Publishing Co. Ltd., London, 1934. Cloth, 51 pp., 15 photographs, 3s.

RIVETING AND ARC WELDING IN SHIP CONSTRUCTION. By Commander H. E. Rossell, U.S.N. Professor of Naval Construction, Massachusetts Institute of Technology. Simmons-Boardman Publishing Co., New York, N. Y., 1934. Cloth, 5 × 7½ in., 210 pp., 46 figs., $2.25.

REVIEWED BY C. H. JENNINGS[2]

MR. ROSSELL'S book is essentially a text and reference book dealing with the design and construction of riveted and welded joints as applied to ship construction. The fact that the book deals specifically with ship construction does not detract from its value, however, because in nearly all cases the joints and problems discussed are directly applicable to structural, machine, and tank construction.

The book is divided into two major sections, riveting and welding. The joint designs considered in each section are carefully analyzed and developed by taking into consideration both the practical and theoretical phases of the problem. Numerous specific examples are worked out as a means of illustrating the method of applying the various formulas that are derived.

Special consideration is given to the practical phases of both welded and riveted construction such as the production of oil-tight and watertight joints and the reduction of warping and residual stresses in welded joints. A critical comparison is made between welds made with bare and "shielded-arc" electrodes, and applications, where each are suitable, are discussed.

The designer of welded constructions, whether the constructions are ships, buildings, bridges, or machines, will find in this book a wealth of valuable data from the standpoint of selecting the proper joint and the design of the same.

Mr. Collinson's article contains a discussion of the important factors he has found to have an influence in the economic design of arc-welded structures. The factors discussed cover both drafting-room and shop practices and although some are not in accordance with the American practice they are worthy of consideration. In some cases the procedures employed in obtaining certain conclusions are rather incomplete and difficult to follow, thereby detracting from their value.

The draftsman and designer of welded machinery will be particularly interested in the author's discussions dealing with the proper developed lengths of formed plates, specification of welds,

[2] Research Engineer, Westinghouse Research Laboratories, East Pittsburgh, Pa.

on drawings, design notes, and cost analysis. The cost analysis of welded structures is of particular importance because the author has attempted to follow the general practice used in estimating the cost of castings, i.e., reduce the castings to a system of classification and weight.

Broadly speaking, Mr. Collinson's article is a worth-while contribution to the art of welding design, a field greatly in need of careful study and analysis if the advantages and savings that welding affords are to be obtained.

Rayleigh's Principle

RAYLEIGH'S PRINCIPLE AND ITS APPLICATIONS TO ENGINEERING. By G. Temple and W. G. Bickley. Oxford University Press, London, 1933, Cloth, 5½ × 8½ in., 156 pp., 22 figs., $4.75.

REVIEWED BY J. N. GOODIER[3]

RAYLEIGH'S PRINCIPLE, the central subject of this book is of great importance in engineering. It provides valuable simple methods for estimating the natural frequencies of vibration of elastic structures and machine elements, especially those which come under the headings of thin bars and plates. A knowledge of the natural frequency is, of course, essential where resonant vibration is to be avoided. The principle is equally useful as a means of investigating stability. It can be made to give good approximate formulas for whirling speeds and buckling loads. This book puts the principle on a sound footing and exhibits its application in a variety of examples of great interest to engineers, including the whirling of non-uniform shafts under the influence of torque and tension, the tippling or sidewise buckling of deep beams, vibrations of rotating disks, and the buckling of non-uniform struts. The simplicity of the method as applied to some of these otherwise rather forbidding problems is often very striking.

In a freely vibrating system the energy is all potential when the system is at the extremity of its swing, and all kinetic when it is passing through its equilibrium position. These two energies must be equal when there is no damping, since each is equal to the total energy, which is necessarily constant. If we know the configurations, or amplitudes, of the system as it vibrates, we can calculate the potential energy. In any simple harmonic motion the kinetic energy of each particle is given by its mass, amplitude, and frequency. It is proportional to the square of the frequency. Consequently, the equality of the maximum kinetic and potential energies becomes a formula for the frequency. Now, even if the configuration of the system at the extremity of its swing is not known *accurately*, it can, nevertheless, often be represented *approximately*, and simply, from observation or intuition, and with this approximation the calculation outlined will give an approximation to the natural frequency. Rayleigh's principle may be expressed by the statement that whatever the approximation chosen for the configuration, or deflection in the vibration, the resulting approximation to the frequency will always be greater than the true value, which would be obtained if the true deflection were used. As a matter of fact it has turned out that any reasonable representation of the deflection gives a frequency surprisingly close to the true value.

It has been customary to judge the accuracy and scope of the method by applying it to systems for which an exact formula for the frequency is known, such as uniform bars, and making a comparison between the Rayleigh approximation and the exact value. The same applies, of course, to the stability problems. There are, however, other simple approximate methods. The use of these, as well as of Rayleigh's principle, provides both upper and lower limits to the value required. These methods are discussed in the book. When the limits so obtained are sufficiently close, nothing more is required. If it is otherwise, the Rayleigh approximation can be repeatedly improved and the error can be estimated by methods given in the book.

The book can be read with an eye to results of engineering value without a detailed study of the mathematical argument. The results of the analysis are conveniently summarized in the introduction and in an appendix to chapters 3 and 4. The introduction also gives a general account of the principle and its applications, including a method for improving the approximation. Chapters 1 and 2 are devoted to stability problems. Chapter 3 contains a rigorous proof of the principle. Chapter 4 describes a second method for improving the approximation, and develops from it a means of estimating the accuracy at any stage. The estimation of the second natural frequency is also discussed. Three of the remaining four chapters are devoted to applications of the results, mainly to engineering problems of the types already mentioned. The other chapter deals with the methods which are supplementary to Rayleigh's. They are based on a group of "comparison and synthetic theorems," which are proved with the help of Rayleigh's principle.

Atomic Structure

ATOMIC STRUCTURE AND SPECTRAL LINES. By Arnold Sommerfeld. Translated from the Fifth German Edition by Henry L. Brose. E. P. Dutton and Company, Inc., New York, 1933. Cloth, 670 pp., 151 diagrams and photographs, $10.80.

REVIEWED BY J. ORMONDROYD[4]

THE Fifth German edition of Professor Sommerfeld's classic work on atomic physics appeared in two parts. This volume, which is a translation of the first of these, contains the older quantum theory. A second volume, to appear shortly in translation, will contain the more recent wave-mechanics theories.

Only ten years ago Bohr was charming American audiences with accounts of his microscopic solar system in which the planets (electrons) repelled each other (although perturbations played no important rôle in the theory of the simple hydrogen and helium atoms) and jumped from orbit to orbit as they gained or lost energy according to Planck's famous quantum theory of radiant energy. This little system explained much in spectral analysis; but not enough. Wave mechanics now rules in the field of atomic theories. But the latest theories can only be understood when the theories which grew around the Rutherford-Bohr atom are completely assimilated. This volume gives that necessary background.

While "Atomic Structure and Spectral Lines" was written for mathematical physicists there are, undoubtedly, some members of the engineering profession who may have an occasional need for the technical information contained in this book. There are many who have a strong cultural interest in the ideas, theories, and results which form the core of present-day physics. To both types of readers this work can be recommended as being authoritative as far as the older quantum mechanics is concerned. It is difficult to imagine a more definitive work than the present volume.

The work is mathematical in form, using vector analysis and Hamiltonian mechanics to arrive at its conclusions. The dynamics of the "special theory of relativity" is used in describing the fine structure of the spectral lines. The mathematical devices are introduced in some extension and are presented persuasively to the reader. If, in spite of this, the engineer is

[4] Experimental Division, Westinghouse Electric and Manufacturing Company, South Philadelphia, Pa. Mem. A.S.M.E.

terrified by the mathematical language, much of the text can be read with a high degree of understanding independent of the formulas—the numerous results being stated, as often as it is possible to do so, in words as well as in symbols.

Chapter 1 contains a critical historical résumé of the important physical developments which bear on the subject, and also fundamental definitions and concepts. Here, as throughout the volume, footnotes give complete references to the original papers which form the basis of the science. Chapter 11 outlines the older theory of the hydrogen spectrum which stands as a foundation for all later developments. The orbital theories of Bohr are given in extenso and an introduction to Hamiltonian mechanics is outlined. After this the natural system of elements, X-ray spectra, the theory of fine structure, the intensity of spectral lines, the series-laws of spectral lines, the complex structure of the series terms, and band spectra are treated in the order named.

Prof. Arnold Sommerfeld, holder of the chair of Theoretical Physics at the University of Munich, has himself contributed much to the subject which he treats in this volume. He has earned the gratitude of physicists throughout the world for carrying out so successfully the monumental task of giving a comprehensive and lucid exposition of modern atomic physics. Professor Brose, of University College, Nottingham, has achieved a smooth and, one feels, a completely authentic translation of the original work.

Seaplane Design

SEAPLANE DESIGN. By Lieut.-Comm. W. Nelson, Lecturer, New York University. McGraw-Hill Book Company, New York, 1934. Cloth, 6 × 9 in., 274 pp., $3.50.

REVIEWED BY SCHUYLER KLEINHANS[5]

THE belief that the seaplane is destined to become increasingly important in the field of transportation has provided sufficient motive for the writing of this book, both as a textbook for the student and a source of information for the practicing engineer. The author's experience as an officer in the Construction Corps of the United States Navy and various tours of duty as both shop superintendent and chief engineer of the Naval Aircraft Factory has well fitted him to write on this subject, so long neglected by engineers and educators because of the scant amount of information available.

In the words of the author, this volume "is a compilation of information and data attained to a great extent from the references." As the references include practically all of the published information on the subject of seaplane design, the book is fairly complete although a bit brief in sections. The subject matter of the book passes successively through the topics of displacement and buoyancy, stability afloat, water resistance, float forms and dimensions, float arrangements, model tests of hulls and floats, take-off of the seaplane, seaplane stresses, watertight subdivision, weight, construction features and details, loft practice, and finally, mooring, towing, and beaching of seaplanes.

The author passes quickly over those branches of aeronautical and naval architecture not specifically connected with the seaplane problem by referring the reader to the many excellent textbooks on these two subjects, and confines himself to the particular questions associated with the design of the seaplane itself. The book is remarkably free from prejudice and causes one to regret that the author's natural modesty prevented his expressing more of his personal ideas. After a summary of the history of seaplanes, the author discusses some applications of seaplanes and then launches into the heart of his subject beginning with the statics of flotation. He here discusses the properties of liquids, Archimedes' principle, Simpson's rules, displacement, coefficients of fineness, permeability, and center of buoyancy location.

The next chapter, dealing with stability afloat, discusses conditions of equilibrium, the metacenter, location of the center of gravity, inclining experiments, free water and its effects on the stability, flooded compartments, righting moments, dynamic stability and metacentric height of seaplanes.

Under water resistance, the author discusses again properties of liquids, waves produced by a vessel, natural sea waves with a brief résumé of the natural-wave theory, and the components of water resistance.

Float forms and dimensions are considered along with the traditional features of seaplane and hydroplane hulls, steps, and general shape of the under-water body. Decks, wing-tip float forms and air resistance are also under this section of the book.

The general topic of float arrangements is expanded to include water stability in detail using the principles of naval architecture developed in earlier chapters, at the same time going over the various arrangements of floats as seen in actual practice.

Model-basin tests are given their fair share of space, and rightly so, for they represent the backbone of seaplane knowledge to date. After discussing the purpose of model tests, there is a section devoted to similitude with paragraphs on Froude's law and Reynolds' number, as well as a comprehensive discussion of model limitations and results. A review of model-basin procedure and apparatus is followed by a description of the hydrovane and the complete float test with some remarks about flight tests of large models on a small inexpensive airplane.

The important problem of the seaplane takeoff occupies a chapter in itself with illustration of take-off calculations including float resistance, propeller thrust and effects of the trimming angle.

Seaplanes, which are subjected to hogging and sagging stresses as well as the stresses caused by landing and take-off, and sometimes special cases such as catapulting, must be designed to withstand these loads. The author has grouped these various stress-producing conditions under "Seaplane Load Determinations," where he also gives a general description of the theories of impact landing as well as a review of the impact-landing requirements of several governments.

The necessity of watertight subdivision is expounded and the questions of stability and change of trim due to flooded compartments are given in detail in a chapter devoted to this subject along with a description of subdividing methods.

After some remarks on the traditional subject of weight, which includes a tabulation of the detail weights of a typical patrol-type flying boat, the author considers various features of construction and discusses some of the materials available for float and hull structures. There are paragraphs on framing, bulkheading, and shell plating. Construction details include types of rivets, efficiency of riveted joints, watertight construction, and closures.

Under line drawings and loft practice, the author gives only a glimpse into this fascinating and most rapidly growing department of a modern aircraft factory. There is, however, sufficient explanation to awaken the reader to the tremendous possibilities of the mold loft as a means of improving aircraft manufacturing technique and materially reducing the cost of the finished article.

Under mooring, towing, and beaching seaplanes the author describes anchors and towing lines as well as hoisting, docking, and beaching procedures.

The material and composition of "Seaplane Design" is such that, except for some twenty-six pages of appendixes devoted to sketches of typical seaplanes which are bound to become obsolete

[5] Douglas Aircraft Corporation, Santa Monica, Calif.

almost as soon as the book is off the press, it should stand the test of time and be as useful some years hence as it is today. The excellent index is a detail that will be appreciated both by the casual reader and the more serious student. The book is a distinct contribution to the small but growing amount of literature on seaplane design and it is to be hoped that the appearance of this volume will be an inspiration to other writers to take up the work where space limitation has caused Mr. Nelson to leave off.

Aerodynamic Theory

AERODYNAMIC THEORY. Dr. William Frederick Durand, Editor-in-Chief. Vol. 1. Julius Springer, Berlin, 1934. Cloth, 6 × 10 in., 398 pp., 151 figs., 20 rm.

REVIEWED BY J. C. HUNSAKER[6]

The Guggenheim Fund for the Promotion of Aeronautics, before closing its active and most useful life, made provision for the preparation of a series of monographs on aerodynamic theory by the outstanding international authorities in this field, to be contained in six volumes of which this is the first. The plan of the editor-in-chief is to present knowledge of aerodynamic theory with especial reference to progress in the past twenty-five years, the period since flight became an element of our civilization. Such a work is most welcome, as the original material is generally unavailable except to those having access to the great libraries; and even here an extensive search through many publications in many languages would be required.

The first volume appropriately furnishes a general introduction, giving in some detail the special mathematical methods of fluid mechanics and a critical review of the development of modern aerodynamic theory from the classical hydrodynamics of the last century. The complete series will present the theory of perfect, viscous, and compressible fluids, with applications to airfoils, bodies, propellers, and cooling, and to the dynamics and performance of airships and airplanes. Aircraft design itself, being an art rather than a science, and hence changed rapidly by economic, political, metallurgical, and other conditions, as well as by unpredictable inventions, is not to be included.

The first volume begins with an elegant yet concise treatment of the mathematical aids used in the later development of the mechanics of fluids. Here the grateful reader will find that, without further preparation than that given by ordinary college mathematics, he may acquire an understanding of the complex variable, vector algebra, vector fields, and the motion of a fluid described by potential functions. Gauss's, Green's, and Stokes's theorems are developed and the method of conformal transformation explained and illustrated. A really adequate and rigorous treatment of the theory of dimensions and of kinematic similitude is set forth by Dr. Durand, whose genius as a teacher is to be noted throughout.

Dr. Durand contributes ten chapters on fluid mechanics, following directly after his development of the necessary mathematical technique. These chapters begin with the fundamental equations of motion and of equilibrium for the perfect fluid and the engineering reader is easily carried through the solution of the elementary problems of parallel flow, sources and sinks, doublets, vortices, and their combinations, as well as the application of conformal transformation to flow fields. This portion of the work is intended to serve as an introduction to more advanced analysis. Dr. Munk then follows with a more comprehensive treatment of somewhat the same ground, using the methods of space-vector analysis, and extending to the solution of problems of motion of solids in a perfect fluid. The generalized three-dimensional method introduces the conceptions of apparent mass, polar and elliptic coordinates, and leads to consideration of the elongated ellipsoid resembling an airship. Here, Munk discusses generalized potential flow and the forces which are of interest in design. These solutions by Munk are frankly for the advanced reader and may be compared with those by Horace Lamb in his "Hydrodynamics" for a somewhat fuller treatment.

The last ninety pages of the book are devoted to a conscientious review of the history of fluid mechanics. This section is the first adequate survey of the contributions of the various workers in the field during the present century. A critical appraisal is badly needed because of the interruption to the free exchange of scientific thought by the war and the inevitable duplication of research effort.

The historical review is divided into three parts: The first covers the period of early thought to the end of the seventeenth century, marked by Leonardo's correct statement of relative motion as the basis for flight. The second period, that of classical hydrodynamics, begins with Newton and ends with the nineteenth century. It is marked by a veritable flowering of applied mathematics in the hands of such giants as Newton, Bernoulli, D'Alembert, Euler, Lagrange, Helmholtz, Kirchoff, Rankine, and Rayleigh. The classical theory, in order to permit mathematical solutions, postulated a perfect frictionless fluid. While useful principles were obtained, the problem of actual flight could not be solved until experiments with real fluids were undertaken by Reynolds, Froude, Wenham, Philips, Mouillard, Lilienthal, Dines, Langley, and the Wrights. The classical theory could not account for the results of experiment.

At the end of the century there was a wide gap between theory and experiment, and aerodynamic theory played but a small part in the early development of the airplane. But with the stimulus given by the first actual flight, scientific attention was sharply focused on the underlying fluid mechanics. Theoretical advances came rapidly thereafter.

In the third part of their review, Giacomelli and Pistolesi trace the remarkable renaissance of hydrodynamics in the hands of Lanchester, Kutta, Joukowski, Prandtl, and their followers. Today aerodynamic theory determines the correct shape and proportions of wings, propellers, etc., and predicts the practical performance of the aircraft built to conform to theoretical considerations. That this can be true, results from the application of the methods of classical hydrodynamics to the mechanics of real fluids (Lanchester-Prandtl wing theory), the theory of dynamic similitude (Reynolds-Rayleigh), and the theory of the boundary layer (Prandtl).

The development of the modern wing theory for finite spans by Prandtl and his collaborators, from the qualitative and intuitional conception of Lanchester and the classical two-dimensional solutions of Kutta and Joukowski, is a fascinating example of the international character of research. It is to be regretted that in the history of theoretical aerodynamics no American contributions are worthy of note, although on the experimental side we might suggest D. W. Taylor, Langley, Zahm, and the Wrights.

The historical survey closes with the wing theory and does not attempt to appraise recent contributions toward the unsolved problem of resistance in real fluids, although the early work of Mallock (1907), Bénard (1908), and von Kármán (1911) is carefully set forth.

In Volume 2, von Kármán and Burgers will deal with the wing theory. In Volume 3, Prandtl will treat the mechanics of viscous fluids, and G. I. Taylor the mechanics of compressible fluids. There has been significant work on turbulence from each of these four, and one may hope that upon completion of the six volumes planned for the Guggenheim series on aerodynamic

[6] Professor of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Mass. Mem. A.S.M.E.

theory, there may be found means to publish a seventh volume to include advances in the theory of turbulence and boundary-layer mechanics, made since the series was planned. The reviewer ventures the prediction that the next important step in aerodynamic theory will give an understanding of the boundary layer by which its apparently whimsical tendency to separate from a wing or other solid body may be predicted and dealt with by practical designers. The problems of boundary-layer separation and of the consequent turbulent wake resistance are fundamental and must be solved before aerodynamic theory can have full engineering application.

From Galileo to Cosmic Rays

"From Galileo to Cosmic Rays," Harvey Brace Lemon, Ph.D., Professor of Physics, the University of Chicago. The University of Chicago Press, 1934. Cloth, 6 × 9 in., 450 pp., 100 photographs, 325 line drawings. Educational edition $3.75, stereoscope $0.75 extra; trade edition $5, includes stereoscope.

Reviewed by J. Ormondroyd[7]

THIS book, with sections on mechanics, heat, electricity and magnetism, electricity and matter, and waves and radiation, is offered as a textbook to be used in an introductory survey course of the physical sciences. Professor Lemon's well-instrumented demonstration lectures at the University of Chicago form a secure basis for this work. While it is difficult to put one's self into the frame of mind of an undergraduate again, those who read this book will wish that the subject had been presented to them in the style and manner used by the author.

The textbook writer usually attempts to satisfy self-imposed demands as to a preconceived quantity of material compressed into a logical order of presentation. With this ideal he succeeds in presenting a number of perfectly correct and desiccated formulas properly cataloged and card-indexed. But he often forgets that it takes two to make a textbook—a reader as well as a writer. Professor Lemon avoids this common pitfall by thinking of his readers first, last, and always.

To the student the material usually presented seems to be arbitrarily selected; unconsciously his reaction is "Yes—What of it?" That contact between his familiar life and the new material is often woefully absent and the professor seems to have little sympathetic intuition of his unvoiced questioning. As far as he can, Professor Lemon ties his physics to every-day objects in the undergraduate's life, and elicits a feeling of comradeship by clearly indicating that he understands the student's psychological reactions. He even talks in the student's slangy idiom at times. Only mathematics of the simplest form is used—a concession filled with wisdom in view of the fact that the book has as its essential purpose the creation of an interest which can be satisfied by subsequent deeper and more detailed delving.

"One picture is better than a thousand words." The reader is never out of sight of one or more of the hundreds of photographs and line drawings. The photographs show views of demonstration apparatus in action adding concreteness to the text; while the line drawings are frequently humorous and always instructive. As a crown to the pedagogical strategy the book is provided with many double-exposure pictures and a stereoscope through which to view them. This not only adds the element of play to reading the book; but also insures close attention and greater revealed detail to the pictures so treated.

The title indicates that the subject matter is treated historically. Living glimpses of the master creative minds as given in this book add another humanizing touch to the text. The arrangement of the text in the order as given is also historically correct and prepares the student for that change from the mechanical point of view to the electromagnetic outlook which dominates physical thought today. Besides technical instruction, the book affords that generalizing view-point which gives it high cultural value.

Why should a book primarily designed for the instruction of youngsters be brought to the attention of practicing engineers? First of all, any engineer who reads this book will be highly amused and delighted. Secondly, most of us really do not know too much about the fundamental physics of the things we create and operate. Perhaps we could learn more than an undergraduate would be prepared to learn from this most human attempt at scientific exposition.

Statics and Dynamics of Shells

Statik und Dynamik der Schalen. By W. Flügge. Julius Springer, Berlin, 1934. Cloth, 6 × 9 in., 240 pp., 98 figs., 22.50 rm.

Reviewed by J. P. Den Hartog[8]

THIS book deals with the subject of stress, deformation, stability, and vibration of *curved* thin shells in a clear and complete manner. Written by a member of the Göttingen school, it forms a worthy counterpart to the excellent book on *flat* plates produced some ten years ago in the same laboratory by Professor Nadai under the title "Die Elastische Platten."

Curved thin plates or "shells" are employed in many important structures, e.g., domes or vaulted roofs of reinforced concrete, pressure vessels, boilers, oil tanks, pipe lines, and airplane fuselages or struts. An extensive literature on the subject has been built up, especially during the last fifteen years, and of this the book gives a complete account. The mathematical methods employed necessarily include a great deal of partial differentiation, but beyond that do not require any further knowledge on the part of the reader. A number of the most important results are illustrated by graphs.

The book is divided in ten chapters, of which the detailed contents are as follows:

The first is an introductory chapter giving the relations between stresses and bending moments at an element and also the relations between the stresses at a point by means of Mohr's circles. This latter method is worked out rather completely for shells of reinforced concrete.

The second chapter deals with the "membrane theory" of shells of revolution, especially with domes of various shapes and liquid reservoirs. By "membrane theory" is meant a theory which neglects bending stresses and only takes account of tensions. It is shown that this approximate theory is quite satisfactory in many cases, and that bending only comes in near the boundaries. The situation is somewhat analogous to structures built up of bars, in which the "primary" stresses are all pure tension, whereas the bending comes in only as a "secondary" effect.

The problem of a dome of equal strength (variable thickness) loaded by its own weight is solved. An interesting discussion and a good photograph is given of an oil-storage tank of equal strength having the shape of a drop of mercury reposing on a horizontal plane. Though the membrane stresses in the shell itself can be calculated from equilibrium conditions only, some statically indeterminates are usually introduced by the supports. For the purpose of calculating these, some methods for finding

[8] Assistant Professor of Applied Mechanics, Harvard University, Cambridge, Massachusetts. Assoc-Mem. A.S.M.E.

the deformations are discussed rather fully. Finally, the energy method for calculating the indeterminates directly is given.

The third and fourth chapters treat the same topics for cylindrical shells and for shells generated by the parallel translation of some curve. The principal applications here are pipe lines on many supports, slightly vaulted cylindrical reinforced-concrete roofs, and also domes made up of intersecting cylinders.

The fifth chapter shows how all previous results can be extended to shells generated from those discussed before by stretching them in one or more directions. For instance, the stresses and deformations of ellipsoidal shells can be deduced from those of the sphere.

The chapters six to eight which form the backbone of the book, discuss the more complete bending theory, taking full account of the literature which has been accumulating on this subject.

Chapter nine deals with the stability or buckling problem of a cylinder under external or endwise pressure with and without stiffened ends, as well as of cylinders under torsion. The stability of a thin-walled sphere under external pressure is also discussed. In the final chapter a brief treatment is given of the vibrations of cylindrical and spherical shells.

A very complete bibliography is appended, taking the place of footnotes in the text.

Through Space and Time

THROUGH SPACE AND TIME. By Sir James Jeans, D.Sc., F.R.S. The Macmillan Company, New York, N. Y. University Press, Cambridge, 1934. Cloth, 6 × 9 in., 218 pp., 106 figs., $3.

REVIEWED BY J. ORMONDROYD[9]

THIS little book, based on the Christmas Lectures of the Royal Institution delivered in 1933, is designed, according to the author, for an eager and critical audience, ranging in age from under eight to over eighty and in scientific knowledge from the aforesaid child to the staid professor of science. In other words it is offered to any one who can read and who is interested in the phenomena that are presented to his senses. It is a notable example, among numerous similar efforts, of the attempt which is being made increasingly by scientists and scholars to interpret and expose to the world at large the results of science and scholarship which are the dominating influences in our lives today, but which seem so remote and so incomprehensible to the major part of the human race. The scientist here stoops to conquer the non-scientific mind.

The objective and general outline of the book are announced by the author somewhat in the following fashion:

> We shall travel—or pretend to travel—so far through space that our earth will look like less than the tiniest of motes in a sunbeam, and so far through time that the whole of human history will shrink to a tick of the clock, and a man's whole life to something less than the twinkling of an eye.
>
> As we travel through space, we shall try to draw a picture of the universe as it is—vast spaces of unthinkable extent and terrifying desolation.
>
> As we travel through time we will show not only the present, but also the past and the future of the universe. We shall see the sky as it was a million-million years ago—vast colonies of stars being born, living their lives and finally dying. We shall watch our sun broken up in great turmoil producing a family of planets. We shall watch our earth, a globe of hot gas, which gradually cools and becomes a suitable abode for life. We shall see, finally, man arriving, taking possession of his tiny speck of dust in space and surveying with astonishment the strange universe in which his life is cast.

It can be seen that the author does not shrink from putting his material into the most popular of forms. If the reader has never been astonished at his universe before, he will be after he reads this little treatise. One inevitably thinks of P. T. Barnum or Mr. Brisbane on reading the above announcement. Because of its avowed intent, no mathematics or involved trains of reasoning are used in the text. The matter is purely descriptive statement of fact which requires merely passive absorption. "One picture is worth ten thousand words," some one has said, and following this psychological hint the book is liberally illustrated with interesting photographs. The book might be justly described as a collection of scientific "Just-So Stories" and is certain to appeal to all engineers who enjoy reading.

This geocentric survey of the universe starts on the earth, glances at the atmosphere which beneficiently surrounds the earth and arrives, in the third chapter, at the phenomena in the sky which form the most extensive part of the matter treated. The moon, the planets, the sun, the stars, and the nebulae are discussed in great detail. Geology, astronomy, the various branches of physics, are touched upon as they are needed to describe the phenomena selected for exposition.

How do we know the earth is round and rotates? How was its size first measured? How far is it from the other bodies swimming in space? Why is the sky blue? Why do radio signals fade? What about this stratosphere every one is attempting to reach? How can pictures be taken in the dark? Would mirrors reflect if their surfaces did not conduct electricity? What would we find if we could visit the other members of our solar system? How big, how hot, how far are the stars? How do nascent universes condense out of nebulae? All these questions and a thousand more are treated in building up this integrated picture of our universe.

To the constant reader of popular scientific outlines or histories some of the facts given will be inevitably familiar; but never have they been joined together so logically into such a pleasing, entertaining and instructive whole.

Sir James Jeans has such an ease of delivery, both in speaking and writing, that his utterances always find a receptive audience. His background of creative work in the subject matter of this little book as represented in his mathematical treatises "Astronomy and Cosmogony" and "Problems of Cosmogony and Stellar Dynamics" renders his simplest statement rich in content and authority. It is rare, indeed, that the mind capable of distilling such scientific output can bend itself to the more lowly task of putting the interesting results into elementary form.

---

A Method of Balancing Reciprocating Machines

By W. E. JOHNSON,[1] SCHENECTADY, N. Y.

General types of balancing problems are classified into three groups: Those requiring perfect balance, those in which the machine inherently is balanced sufficiently well for practical purposes, and those requiring a distinct compromise, such as single-cylinder engines. It is a method of securing an optimum condition for the last class that is presented.

The method consists, first, of the selection of a suitable criterion for the particular problem, such as minimizing the average potential energy of vibration in a spring mounting, which tends to secure the least possible transmission of vibration. Another criterion may reduce the vibration of the machine itself to a minimum. The selection of a suitable criterion is a matter for the judgment of the designer. When the selection is made, the attainment of the optimum sought is carried out by mathematical analysis. This general method is particularly useful for balancing spring-mounted machines. An illustrative problem is given for this case, showing the effects of working to several different criteria.

THE problem of balancing a machine is not one that offers a definite solution in each case, for often the problem has an economic side that makes the expense of a perfect balance prohibitive. It assists one's comprehension of the general situation if the various types of balancing problems are classified as follows:

1 There are occasional problems which require a perfect balance, regardless of cost. This makes the problem perfectly definite. Moreover, if the machine is self-contained, it is theoretically possible to obtain a perfect balance both of the dynamic forces and couples, and of couples derived from gas forces. As a proof of this statement, consider a conventional gasoline motor. If two identical motors were fastened head to head, the crankshafts being geared together properly to give correct timing, and the corresponding cylinders being connected with gas passages to equalize the pressures, it is obvious that the resulting composite machine would be perfectly balanced, provided it does not have to transmit torque to an external machine. However, if the external machine which absorbs the power is perfectly balanced and made to absorb the power equally from each crankshaft, it becomes part of a larger system which is in perfect balance, both with respect to dynamic and gas forces. (The term "force" is often generalized to include couples.) So this type of problem, while it may not be simple, is certainly straightforward, and one may well add, rather unusual in engineering practice.

2 One of the most frequent problems is that of obtaining a reasonably good balance in a machine that is not designed primarily for perfect balance but which, nevertheless, is inherently capable of being sufficiently well balanced for practical purposes by the addition of relatively simple counterweights. In such machines it is usually possible to balance out all the first harmonic forces and couples perfectly. The second and higher harmonics may be small enough in magnitude to be neglected. If they are not, it may be necessary to use a special device for balancing one or more of the higher harmonics. A machine falling into this general class, for example, is the multicylinder automobile engine. Other examples may be found in certain rotary compressors, where all parts are balanced except, perhaps, a small blade whose inertia force is negligible. The balancing problems presented by these machines are definite, and can all be solved by the fundamental method of balancing forces and couples. It may not be amiss, before leaving this general problem, to point out that occasionally a machine can be thrown off balance dynamically partially to balance torques introduced by gas forces, with a net reduction in the vibration. The author is aware of one case where this was done in a high-speed compressor in order to improve the performance at working pressures. Of course, the compressor was then not as well balanced under no-load conditions as it could have been.

3 In the third group may be placed those problems which require a distinct compromise as far as balancing is concerned. Single-cylinder reciprocating engines or compressors furnish examples of such problems, for usually cost is all important, the expense of perfect balance being prohibitive. These machines, when balanced as well as possible with a simple counterweight will still be appreciably out of balance. For this reason, and also to isolate noise, small compressors of this type are often spring mounted. The real heart of the balancing problem in this case lies in the realization of the best balance attainable. It is this problem that is to be treated in this article.

The Selection of Suitable Criteria

Perhaps it is not obvious at first sight, but it is a quite difficult task in many cases to define the "best" balance, or optimum condition. Yet this must be done before the problem of balancing can be solved. Some of the criteria that may furnish optimum conditions in various instances will, therefore, be discussed.

1 The maximum forces may be kept to a minimum. This, in effect, is what a designer does when he balances all of the rotating plus half of the reciprocating weight in a single-cylinder machine. The weakness of the method is that couples may be neglected, and the response of the system to the forces is disregarded. Fundamentally, there is no basic assurance that the minimum of human response is obtained, and, therefore, no philosophical basis can be claimed for the method. Actually, it has some practical value in cases where the machine and its mounting are symmetrical and uniformly responsive.

2 The average kinetic energy of vibration of the machine produced by the unbalanced forces may be minimized, considering the frame of the machine to be a free body in space. This method will produce an optimum condition for the machine itself provided the mounting is extremely flexible. It does not, however, assure attainment of the least possible transmission of

[1] Designing Engineer, Refrigeration Engineering Department, General Electric Company. Assoc-Mem. A.S.M.E.

Presented at the National Applied Mechanics Meeting, University of Michigan, Ann Arbor, Mich., June 18–19, 1935, of The American Society of Mechanical Engineers.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until November 11, 1935, for publication at a later date.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

vibration to the foundation. In any case, it will produce a reasonably good balance at the expense of very little effort in the computations.

3 The average kinetic energy may be minimized, taking account of the effect of flexibility in the mounting. This will result in an optimum state of vibration of the machine, whatever the mounting, but will not necessarily produce the least transmission of vibration that is possible.

4 The average potential energy in the mounting may be minimized, thus obtaining directly the least transmission of vibration to the foundation. This method is very sound from the philosophical viewpoint, and practically is very useful in the treatment of spring-mounted machines. One difficulty, though, will arise occasionally in its application, for mathematically there is no regard whatever for the balance of the machine itself, and occasionally the optimum condition is obtained in the mounting at the expense of excessive vibration of the machine itself. When this occurs, it is advisable to use the next method, mentioned under (5).

5 In order to prevent a disagreeable vibration of the machine itself, and at the same time have as little transmission as possible, it may be desirable to minimize the total average energy of vibration, which is the sum of the average kinetic and average potential energies. This will undoubtedly produce good results, although the method in (4) may surpass it in certain cases.

6 Occasionally it is desirable to apply a modification of the method discussed in (4). In a domestic refrigerator, for example, if the compressor unit is mounted on top of the cabinet, the cabinet will be much more susceptible to horizontal vibration than to vertical. In this case it is advantageous to minimize a modified potential or force function which recognizes only horizontal displacements of the mounting springs. Generally speaking, either the kinetic or potential functions or both may be minimized in modified forms to suit the needs of a particular problem, or a particular force function may be minimized.

After surveying these available criteria, it is evident that the particular one to be used in any instance will depend upon the circumstances and upon the results desired. For example, there should be a different treatment for a spring-mounted machine than for one that is rigidly mounted, and it must be decided whether the vibration of the machine is more important than the vibration transmitted by the machine. These things the designer must decide for himself, using his own judgment as a guide. The method of obtaining, mathematically, the optimum conditions sought will now be treated.

Method of Obtaining Optimum Conditions

Fundamentally, the method of obtaining these optimum conditions is simple. Suppose that the condition sought is that of minimum potential. Then it is only necessary to determine the average potential energy V_a as a function of the counterweight force ϕ. Briefly

$$V_a = V_a(\phi) \quad [1]$$

If two counterweights are to be used, then

$$V_a = V_a(\phi_1, \phi_2) \quad [2]$$

etc. The value of the counterweight force required for minimum V_a is determined from the equation

$$\frac{dV_a}{d\phi} = 0 \quad [3]$$

for one counterweight, or from the equations

$$\frac{\partial V_a}{\partial \phi_1} = 0 \text{ and } \frac{\partial V_a}{\partial \phi_2} = 0 \quad [4]$$

for two counterweights. The method may be generalized to include n variables, of course, except that the resulting simultaneous equations must be independent. The treatment of the problem will now be further elucidated.

The frame of a machine, together with all stationary parts attached to it, may be considered as a rigid body. When the machine is operating at constant speed, this body is acted upon by the unbalanced forces, and will, as a result, have a certain kinetic energy of vibration. The moving links of the machine will also vibrate with the frame except, theoretically, in the coordinate for which their motion is independent. For example, the piston of a reciprocating engine will not follow the vibration of the frame in the direction of its motion except when it is at the two dead-center positions. Actually, the friction coupling between the links and the frame may cause it to follow the vibration very closely. Again, a heavy rotating member, with a relatively small friction coupling, will not follow angular vibration of the frame about the axis of the rotating member. When determining the mass and moments of inertia to be used,

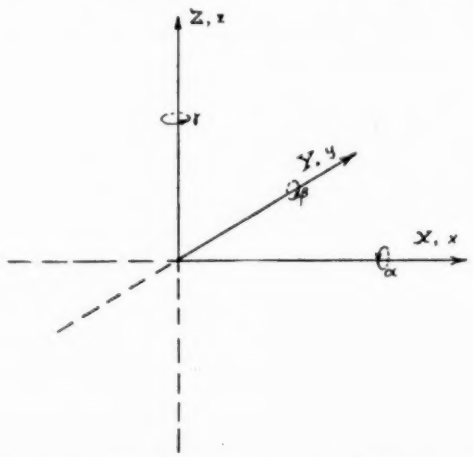

Fig. 1 Reference Axes Used in Writing an Expression for the Kinetic Energy of a Machine in Terms of Its Velocities

these facts must be considered. For instance, if the axis of a heavy rotating member is parallel to one of the coordinate axes, its effective moment of inertia is the product of its mass by the square of the distance between the two axes, the moment of inertia about its own axis being neglected.

Let it be assumed, for the sake of clarity, that the machine is spring mounted. Obviously, the vibration of the machine will produce oscillating displacements of the springs, and because of this fact there will reside in the springs a certain potential energy as a result.

Both the kinetic and potential energies will be fluctuating in time, but if the cyclic speed of the links is constant, each will have a constant average value. Moreover, the kinetic and potential functions, and also their sum, are positive definite forms, so that when the average value of one of these functions is reduced to zero, its value at any instant is also zero. The significance of this lies in the fact that when the average potential energy is reduced to zero, there can be no vibration transmitted through the mounting springs. Similarly, if the average kinetic energy is reduced to zero, there can be no vibration of the machine itself. By minimizing these functions, we, therefore, approach the ideal condition as closely as possible.

Now, the first mathematical step is to write an expression for the kinetic energy of the machine in terms of its velocities. To accomplish this, consider a set of Cartesian axes, *OXYZ*, fixed

in space, with the origin at the center of gravity of the machine when it is at rest. Any suitable orientation may be used. Consider also that the frame of the machine has fixed within it a set of axes, $oxyz$, which coincide exactly with the axes, $OXYZ$, when the machine is at rest in equilibrium. The relation of the axes is shown in Fig. 1.

Let the displacement of o with respect to O be denoted by x, y, z. Also, let α = the rotation of ox with respect to OX, β = the rotation of oy with respect to OY, and γ = the rotation of oz with respect to OZ, all rotations being positive when counterclockwise, looking toward the origin.

Obviously, simultaneous rotations will produce inaccuracies in these definitions, but for small vibration, the errors introduced are negligible.

Regarding the dynamic specifications of the machine, let M = the total mass, and A, B, and C = the moments of inertia about ox, oy, and oz, respectively. Also, let F = the product of inertia about oy and oz; let G = the product of inertia about ox and oz; and let H = the product of inertia about ox and oy.

The definitions of the products of inertia, incidentally, are

$$F = \Sigma myz; \quad G = \Sigma mxz; \quad \text{and } H = \Sigma mxy$$

the summations extending over all particles of mass m in the body.

With these definitions, it may be shown that the kinetic energy T of the machine frame is

$$T = \frac{1}{2} M (\dot{x}^2 + \dot{y}^2 + \dot{z}^2) + \frac{1}{2} (A\dot{\alpha}^2 + B\dot{\beta}^2 + C\dot{\gamma}^2 - 2F\dot{\beta}\dot{\gamma} - 2G\dot{\alpha}\dot{\gamma} - 2H\dot{\alpha}\dot{\beta}) \quad [5]$$

where the dots denote differentiation with respect to time.

Very often, a coordinate plane will be a plane of symmetry, in which case two of the products of inertia are zero. If two planes of symmetry coinciding with coordinate planes exist, all the products of inertia are zero. In cases where a machine is very nearly symmetrical about two of the chosen coordinate planes, it may be permissible to neglect the products of inertia.

The potential function V will in general involve the squares of all coordinates and all possible products. In any particular case it may be difficult to derive, but the form of the function for a helical-spring mounting, where the springs are "built in" at each end, has been obtained and will be given here. It is first necessary to define the spring constants and the coordinates, which are as follows:[2]

K_1 = the spring constant (lb per in., or similar units) for a displacement of one end of the spring along the axis of the coil

K_2 = the spring constant for a displacement of one end at a right angle to the axis of the coil, both ends remaining parallel with the axis of the unstrained coil

K_3 = the spring constant (lb-in. per radian) for an angular displacement of one end about an axis at a right angle to the axis of the coil, with no translation permitted

K_4 = the spring constant for an angular displacement of one end about the axis of the coil

h = the active length of the coil.

The spring is assumed to be placed with its axis vertical, the lower end being fixed to the foundation, and the upper end fixed to the machine at a point whose x, y, and z coordinates are, respectively, a, b, and c. Using these definitions, it can be shown that the potential energy stored in a single spring because of a general displacement of the machine is

$$V = \frac{1}{2} [K_2x^2 + K_2y^2 + K_1z^2 + (K_2c^2 + K_1b^2 + K_3 - hcK_2)\alpha^2 + (K_2c^2 + K_1a^2 + K_3 - hcK_2)\beta^2 + (K_2b^2 + K_2a^2 + K_4)\gamma^2 + K_2(2c - h)\beta x - K_2b(2c - h)\beta\gamma - K_2(2c - h)\alpha y - K_2a(2c - h)\alpha\gamma - 2bK_2\gamma x + 2aK_2\gamma y + 2K_1ba z - 2K_1a\beta z - 2K_1ab\alpha\beta] \quad [6]$$

The total potential, of course, is the sum of the potentials of all the springs. If the mounting is symmetrical about the oz axis, a large number of the terms in Equation [6] will vanish.

The next important step is to evaluate x, y, z, α, β, and γ in terms of the forces, and to substitute these values in either T or V, depending on which is to be minimized. To accomplish this, the equations of motion must be derived and solved. This is most conveniently done by using Lagrange's equations, which are in the form

$$\frac{d}{dt}\left(\frac{\partial T}{\partial q_i}\right) + \frac{\partial V}{\partial q_i} = Q_i \quad [7]$$

where q_i = one of the coordinates, x, y, etc.

Q_i = the force acting in this coordinate.

There will, in general, be six equations which must be solved simultaneously. The number may, however, be reduced to two identical sets of two simultaneous equations in special cases of symmetry, and where certain of the forces are zero. When the solutions of Equation [7] are obtained, they will be in the form

$$x = f(Q_x, Q_y, Q_z, Q_\alpha, Q_\beta, Q_\gamma) \quad [8]$$

with similar solutions for y, z, etc. Now, the Q_i's will contain the counterweight forces ϕ_1, ϕ_2, etc. Hence, when Equation [8] is substituted in Equation [6], there is obtained the explicit function

$$V = V(\phi_1, \phi_2, \ldots) \quad [9]$$

From this, the time is eliminated by taking the average value V_a, which is minimized by equating its differential to zero. A similar method is followed if it is desired to minimize T_a, or any modifications of T_a and V_a. It will be noted that the solution is much simpler if $V = 0$ and T_a only is minimized. This corresponds to a body floating in space, and is only approached practically with extremely flexible mountings.

Before leaving this technique, it may be well to touch upon the matter of modified, or restricted, potential functions. As explained in the discussion of criteria, it may be desired to obtain the least possible disturbance in, say, the horizontal plane only. One may, in such a case, without a serious violation of logic, select from the potential function only those terms from which horizontal forces may be obtained, calling this collection of terms a "modified" potential function.

One disconcerting result of this procedure, however, is that the new function, being only a part of some true potential function, may sometimes be negative in value, and a negative potential function in this case *is* disconcerting because one loses his concept of what is being accomplished. This difficulty can be obviated in a straightforward manner by minimizing the average of the square of the force acting in the horizontal (or other) plane.

In order to illustrate this method it will be applied to the case in which the mounting consists of a plurality of vertical springs, and translatory disturbances in the horizontal plane are to be minimized. The notation used previously is continued, and in addition the displacements of the upper end of a single spring are denoted as follows:

δ_1, δ_2, and δ_3 = displacements of translation in the x, y, and z directions, respectively

[2] Expressions for these spring constants will be found in the appendix.

ζ_1, ζ_2, and ζ_3 = respective angular displacements about axes ox', oy', and oz', parallel to ox, oy, and oz, but with the origin o at the top, and on the center line of the spring.

The relations between these coordinates and those of the machine are

$$\left.\begin{aligned} \delta_1 &= x + c\beta - b\gamma, \\ \delta_2 &= y - c\alpha + a\gamma, \\ \delta_3 &= z + b\alpha - a\beta, \\ \zeta_1 &= \alpha, \quad \zeta_2 = \beta \quad \text{and} \quad \zeta_3 = \gamma \end{aligned}\right\} \ldots\ldots\ldots [10]$$

Using this notation, it may be shown that the expression for the potential energy stored in a single spring is

$$V_n = \frac{1}{2} K_2\delta_1^2 + \frac{1}{2} K_2\delta_2^2 + \frac{1}{2} K_1\delta_3^2 + \frac{1}{2} K_3\zeta_1^2 + \frac{1}{2} K_3\zeta_2^2 + \frac{1}{2} K_4\zeta_3^2 + \frac{h}{2} K_2\delta_2\zeta_1 - \frac{h}{2} K_2\delta_1\zeta_2 \ldots\ldots [11]$$

The subscript n is used to relate the function V to a particular spring, "n."

Denoting by i and j the unit vectors in the ox and oy directions, respectively, the horizontal force acting is

$$i\frac{\partial V_n}{\partial \delta_1} + j\frac{\partial V_n}{\partial \delta_2} \ldots\ldots\ldots\ldots\ldots [12]$$

The net force acting in the horizontal plane because of simultaneous displacements of "m" springs is

$$\psi = i\sum_1^m \frac{\partial V_n}{\partial \delta_1} + j\sum_1^m \frac{\partial V_n}{\partial \delta_2} \ldots\ldots\ldots [13]$$

The absolute value is

$$|\psi| = \sqrt{\left[\left(\sum_1^m \frac{\partial V_n}{\partial \delta_1}\right)^2 + \left(\sum_1^m \frac{\partial V_n}{\partial \delta_2}\right)^2\right]} \ldots\ldots [14]$$

and the function to be minimized is the average value of

$$\psi^2 = \left(\sum_1^m \frac{\partial V_n}{\partial \delta_1}\right)^2 + \left(\sum_1^m \frac{\partial V_n}{\partial \delta_2}\right)^2 \ldots\ldots\ldots [15]$$

By using Equations [10], Equation [15] may be written in terms of the coordinates of the frame thus

$$\psi^2 = K_2^2\left[mx + \left(\sum_1^m c_n - \frac{1}{2}mh\right)\beta - \sum_1^m b_n\gamma\right]^2 + K_2^2\left[my - \left(\sum_1^m c_n - \frac{1}{2}mh\right)\alpha + \sum_1^m a_n\gamma\right]^2 \ldots\ldots [16]$$

It will be found that this expression is very similar to a potential function. This force function, as it may be called, is essentially positive, and in using it (or functions of its type) for such problems as that cited here, one has the advantage of clearly visualizing what is being accomplished. Such functions cannot, of course, be derived in this manner when the general disturbance is to be minimized. The energy functions, as pointed out previously, should be used in the general case. Incidentally, the greatest weakness of the "force function" lies in the fact that couples acting in the plane must be neglected if the forces are minimized and vice versa. In the elimination of this weak point lies the power of the energy method.

An Illustrative Problem

The problem to be solved here is that of obtaining an optimum balance for the machine that is shown in Fig. 2. For purposes of illustration, the optimum will be obtained for each of several criteria.

As shown in Fig. 2, the machine, a simple compressor, has a vertical, overhung crankshaft. The machine itself is symmetrical about two vertical planes through the center line of the crankshaft, on which the center of gravity lies, and the mounting springs are symmetrically placed about the vertical axis.

The first necessary step is that of writing the potential-energy and kinetic-energy functions, V and T. Equation [6] is used for obtaining V, the evaluation requiring substitution of the values of the spring coordinates a, b, and c for each spring. For the present it will be convenient to leave these values in algebraic form, the substitutions being made according to the following table:

VALUES OF a, b, AND c

Spring number	a	b	c
1	0	R	$-d$
2	$0.866R$	$-0.5R$	$-d$
3	$-0.866R$	$-0.5R$	$-d$

Making these substitutions, the function V becomes, for this case

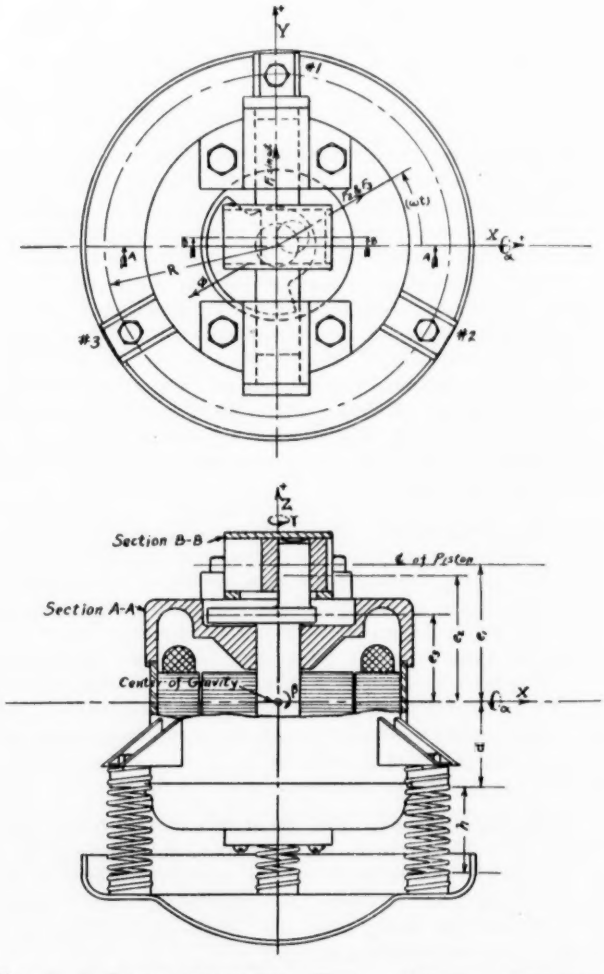

FIG. 2 A SIMPLE COMPRESSOR WITH A VERTICAL, OVERHUNG CRANKSHAFT USED IN THE PROBLEM FOR OBTAINING OPTIMUM BALANCE

$$V = \frac{1}{2}[3K_2x^2 + 3K_2y^2 + 3K_1z^2 + 3(K_2d^2 + \frac{1}{2}K_1R^2 + K_3 + dhK_2)\alpha^2 + 3(K_2d^2 + \frac{1}{2}K_1R^2 + K_3 + dhK_2)\beta^2 + 3(K_2R^2 + K_4)\gamma^2 - 3K_2(2d + h)\beta x + 3K_2(2d + h)\alpha y] \quad [17]$$

Similarly, from Equation [5], noting that F, G, and H are zero because of the symmetry

$$T = \frac{1}{2}M(\dot{x}^2 + \dot{y}^2 + \dot{z}^2) + \frac{1}{2}(A\dot{\alpha}^2 + B\dot{\beta}^2 + C\dot{\gamma}^2) \quad [18]$$

In this problem, the numerical data are: ω = the shaft speed = 182 radians per sec, K_1 = 75 lb per in., K_2 = 42 lb per in., K_3 = 58 lb-in. per radian, K_4 = 17 lb-in. per radian, M = 0.086 lb sec^2 per in., $A = B$ = 0.60 lb-in.-sec^2, d = 1.92 in., h = 2 in., R = 4 in., e_1 = 3.2 in., e_2 = 2.98 in., and e_3 = 2.2 in.

The dimensions e_1, e_2, and e_3, locate, respectively, the piston, crank pin and counterweight from the center of gravity, as shown in Fig. 2. It is usually desirable, when a numerical solution is sought, to start numerical work immediately by substitution of numerical coefficients in V and T. In the present instance, this is delayed for other reasons, and V written with abridged coefficients is

$$V = \frac{1}{2}(a_{11}x^2 + a_{22}y^2 + a_{33}z^2 + a_{44}\alpha^2 + a_{55}\beta^2 + a_{66}\gamma^2 + 2a_{51}\beta x + 2a_{42}\alpha y) \quad [19]$$

Substituting Equations [18] and [19] in Equation [7], the equations of motion are obtained. Thus

$$\left.\begin{aligned} M\ddot{x} + a_{11}x + a_{51}\beta &= Q_x \\ M\ddot{y} + a_{22}y + a_{42}\alpha &= Q_y \\ M\ddot{z} + a_{33}z &= Q_z \\ A\ddot{\alpha} + a_{44}\alpha + a_{42}y &= Q_\alpha \\ B\ddot{\beta} + a_{55}\beta + a_{51}x &= Q_\beta \\ C\ddot{\gamma} + a_{66}\gamma &= Q_\gamma \end{aligned}\right\} \quad [20]$$

Of these six equations, the two in z and γ are independent. Moreover, it will be seen that the forces Q_z and Q_γ, acting in these coordinates, are zero, so that z and γ are both zero and may be neglected in the rest of the problem. Of the remaining four equations, the two in x and β are independent of the two in y and α. So the system reduces to two pairs of simultaneous equations, a very simple system to solve. The simplicity, of course, is a result of the symmetry.

Before proceeding further it may be well to consider the nature of the forces Q_x, etc. The mechanism illustrated is the simple Scotch yoke (see Fig. 2), so that all inertia forces will be simple-harmonic in form. Denoting component forces by q_y, q_α, etc., the forces due to the piston are

$$q_y = F_1 \sin \omega t; \quad \text{and} \quad q_\alpha = -e_1F_1 \sin \omega t$$

The slide block contributes the components

$$q_y = F_2 \sin \omega t; \quad \text{and} \quad q_x = F_2 \cos \omega t$$
$$q_\alpha = -e_1F_2 \sin \omega t; \quad \text{and} \quad q_\beta = e_1F_2 \cos \omega t$$

The crankpin gives

$$q_y = F_3 \sin \omega t; \quad \text{and} \quad q_x = F_3 \cos \omega t$$
$$q_\alpha = -e_2F_3 \sin \omega t; \quad \text{and} \quad q_\beta = e_2F_3 \cos \omega t$$

Finally, the counterweight force, considered variable, gives

$$q_y = -\phi \sin \omega t; \quad \text{and} \quad q_x = -\phi \cos \omega t$$
$$q_\alpha = e_3\phi \sin \omega t; \quad \text{and} \quad q_\beta = -e_3\phi \cos \omega t$$

Adding the components in each coordinate, the results are

$$\left.\begin{aligned} Q_x &= (F_2 + F_3 - \phi)\cos \omega t \\ Q_y &= (F_1 + F_2 + F_3 - \phi)\sin \omega t \\ Q_\alpha &= (-e_1F_1 - e_1F_2 - e_2F_3 + e_3\phi)\sin \omega t \\ Q_\beta &= (e_1F_2 + e_2F_3 - e_3\phi)\cos \omega t \end{aligned}\right\} \quad [21]$$

Considering the sinusoidal nature of these forces, and making the numerical substitutions, the steady-state solutions of Equations [20] are

$$\left.\begin{aligned} x &= (0.0805Q_\beta - 3.7Q_x) \times 10^{-4} \\ \beta &= (0.0805Q_x - 0.595Q_\beta) \times 10^{-4} \\ y &= -(0.0805Q_\alpha + 3.7Q_y) \times 10^{-4} \\ \alpha &= -(0.0805Q_y + 0.595Q_\alpha) \times 10^{-4} \end{aligned}\right\} \quad [22]$$

Now, in Equations [21], let

$$\left.\begin{aligned} \theta_1 &= F_2 + F_3 \\ \theta_2 &= F_1 + F_2 + F_3 \\ \theta_3 &= e_1F_1 + e_1F_2 + e_2F_3 \\ \theta_4 &= e_1F_2 + e_2F_3 \end{aligned}\right\} \quad [23]$$

Then substituting Equations [21] in [22]

$$\left.\begin{aligned} x &= (0.00805\theta_4 - 0.37\theta_1 + 0.352\phi)\cos \omega t \times 10^{-3} \\ y &= (0.00805\theta_3 - 0.37\theta_2 + 0.352\phi)\sin \omega t \times 10^{-3} \\ \alpha &= (0.0595\theta_3 - 0.00805\theta_2 - 0.123\phi)\sin \omega t \times 10^{-3} \\ \beta &= (-0.0595\theta_4 + 0.00805\theta_1 + 0.123\phi)\cos \omega t \times 10^{-3} \end{aligned}\right\} \quad [24]$$

Also, from Equations [17] and [18]

$$V = 63x^2 + 63y^2 + 1462\alpha^2 + 1462\beta^2 - 367.53x + 367.5\alpha y \quad [25]$$

$$T = 0.043(\dot{x}^2 + \dot{y}^2) + 0.3(\dot{\alpha}^2 + \dot{\beta}^2) \quad [26]$$

Substituting the Equations [24] in [25], it will be observed that the factors involving the time are all of the form $\sin^2 \omega t$ or $\cos^2 \omega t$, the average values of which are 0.5. Denoting differentiation with respect to ϕ by primes

$$\frac{dV}{d\phi} = (126x' - 367.5\beta')x + (126y' + 367.5\alpha')y + (2924\alpha' + 367.5y')\alpha + (2924\beta' - 367.5x')\beta \quad [27]$$

Making numerical substitutions in this expression, taking its average, and setting the result equal to zero, there is obtained the value of the counterweight force for minimum average potential energy. That is

$$\phi = 0.72F_1 + 1.48F_2 + 1.378F_3 \quad [28]$$

It is interesting to note that in this case, which results in a minimum of transmission, the counterweight is called upon to balance considerably more than "all of the rotating plus half of the reciprocating mass."

The method of computation has been indicated in sufficient detail to make further work unwarranted. However, it will be of interest to tabulate the results of working to other criteria in this same machine. For instance, if the average kinetic energy is minimized, considering the effect of the mounting, the result is

$$\phi = 0.605F_1 + 1.210F_2 + 1.164F_3 \quad [29]$$

which is considerably less than in Equation [28]. On the other hand, if the total energy $T_a + V_a$ is minimized

$$\phi = 0.611F_1 + 1.222F_2 + 1.173F_3 \quad [30]$$

which value is found to fall between the two previous results.

If the machine is considered to be floating in space, and T_a is minimized, then

$$\phi = 0.560F_1 + 1.119F_2 + 1.049F_3 \quad [31]$$

requiring the smallest counterweight of all.

One other particular case is important. Suppose that it is possible to use two counterweights rather than one. Such a system can be represented by a rotating force at the center of gravity and a rotating couple acting in the plane of the force and the shaft center-line. Let the force be ϕ_1, and the couple ϕ_2. Then it may be shown by a general proof that for a symmetrical machine with a symmetrical mounting, and with $dV_a = 0$

$$\phi_1 = \frac{1}{2} F_1 \qquad \text{and} \qquad \phi_2 = \frac{1}{2} e_1 F_1 \quad [32]$$

where F_1 is the maximum piston force, and e_1 the distance of the center of gravity of the piston from the center of gravity of the machine, as before. This solution is obtained by minimizing V_a, and is independent of either spring characteristics or location, as long as symmetry is observed. This does not mean, of course, that V_a cannot be reduced by shifting the plane of attachment of the springs. It does mean that for any given location the minimum V_a is obtained by the relations expressed in Equations [32].

Conclusion

The method of balancing explained here has been used by the author for two or three years with a marked degree of success. The results obtained have been checked experimentally, and have shown a definite improvement over those obtained by less scientific methods.

That there are distinct advantages in using such a method can scarcely be questioned, for there is sound philosophy behind reasoning that goes back as nearly as possible to human response for its measuring stick. Aside from this, there is definite power in the method of attack. Even the so-called "rigid mounted" machines may be treated by simply realizing that in this case the kinetic energy of the machine tends to vanish and the energy of the mounting is all that remains to be minimized. There is also the possibility of studying other variables than counterweights, such as spring positions, and adjusting these to obtain optimum conditions by the same general procedure.

Designers, by acquainting themselves with this method, will be able to approach their vibration problems with a new viewpoint and a powerful technique. It is reasonable to expect that this will, in time, bear its fruit—less vibration in machinery.

Appendix

The Constants for Helical-Spring Deflections

The expressions which follow are approximate, and apply only to helical springs of round wire. The approximations involved require that:

(*a*) If ϕ is the angle of lead (radians), then ϕ^2 is negligible compared to unity.

(*b*) There is either an integral number of turns or else a sufficient number of turns so that a fractional number may be used in the formulas without appreciable error. Ordinarily, the formulas will be sufficiently accurate if the spring has eight or more active turns.

(*c*) In the case of transverse constants, the displacement must be small.

Notation:

- G = modulus of rigidity
- E = Young's modulus
- J = polar moment of inertia of the wire cross-section
- I = plane moment of inertia of the wire cross-section about a diameter
- l = total length of wire in the active part of the spring
- R = radius of cylinder in which lies the helix formed by the center line of the wire
- h = active height of the spring
- n = number of active turns

Formulas:

$$K_1 = \frac{GJ}{lR^2} \quad [33]$$

$$K_2 = \frac{2EI}{l\left[\left(\frac{3}{16} + \frac{41}{48\pi^2 n^2}\right) h^2 + R^2\right]} \quad [34]$$

$$K_3 = \left[\frac{1}{3} h^2 + \frac{GR^2}{2G + E}\right] K_2 \quad [35]$$

$$K_4 = \frac{E}{2G} R^2 K_1 \quad [36]$$

where definitions of these constants are the same as given previously.

Investigations of the Turbulent Mixing Regions Formed by Jets

By ARNOLD M. KUETHE,[1] AKRON, OHIO

The turbulent mixing of two jets of fluid of the same density is investigated theoretically by means of Prandtl's theory of turbulence and the results compared with experiment.

A solution obtained by Tollmien for the mixing region of a plane jet, in which he considers the fluid bounding the jet at rest, is extended to the general case of the mixing of two parallel streams of different velocities. Distributions of the tangential and normal velocities in the mixing region are given. The solution is worked out for two different conditions imposed on the normal velocity at the boundary of the mixing region.

Next, the turbulent mixing region surrounding an axially symmetrical jet issuing into fluid at rest is considered. The problem is solved, as far as the core of potential flow extends, by the application of a new method of approximation. The velocity field, as determined by a second approximation to the velocity profiles, is given. An extension of the method of solution, applicable to problems in which the velocity profiles differ widely, is mentioned.

In the theory applied in this paper, the mixing length is assumed proportional to the breadth of the mixing region. The proportionality factor which is the only empirical quantity in the theory was experimentally evaluated. Velocity profiles in the mixing region of an axially symmetrical jet were measured by means of a pitot tube and good agreement is found between theory and experiment.

Measurements of velocity fluctuations in the core of potential flow near the jet mouth and in the mixing region at a distance of 9.3 diameters were made by means of the hot-wire anemometer.

THIS investigation deals with the turbulent mixing of two parallel streams of fluid of the same density moving at different velocities. Such cases occur often in practical applications of such streams, and it is of some importance to know at which rate the discontinuity between the two streams is "washed out," and what is the magnitude of the thickness of the layer which is affected by the mixing. The boundaries of the open-jet wind tunnel and of the slipstream of a propeller are two examples to which the results of the present investigation can be applied.

Considering first a perfect fluid, it is well known that a surface of discontinuity in the velocity, though not in the pressure, may exist at the boundary separating the two streams. Helmholtz[2] first pointed out the possibility of the existence of this surface, but proved it to be unstable,[3] i.e., a slight disturbance will build up into a regular succession of vortices traveling along the surface. The vena contracta and the boundaries of the dead-water region behind a flat plate are examples which have been treated by Kirchhoff, Rayleigh, and others.

The regular succession of vortices which are given off at the rim can be observed only below a certain velocity limit. As the velocity is increased the periodic vortex system is replaced by a turbulent mixing region.

Turbulence, as distinct from those cases in which a regular succession of vortices is formed, is characterized by an irregular fluctuating motion superposed on a mean flow. These fluctuations give rise to a momentum transport between neighboring fluid regions and, as a result, "apparent stresses" will act between these regions. If we consider a flow, the main component of which is in the x-direction, its magnitude being a function of y, the momentum transport will depend upon the velocity gradient and the most important apparent stress will be τ_{xy}. Prandtl[4] gives the expression

$$\tau_{xy} = \rho l^2 \left(\frac{\partial u}{\partial y}\right) \left|\frac{\partial u}{\partial y}\right| \quad \ldots\ldots\ldots\ldots\ldots [1]$$

where ρ is the density of the fluid, u is the mean velocity, and l the "mixing length." The length l is analogous to the mean free path in the kinetic theory of gases and is proportional to the mean distance which a fluid mass will travel in the y-direction while retaining its initial momentum. Briefly, the mechanism is assumed to be the following: Fluid masses entering a constant velocity layer from opposite sides have x velocities $u + l\frac{\partial u}{\partial y}$ and $u - l\frac{\partial u}{\partial y}$, respectively. Then, at this place, fluctuations in the x-direction about the mean velocity will be $\pm l\frac{\partial u}{\partial y}$. The resulting y-component is assumed to be proportional[5] to $l\left|\frac{\partial u}{\partial y}\right|$; the proportionality constant may be included in l since this quantity is not defined exactly. The mean value over the time of the product of these two velocity components and the density of the fluid gives the magnitude of the turbulent shearing stress. The sign of the product is chosen as in Equation [1] since the shearing stress must have the same sign as the velocity gradient. In cases of free turbulence, i.e., cases in which there are no confining walls, the very simple assumption that l is constant over any

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until November 11, 1935, for publication at a later date.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[3] On the other hand, Ackeret (Helvetica Physica Acta I:V, p. 301, 1928, published by E. Birkhauser & Co., Basilae, Switzerland) has shown that the surface is stable for hypersonic velocities.

[4] "Bericht über Untersuchungen zur ausgebildeten Turbulenz," by L. Prandtl, *Zeit. für angewandte Mathematik und Mechanik*, vol. 5, 1925, p. 136.

[5] Th. von Kármán (Nachrichten von der Gesellschaft der Wissenschaften zu Göttingen, 1930) pointed out that this assumption implies a constant correlation between the fluctuation of the two considered velocity components over the whole turbulent region. He showed that, assuming constant correlation, Equation [1] can be deduced without the assumption of a special mechanism for the turbulent interchange.

cross-section and proportional to the breadth of the mixing region gives results in good agreement with practice. The proportionality constant must be evaluated empirically for each case.

Tollmien[6] with the aid of Equation [1] solved the problem of the plane jet issuing into a medium at rest and also obtained a solution valid at great distances from an axially symmetrical jet. In these cases the mean motion is not exactly parallel; however, the shearing-stress component τ_{xy} is large in comparison with the other stress components and Equation [1] represents a good approximation for τ_{xy}. These solutions hold for a wide range of velocities and this is not surprising when we consider the strong discontinuity in the velocity at the rim of the jet. Very large velocity disturbances result and the completely turbulent state is realized at a comparatively low velocity.

The object of the present work was to extend Tollmien's results to other cases of practical importance. We treat, first, the two-dimensional problem and, second, that of the axially symmetric jet.

2 The Plane Jet

The arrangement, as shown in Fig. 1, in which η_1 and η_2 are the boundaries of the turbulent mixing region, finds practical

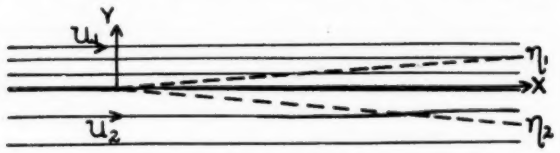

Fig. 1 Schematic Diagram of the Plane Jet

application both in the case of the open-jet wind tunnel and the propeller slipstream. The limit of its applicability, because of the finite diameter of the wind tunnel or the propeller, will be discussed in part 3.

Tollmien's solution for $u_2 = 0$ is here extended to the case in which u_2 has any value from 0 to u_1. In the boundary-layer theory we assume that no appreciable pressure difference exists normal to the main-flow direction, and, since the pressure in the jets outside the mixing region is constant, the pressure gradients can be completely neglected. Hence, we need consider only the first equation of motion, and this reduces to

$$u\frac{\partial u}{\partial x} + v\frac{\partial v}{\partial y} = \frac{1}{\rho}\frac{\partial}{\partial y}\tau_{xy} \quad [2]$$

where v is the y component of the mean velocity and τ_{xy} is given by Equation [1]. This equation, combined with the continuity equation

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \quad [3]$$

and suitable boundary conditions then describes the field of flow in the mixing region.

We assume

$$u = f(y/x)$$

i.e., that the breadth of the mixing region is proportional to x. Hence, the assumption that the mixing length is proportional to the breadth of the mixing region can be expressed as

$$l = cx \quad [4]$$

where c is an empirical constant.

We obtain, from Equation [3], the stream function

$$\psi = xF(y/x)$$

and, consequently

$$\left.\begin{aligned} u &= F' \\ v &= -F + \frac{y}{x}F' \end{aligned}\right\} \quad [5]$$

Substituting Equations [1], [4], and [5] in Equation [2] leads to the ordinary differential equation

$$F(\eta) + F'''(\eta) = 0 \quad [6]$$

where

$$\eta = \frac{y}{\sqrt[3]{(2c^2)x}}$$

The solution to Equation [6] can be expressed in the following form:

$$F(\eta') = d_1e^{-\eta'} + d_2e^{\eta'/2}\cos\frac{\sqrt{3}}{2}\eta' + d_3e^{\eta'/2}\sin\frac{\sqrt{3}}{2}\eta' \quad [7]$$

where $\eta' = \eta - \eta_1$, and d_1, d_2, and d_3 are constants.

Four of the five boundary conditions necessary to determine the constants d_1, d_2, d_3, η_1, and η_2 as functions of the ratio of the two jet velocities are

$$\text{at } \eta = \eta_1(\eta' = 0)\begin{cases} u = u_1 \\ \dfrac{\partial u}{\partial y} = \dfrac{\partial u}{\partial \eta'} = 0 \end{cases}$$

$$\text{at } \eta = \eta_2(\eta' = \eta_2')\begin{cases} u = u_2 \\ \dfrac{\partial u}{\partial y} = \dfrac{\partial u}{\partial \eta'} = 0 \end{cases} \quad [8]$$

For the fifth boundary condition, Tollmien (for the case $u_2 = 0$) chose $v_1 = 0$ at $\eta' = 0$ and the present calculation was at first carried out retaining this condition. $v_1 = 0$ was chosen with a view to its applicability to the mixing region near the mouth of a closed, say a circular, jet. It was later pointed out by von Kármán that for the plane boundary between two jets the condition

$$u_1v_1 = -u_2v_2 \quad [9]$$

is preferable. This corresponds to the assumption that no external forces are acting on the total fluid system perpendicular to the main flow. For $x < 0$, $v_1 = 0$, $v_2 = 0$, i.e., the two jets are exactly parallel. In the region $x > 0$, both are deflected. Equation [9] expresses the condition that the reactions of the two jets, corresponding to their deflection, perpendicular to x, are equal and opposite.

Since all of the quantities in Equation [8] are functions of η_2', d_1, d_2, d_3, i.e., neither η_1 nor η_2 enters explicitly, the four resulting equations determine these four quantities independent of the remaining boundary condition. Hence, neither the width of the wedge-shaped mixing region nor the u-velocity profiles are affected by the use of the condition $u_1v_1 = -u_2v_2$ instead of $v_1 = 0$. The v-velocity profiles and η_1 and η_2 are affected an appreciable amount.

In terms of the function $F(\eta')$, Equations [8] and [9] reduce to

$$F'(0) = u_1 \qquad F'(\eta_2') = u_2$$

$$F''(0) = 0 \qquad F''(\eta_2') = 0$$

$$m[-F(\eta_2') + \eta_2F'(\eta_2')] = F(0) - \eta_1F'(0)$$

where $m = \dfrac{u_2}{u_1}$. For the boundary condition $v_1 = 0$, it was possible to solve for d_1, d_2, d_3, η_1, and η_2. Then, since only η_1

and η_2 change when $u_1v_1 = -u_2v_2$ is used instead of $v_1 = 0$, we can substitute in the last equation given, using the previously determined values for d_1, d_2, d_3, and η_2'. This equation and the relation $\eta_2' = \eta_2 - \eta_1$ allow the determination of η_1 and η_2 as functions of m.

Table 1 gives the quantities d_1, d_2, d_3, η_1, η_2, and η_2' for both choices of the v-boundary condition as functions of m. In Fig. 2 η_1 and η_2 are plotted as functions of m.

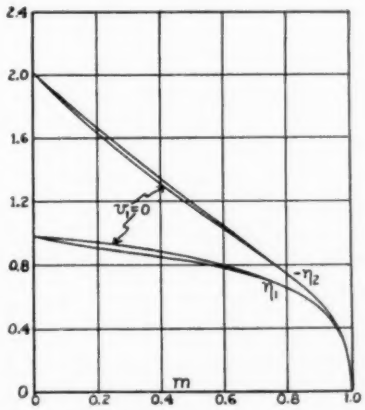

FIG. 2 BOUNDARIES OF THE TURBULENT MIXING REGION AS FUNCTIONS OF $m = u_2/u_1$

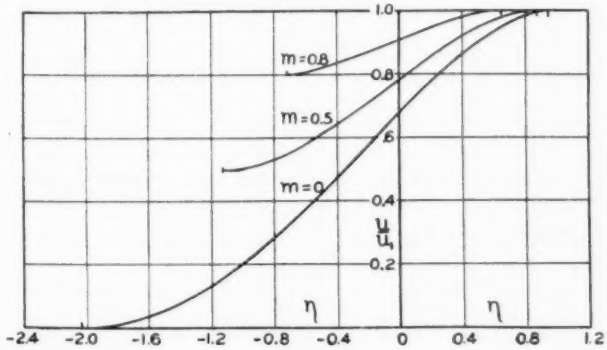

FIG. 3 DISTRIBUTION OF u/u_1 FOR THREE VALUES OF $m = u_2/u_1$

It is seen that for $m = 0$ the mixing region is not symmetrical about the extension of the boundary initially separating the two jets, but, as m increases, the boundaries gradually approach a position symmetrical about this line. Fig. 3, in which u-velocity profiles for three values of m are plotted, shows clearly this transition.

Velocity profiles can be plotted for any given m by the use of Table 1 and Equations [5] and [7]. It must be remembered, however, that the scale of y/x has been reduced by the factor $\sqrt[3]{(2c^2)}$.

To show the change in shape resulting from a change in m, two of the profiles of Fig. 3 are replotted, along with the limiting expression, in Fig. 4.

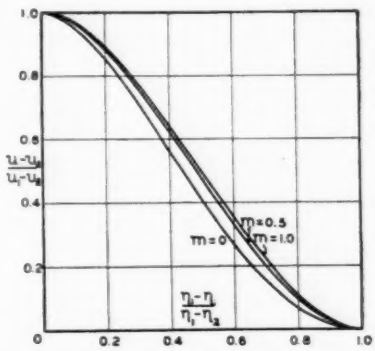

FIG. 4 DISTRIBUTION OF $u - u_2/u_1 - u_2$ FOR THREE VALUES OF $m = u_2/u_1$

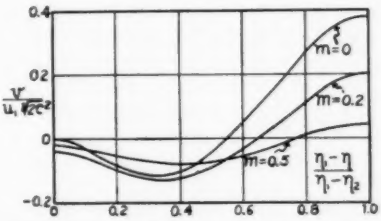

FIG. 5 DISTRIBUTION OF THE NORMAL VELOCITY FOR THREE VALUES OF $m = u_2/u_1$

The limiting expression is found by substituting the series expansions for the transcendental terms in the equation $\frac{u}{u_1} = F'(\eta')$, suppressing all terms of order higher than η_1^3. As is to be expected from the fact that the boundaries of the mixing region become symmetrical near $m = 1$, the limiting curve for $m = 1$ is anti-symmetrical about the center line. This calculation was carried out for the condition $v_1 = 0$, since in this case d_1, d_2, d_3 were found as analytical functions of η_1. However, as m approaches unity, η_1 and η_2 for the two choices of the v-condition are nearly identical. Hence, we would expect the limiting profile to be independent of this choice.

Measurements of the mean velocities in the mixing region at the boundary of the open-jet wind tunnel at Göttingen show good agreement with theory if the value $c = 0.0174$ or $\sqrt[3]{(2c^2)} = 0.0845$ is used.

Tollmien carried out an investigation of the pressure difference existing between the center of the mixing region and the undisturbed flow by substituting his results for u, v, $\tau_{xy}(u_2 = 0)$ in the second equation of motion

$$u\frac{\partial v}{\partial x} + v\frac{\partial v}{\partial y} = -\frac{1}{\rho}\frac{\partial p}{\partial y} + \frac{1}{\rho}\frac{\partial \tau_{xy}}{\partial x}$$

and determining p by integrating with respect to y. He found this difference in pressure to be $0.00482\,\frac{\rho}{2}\,u_1^2$, which, if taken into account in determining a second approximation, would not appreciably alter the stream lines.

3 The Axially Symmetrical Jet

The case of the discharge of an axially symmetrical jet into fluid at rest occurs very frequently, especially in experimental arrangements. Tollmien's solution for this case in which he considers the jet as issuing from a point holds very well for values of x greater than about eight diameters. However, if we wish to obtain a solution valid near the mouth of the jet, it appears to be impossible to transform the equation for the mean motion into a total differential equation. Accordingly, a method for obtaining an approximate solution was applied directly to the partial-differential equation.

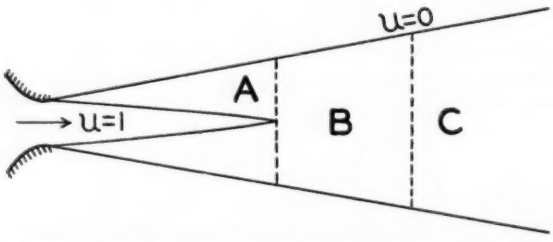

Fig. 6 Schematic Section of the Flow From a Circular Nozzle

We can form a qualitative picture of the flow from a consideration of the building up of the turbulent mixing region. This region, originating at the rim of the jet mouth, will form an annular ring enclosing a core of potential flow in which the velocity is constant and equal to the outflow velocity. At a point $x = x_1$ this core will vanish and the entire jet then becomes a turbulent mixing region. A schematic longitudinal section of the flow is shown in Fig. 6. Region A consists of the annular mixing region surrounding the core of potential flow. In region B the entire jet is a mixing region and the central velocity u_0 decreases as x increases. The velocity profiles and the x gradient of u_0 finally reach an asymptotic state as the fluid enters region C. In C, the central velocity is inversely proportional to the distance from some point near the jet mouth and all profiles are similar, i.e., plotting u/u_0 against y/b where y is the radial distance of a point from the axis and b is the breadth of the jet, all points fall on a single curve. It is in this last region that Tollmien's solution is valid.

At the point $x = x_1$, i.e., where the potential core vanishes, we can, for physical and mathematical reasons, expect considerable difficulty in finding a solution reasonably close to practice. Consequently, we will consider at first only region A.

For the same reasons as in part 2, the pressure gradients are neglected and the equation for the mean motion is

$$u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = \frac{1}{\rho y}\frac{\partial}{\partial y}(\tau y) \quad \ldots\ldots [10]$$

The continuity equation is

$$\frac{\partial}{\partial x}(uy) + \frac{\partial}{\partial y}(vy) = 0 \quad \ldots\ldots [11]$$

For region A we have the following boundary conditions:

$$\text{at } y = d \begin{Bmatrix} u = 1 \\ \dfrac{\partial u}{\partial y} = 0 \\ v = 0 \end{Bmatrix}; \quad \text{at } y = d + b \begin{Bmatrix} u = 0 \\ \dfrac{\partial u}{\partial y} = 0 \end{Bmatrix} \ldots [12]$$

where d is the radius of the potential core, b is the breadth of the mixing region, and $v = 0$ at $y = d$ is necessary, as for the plane jet for $u_2 = 0$, if the fundamental assumption that no pressure difference exists between the jet and the surrounding air is to be satisfied.

At $x = 0$, $y = 1$ (taking the jet mouth to be of unit radius), Equation [10] reduces to the two-dimensional Equation [2], so that the limiting profile is that for $m = 0$ in Fig. 4. Then, as x increases, there must be a gradual transition from this profile to that obtained by Tollmien for large values of x. These two solutions are shown in Fig. 7.

In both cases, the mixing length l was taken proportional to the breadth of the mixing region, but this is justified only when the profiles are similar. However, since the profiles do not differ markedly, we can, to a good approximation, again set

$$l = cb \quad \ldots\ldots [13]$$

where the value of c is not the same as it was in part 2. Substituting Equations [1] and [13] in Equation [10] we obtain

$$u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = \frac{c^2b^2}{y}\frac{\partial}{\partial y}\left\{y\left(\frac{\partial u}{\partial y}\right)\left|\frac{\partial u}{\partial y}\right|\right\} \quad \ldots\ldots [14]$$

To solve this differential equation approximately, we assume, as a first approximation, a reasonable velocity distribution in the mixing region. Then, by means of the differential equation we obtain a second approximation to the solution.

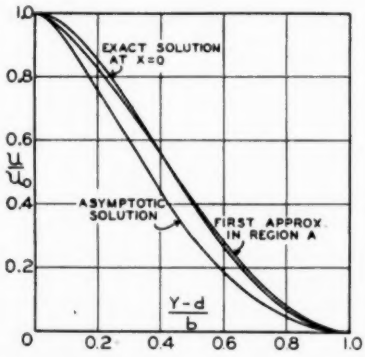

Fig. 7 Comparison Between Solutions for $x = 0$ and for x Large. First Approximation to All Profiles in Region A

We can consider u as a function of y, d, and b, where d and b are as yet undetermined. We assume, for simplicity, that u_1, where here as in subsequent expressions the subscript refers to the order of the approximation, is a function only of θ, defined by the formula

$$u_1 = f(\theta), \quad \text{where} \quad \theta = \frac{y - d}{b} \quad \ldots\ldots [15]$$

This assumption expresses the fact that the first approximation is made up of similar profiles. The dependence expressed by Equation [15] is in complete agreement with the results of part 2 at the rim of the jet mouth when the origin of coordinates is transformed to that point.

The simple expression[7]

$$u_1 = (1 - \theta^{3/2})^2 \quad \ldots\ldots [16]$$

satisfies the boundary conditions of Equation [12] (3.3) and, as is

[7] The corresponding expression,

$$u = \left\{1 - \left(\frac{y}{b}\right)^{3/2}\right\}^2$$

was found by Miss Swain, Proceedings, Royal Society of London, 105A, 1929, pp. 647–659; and Schlichting, *Ingenieur Archiv*, vol. 1, 1930, p. 533, as a first approximation to the velocity profiles for the axially symmetric and the plane wind shadows, respectively.

shown in Fig. 7, is reasonably close to the limiting profile at $x = 0$. It was, therefore, chosen as a first approximation to the profiles in region A. The corresponding value of v_1, as determined from Equation [11] is

$$v_1 = -\frac{1}{y}\int_d^y \frac{\partial u_1}{\partial x}\, y\, dy \quad \ldots\ldots\ldots\ldots [17]$$

In the first approximation, Equation [16], the quantities d and b are still unknown. The first attempt to find these parameters was made by means of the well-known momentum theorem. Multiplying both sides of Equation [14] by y and integrating with respect to y, we get

$$uvy - \frac{\partial}{\partial x}\int_y^{d+b} u^2 y dy = c^2 b^2 \left(\frac{\partial u}{\partial y}\right)^2 y \quad \ldots\ldots [18]$$

This relation is specialized for $y = 0$, corresponding to the axis of the jet. Then

$$\int_0^{d+b} u^2 y dy = \text{constant} = 0.5 \ldots\ldots\ldots [19]$$

where the integral represents, to a factor of 2π, the total momentum passing any section per second. This is set equal to the momentum issuing at the mouth of the jet. Secondly, we place y in Equation [18] equal to unity, corresponding to the point in the mixing region on the cylindrical extension of the jet mouth. We now substitute $u = u_1$ and $v = v_1$ from Equations [16] and [17] in Equation [19]. There result two relations between b, d, $\frac{db}{dx}$, and $\frac{dd}{dx}$ from which we can easily determine b and d as functions of x. This method of building up a first approximation is similar to one suggested by von Kármán and applied by Pohlhausen[8] in the theory of the laminar boundary layer.

To obtain a second approximation u_2, we substitute the first approximation u_1, v_1 in the left side of Equation [18] and identify the right side with the second approximation. One integration then gives

$$u_2 = \int_y^{d+b} \sqrt{\frac{1}{c^2 b^2 y}\left(u_1 v_1 y - \frac{\partial}{\partial x}\int_y^{d+b} u_1^2 y dy\right)}\, dy \quad \ldots\ldots [20]$$

This expression is so constructed that the boundary conditions $u_2 = \frac{\partial u_2}{\partial y} = 0$ at $y = d + b$ are satisfied. Unfortunately, the second approximation had a strong deviation, amounting to from 5 to 10 per cent, from u_1 at the inner boundary $y = d$ of the mixing region of the first approximation. This behavior would have been very difficult to correct since it signifies an overlapping of the mixing regions for the two approximations. Accordingly a method, suggested by Tollmien, was applied by which the coincidence of the boundaries of the two approximations was immediately insured.

We shall delay, for the moment, the determination of the parameters b and d in the first approximation in order to develop a different and more convenient method for proceeding from u_1 to u_2. For this purpose we write Equation [14], the equation of motion, in the form

$$2b^2c^2 \frac{\partial^2 u}{\partial y^2} = -\frac{u\dfrac{\partial u}{\partial x}}{\dfrac{\partial u}{\partial y}} - v - \frac{b^2c^2}{y}\frac{\partial u}{\partial y} \quad \ldots\ldots\ldots [21]$$

The denominator $\frac{\partial u}{\partial y}$ causes no singularity at its vanishing points, since at these points $\frac{\partial u}{\partial x}$ vanishes with at least the same order. We now place u_1 in the right and u_2 in the left side of Equation [21] and get for the second approximation

$$\frac{\partial u_2}{\partial y} = \int_y^{d+b} \frac{1}{2b^2c^2}\left\{-\frac{u_1\dfrac{\partial u_1}{\partial x}}{\dfrac{\partial u_1}{\partial y}} - v_1 - \frac{b^2c^2}{y}\frac{\partial u_1}{\partial y}\right\} dy \ldots [22]$$

$$u_2 = \int_y^{b+d}\int_d^y \frac{1}{2b^2c^2}\left\{-\frac{u_1\dfrac{\partial u_1}{\partial x}}{\dfrac{\partial u_1}{\partial y}} - v_1 - \frac{b^2c^2}{y}\frac{\partial u_1}{\partial y}\right\} dydy \quad \ldots\ldots [23]$$

where the integration limits are chosen so that $\frac{\partial u_2}{\partial y} = 0$ at $y = d$, $u_2 = 0$ at $y = d + b$. According to the idea already outlined the boundaries of both approximations shall coincide, i.e., the boundary conditions $u_1 = u_2 = 1$ at $y = d$ and $\frac{\partial u_1}{\partial y} = \frac{\partial u_2}{\partial y} = 0$ at $y = d + b$ shall be satisfied. Then, from Equations [22] and [23]

$$\int_d^{b+d} \frac{1}{2b^2c^2}\left\{-\frac{u_1\dfrac{\partial u_1}{\partial x}}{\dfrac{\partial u_1}{\partial y}} - v_1 - \frac{b^2c^2}{y}\frac{\partial u_1}{\partial y}\right\} dy = 0$$

$$\int_d^{b+d}\int_d^y \frac{1}{2b^2c^2}\left\{-\frac{u_1\dfrac{\partial u_1}{\partial x}}{\dfrac{\partial u_1}{\partial y}} - v_1 - \frac{b^2c^2}{y}\frac{\partial u_1}{\partial y}\right\} dydy = 1$$

We again assume that

$$u_1 = f(\theta)$$

Then the above conditions are transformed into

$$\frac{1}{2}\int_0^1 \left\{u_1(d' + b'\theta) - \frac{v_1}{c^2} - \frac{\partial u_1}{\partial \theta}\frac{1}{\theta + \delta}\right\} d\theta = 0 \ldots [24]$$

$$\frac{1}{2}\int_0^1\int_0^\theta \left\{u_1(d' + b'\theta) - \frac{v_1}{c^2} - \frac{\partial u_1}{\partial \theta}\frac{1}{\theta + \delta}\right\} d\theta d\theta = 1 \ldots [25]$$

where

$$\delta = \frac{d}{b}; \qquad d' = \frac{1}{c^2}\frac{dd}{dx}; \qquad b' = \frac{1}{c^2}\frac{db}{dx}$$

Equations [16] and [17] are again used as a first approximation. If these are substituted in Equations [24] and [25] the integrations can be carried out analytically and result in equations of the type

$$\left.\begin{aligned} b'f_1(\delta) + d'f_2(\delta) + f_3(\delta) &= 0 \\ b'f_4(\delta) + d'f_5(\delta) + f_6(\delta) &= 0 \end{aligned}\right\} \quad \ldots\ldots\ldots [26]$$

Eliminating b' and d' successively gives

$$\left.\begin{aligned} b' &= g_1(\delta) \\ d' &= g_2(\delta) \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [27]$$

[8] "Zur Integration der differentialgleichung der laminaren Grenzschicht," by K. Pohlhausen, *Zeit. für angewandte Mathematik und Mechanik*, vol. 1, 1921, pp. 252–268.

or

$$\frac{dd}{db} = \frac{g_2(\delta)}{g_1(\delta)} = b\frac{d\delta}{db} + \delta$$

Integration of this differential equation gives

$$\log \frac{b}{b_1} = \int_0^\delta \frac{g_1 d\delta}{g_2 - g_1\delta}$$

where b_1 is an integration constant. The indicated integration can be carried out graphically and we have

$$\frac{b}{b_1} = h(\delta) \quad \ldots\ldots\ldots\ldots\ldots\ldots [28]$$

In order to determine b as a function of x we first plot the first equation of [27] and Equation [28] and eliminate δ. Then, plotting $c^2\frac{dx}{db} = \frac{1}{b'}$ against b/b_1 and integrating, we obtain

$$\int_0^{b/b_1} \frac{d(b/b_1)}{b'} = \frac{c^2x}{b_1} = F\left(\frac{b}{b_1}\right) \quad \ldots\ldots\ldots\ldots [29]$$

where the condition that $b = 0$ at $x = 0$ has been used. Further, from Equation [28] we get δ as a function of $\frac{c^2x}{b_1}$. Then, from the relation $d = \delta b$

$$\frac{c^2x}{b_1} = G\left(\frac{d}{b_1}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots [30]$$

Finally, by the condition $d = 1$ at $x = 0$, the integration constant b_1 is determined and we have both parameters in the form

$$\left.\begin{aligned} b &= b(c^2x) \\ d &= d(c^2x) \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots [31]$$

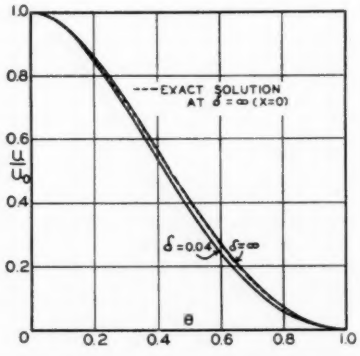

FIG. 8 SECOND APPROXIMATION TO PROFILES IN REGION A. COMPARISON BETWEEN SECOND APPROXIMATION AND EXACT SOLUTION FOR $x = 0$

The boundaries of the mixing region are now fixed and u_2 is calculated from Equation [23]. Fig. 8 shows two profiles ($\delta = 0.04$ and $\delta = \infty$) calculated in this manner. We know the limiting profile for $\delta = \infty$ to be that for the plane jet for $m = 0$, where m is again the ratio of the outside velocity to the jet velocity. This profile is also plotted in Fig. 8 and we see that the agreement between the second approximation and the exact solution is very good indeed.

Fig. 9 shows the boundaries of the mixing region as given by Equation [31] and also the lines of constant velocity as derived from the profiles for various values of δ. At $\delta = 0$ the main correction term in u_2 vanished, having an infinite derivative at that point. The calculated profile was obviously considerably in error and consequently is not given here.

Since the momentum integral Equation [19] has not yet been used in this process, we can, by its use, determine how far we may consider the approximation good. The momentum for the profile at $\delta = 0$ was 12 per cent high while that for $\delta = 0.04$ was still within 2 per cent of the correct value. This indicates that, in spite of the unfortunate behavior near $\delta = 0$ or $c^2x = 0.0473$, we can still describe, to a good approximation, the velocity field as far as $\delta = 0.04$ or $c^2x = 0.044$, which is quite near to the end of the core of potential flow.

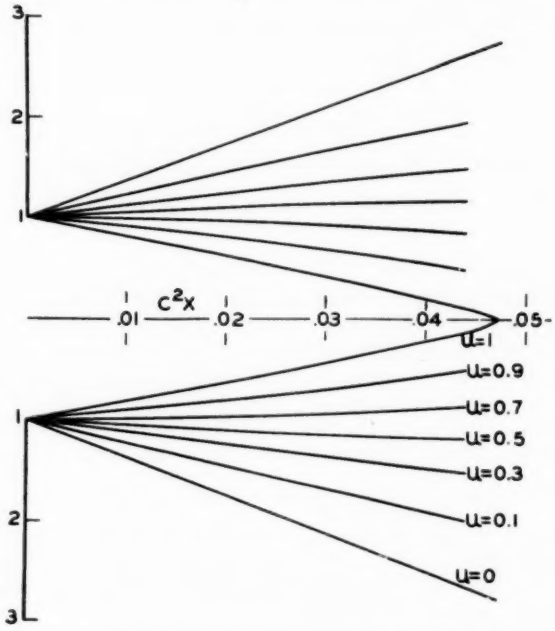

FIG. 9 SECOND APPROXIMATION TO THE VELOCITY FIELD IN REGION A

Fig. 9 shows that the lines of equal velocity are very nearly straight and we know that, for small values of x, they agree with those for the plane case. Furthermore, Fig. 8 shows that the divergence between profiles in region A is not large.

We can then easily predict the approximate flow picture if the jet is issuing into a moving fluid, which is the problem analogous to that considered in part 2 for the plane jet. We know that the limiting conditions at the jet mouth will be those already found for the plane jet. For $m = 0$, the results of the foregoing analysis show that the change, both in the boundaries of the mixing region and the velocity profiles, is not large. This indicates that, for any m, the results of part 2 for the plane jet can be used to a first approximation as far as the core of potential flow extends.

A refinement of the foregoing method was applied in region B. However, near the point where the core of potential flow vanishes, the results were not in accord with experiment. Since, at this point, the physical behavior is not clear, making the assumption for l very doubtful, no further attempt was made to describe the field of flow in this region.

The refined method consisted essentially of introducing dissimilar profiles for the first approximation. Hence, u_1 must contain a "shape factor." For region A this proposal would lead, to an assumption

$$u_1 = \left[1 - \left(\frac{y-d}{b}\right)^p\right]^3$$

In addition to b and d we must now determine p, the shape factor,

as a function of x. To carry out this determination we must have three conditions, one more than was required by the preceding method. The momentum theorem Equation [19] applied to u_1 gives us this third condition. This is differentiated with respect to x and we have three simultaneous differential equations to solve for b, d, and p. The method of solution is similar to that outlined for the preceding method.

The utility of these methods is by no means restricted to the foregoing problem. The methods are equally useful for the solution of various problems in laminar as well as turbulent flow. It is necessary, of course, to know the approximate shape of the velocity profiles. Higher approximations can be found by repeating the processes, though a considerable amount of calculation is involved.

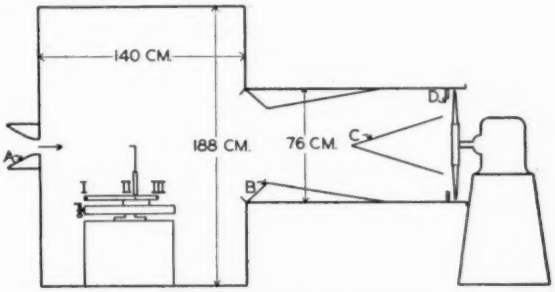

FIG. 10 LONGITUDINAL SECTION OF EXPERIMENTAL ARRANGEMENT SHOWING THE MEASURING DEVICE IN POSITION

Tollmien, by the method described in part 2, carried out an investigation of the pressure difference between the center of the mixing region and the undisturbed fluid for x large. This difference was found to be $-0.00295 \frac{\rho}{2} u_0^2$ where u_0 is the central velocity in the jet at the point considered. This quantity is again negligible in so far as its consideration would alter the mean stream lines. Since the case considered is intermediate between those considered by Tollmien, no investigation of the pressure difference was made.

4 EXPERIMENTAL DETERMINATION OF c

For the purpose of evaluating the empirical constant in the calculation of part 3, measurements were made of mean-velocity distributions in an axially symmetrical jet.

The arrangement, a longitudinal section of which is shown in Fig. 10, was essentially an Eiffel-type wind tunnel, the observation room being 140 × 188 × 188 cm and the outlet tube 76 cm in diameter. This part of the apparatus with the motor and fan already existed, so it was necessary to use an entrance small enough to permit an exploration of the velocity field as far as the asymptotic region.

A 10-cm nozzle with fairing as shown in Fig. 10 was used. Air was drawn through the arrangement by a two-bladed fan driven by a 7.5-hp a-c motor, the speed of which was varied by varying the frequency of the current. With the outlet unobstructed, strong pulsations, backflow, and rotation of the stream were observed. The bell mouth B eliminated the pulsations and the cone C, supported by three symmetrically placed guide-vanes, and the annular ring D eliminated the greater part of the backflow and rotation. In order to obtain a uniform velocity distribution across the inlet, it was necessary that the nozzle have a cylindrical section at least 0.3 diameter in length.

A two-way traversing mechanism carried the measuring device. By bolting the device in positions I, II, and III successively it was possible to obtain a longitudinal traverse of 9.3 diameters, which, along with a lateral motion of 27 cm, was sufficient for the investigation.

Lateral traverses were made with a pitot tube at distances from 3 to 9.3 diameters from the jet mouth, the inflow velocity being maintained at 26.5 meters per sec. Because of the high velocity gradient and large fluctuations about the mean velocity, measurements at distances less than three diameters could not be relied upon. However, Tollmien checked his results for the plane jet by comparison with measurements[9] made in Göttingen at the boundary of the jet, one-half diameter from the mouth of an open-jet wind tunnel 2.24 m in diameter. At that dis-

[9] Göttingen Ergebnisse, II Lief., 1923, pp. 69–73, R. Oldenbourg, Munich.

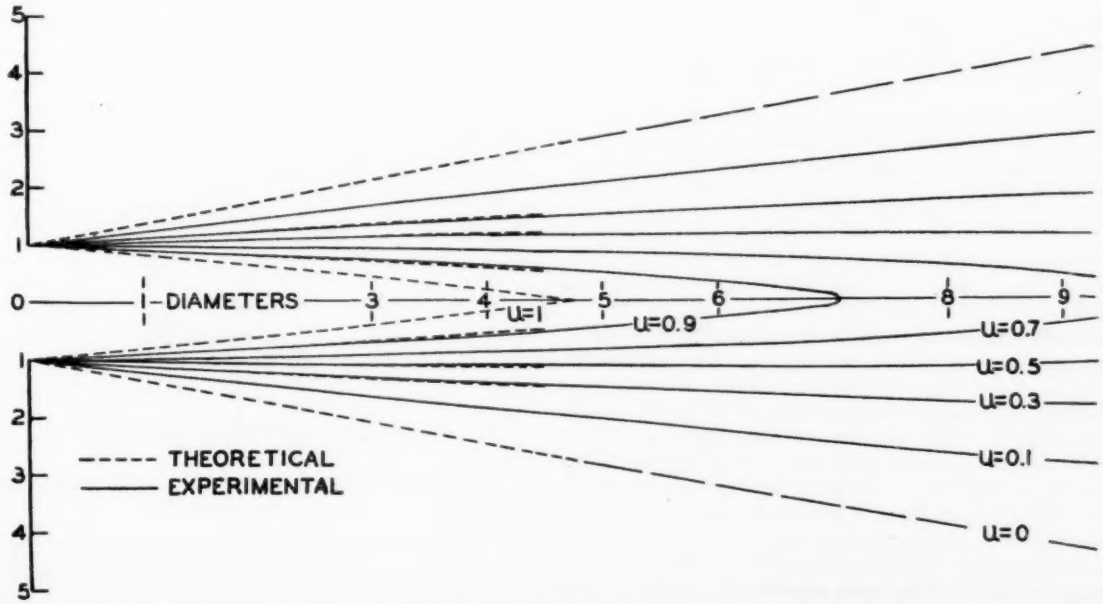

FIG. 11 EXPERIMENTALLY DETERMINED VELOCITY FIELD OF THE JET AND COMPARISON WITH THEORY FOR $c^2 = 0.00496$. THE BOUNDARIES OF THE JET AT 9.3 DIAMETERS ARE CALCULATED FROM TOLLMIEN'S SOLUTION FOR x LARGE. BETWEEN 4.76 AND 9.3 DIAMETERS THE OUTER BOUNDARIES ARE INTERPOLATED

tance the mixing region was wide enough so that this difficulty was not encountered. Those measurements showed very good agreement between theory and experiment for a value of c very close to the one used here. Hence, for the present purpose, the velocity field for distances up to three diameters from the mouth could be interpolated very closely. The lines of equal velocity are shown in Fig. 11, in which, for convenience in carrying over the theoretical results, the radial distance is measured in radii while the longitudinal is measured in diameters.

The dotted lines in Fig. 11 show the agreement between the theory of part 2 and experiment for $c^2 = 0.00496$, i.e., $c = 0.0705$.

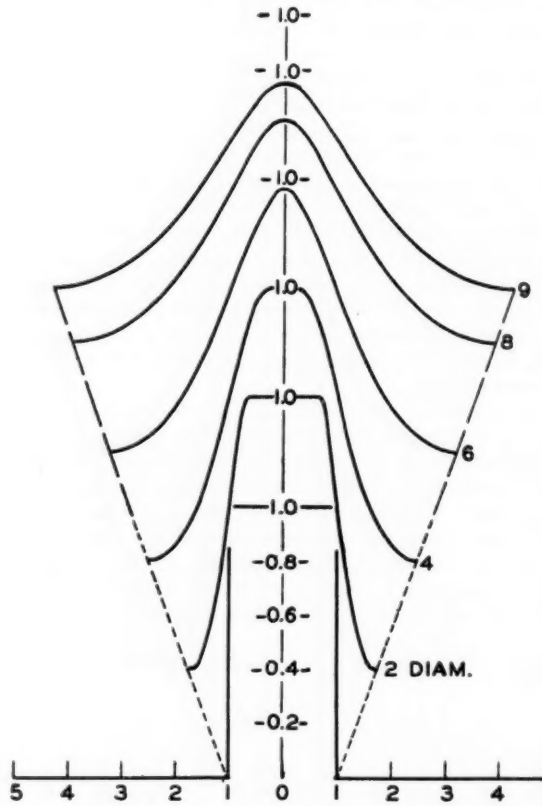

FIG. 12 EXPERIMENTAL PROFILES AT VARIOUS DISTANCES FROM JET MOUTH. SLOPES OF THE OUTER BOUNDARIES ARE MAGNIFIED IN THE RATIO 2:1. THE ORDINATE IS DISPLACED 0.2 D, WHERE D IS THE NUMBER OF DIAMETERS FROM THE JET MOUTH ALONG THE VELOCITY AXIS

Fig. 12 shows profiles at 0, 2, 4, 6, 8, and 9 diameters. The ordinates in this figure are displaced 0.2 along the velocity axis for each diameter from the mouth.

Fig. 13 shows the scatter of the experimental points and their agreement with the theoretical curve at $x = 4.44$ diameters, which is the last point for which the theory is given. Aside from a small systematic difference near the center of the jet the agreement is quite good. This difference is in the direction indicated by the fact that the momentum calculated from the theoretical profile was 2 per cent low. In Fig. 14 the experimental points are plotted along with Tollmien's solution for large values of x. There is again a very small systematic difference near the center.

Since the completion of this work an experimental investigation similar to that cited has been reported by Ruden.[10] The agreement between the two, in so far as the data given allow, is as good as can be expected. The two arrangements may not be quite comparable and this would preclude the possibility of accurate agreement.

the assumption that there are no velocity fluctuations in the core of potential flow. This was investigated[11] by means of the hot-

[11] F. L. Wattendorf and A. M. Kuethe, *Physics*, vol. 5, no. 6, pp. 153–165, June, 1934. For details of the apparatus, the reader is referred to this paper.

wire anemometer and auxiliary apparatus developed by F. L. Wattendorf and the author.

The fluctuations in the velocity of air passing an electrically heated platinum wire (the wire used was 0.0005 in. diam, and 3 mm long) cause a fluctuation in the temperature of the wire. The consequent fluctuations in voltage drop across the wire (the current is kept at an approximately constant value) are impressed across the input of a five-stage amplifier containing a circuit which compensates for the lag in amplitude of the response of the hot wire due to the relatively high frequency (frequencies from 40 to 500 cycles per sec are reproduced with small relative error) of the air-speed fluctuations.

By means of calibration curves of the hot wire and the amplifier plus compensation, the mean-square value of the output, as measured on a thermogalvanometer, is converted into percentage fluctuations in velocity where u' is the x component of the fluctuations.

Fig. 15 shows $\frac{\sqrt{(\bar{u}'^2)}}{u_0}$ at the center of the jet as a function of the distance from the jet mouth. Two lateral traverses across the potential core are also shown. In the mixing region surrounding the potential core the velocity fluctuations were very high (on the order of 50 to 100 per cent of the mean velocity) and the results were erratic. The mean jet velocity was again 26.5 meters per sec. The hump in the longitudinal traverse at $x = 3$ diameters was also present at a velocity of 20 meters per sec.

The relatively high fluctuations in the region of potential flow probably originate in the surrounding mixing region. In the experiments described in reference 11, an analogous phenomenon was observed in the region of potential flow between two boundary layers in a channel. Since the velocity gradient is zero, precluding any possibility of the existence of a shearing stress, the fluctuations in both cases must be purely random in character.

Measurements of the velocity fluctuations were made at $x = 9.3$ diameters. Fig. 16 shows the distribution of $\frac{\sqrt{(\bar{u}'^2)}}{u}$ and $\frac{\sqrt{(\bar{u}'^2)}}{u_0}$ where the latter is derived from the former by means of the velocity profile (Fig. 15).

A complete study of the fluctuations in the jet was not made. The magnitude of the fluctuations is so high that the response of the hot wire may be in error by a considerable amount. The problem is further complicated by the fact that the velocity fluctuations calculated from hot-wire results represent $\frac{\sqrt{(\bar{u}'^2)}}{u}$ only when u' is small compared with u.[11]

When the fluctuations become large, the measured value may be seriously affected by the v' and w' components.

Acknowledgment

The author wishes to express his sincere appreciation to Dr. W. Tollmien and to Dr. Th. von Kármán. The investigation was undertaken at the suggestion of Dr. von Kármán; Dr. Tollmien made many helpful suggestions in the course of the work.

The Temperature History During the Constant-Rate Heating of a Solid Circular Cylinder

By ALBERT B. NEWMAN[1] and AUSTIN H. CHURCH,[2] NEW YORK, N. Y.

The authors present a solution of the partial-differential equation for heat conduction in a solid circular cylinder for the condition where the heat is forced into the cylindrical surface at a constant rate. A mathematical analysis is made of the temperature-history curve at the heated face and at the axis of the cylinder and the results are reduced to tabular and graphical form for practical application.

SOLUTIONS of the partial-differential equation for heat conduction are available for cases of solid circular cylinders in which the cylinder is initially at a known uniform temperature and the cylindrical surface is either suddenly heated to a higher known temperature and maintained at that temperature or is placed in a fluid of known temperature under conditions such that the fluid temperature remains constant. These solutions enable one to trace the temperature-history curve for the axis or for any cylindrical distance from the axis; or the temperature distribution at any instant can be calculated and plotted. The tabulated values of these solutions have been plotted by Gurney and Lurie[3] and have been reproduced in several books.[4]

An important case for which no solution has been published, as far as the authors are aware, is that in which heat is forced into the cylindrical surface at a constant rate, such as might be approximately accomplished by electrical heating or by the application of a constant frictional force. Frequently, it is desirable to predict the temperature-history curve at the heated face and at the axis, and it is the purpose of this paper to present a mathematical analysis of this case and to reduce the results to tables and curves which can be used with ease in practical work. The analogous case for slab heating has been published recently by Newman.[5]

Nomenclature

K = thermal conductivity, Btu per ft per sq ft per hr per deg
C = specific heat, Btu per lb per deg
ρ = density, lb per cu ft
$k = K/C\rho$ = thermal diffusivity, sq ft per hr
θ = time from the beginning of heating, hr
θ_1 = time at end of heating period
q = constant rate of heat input, Btu per sq ft per hr
r = distance from axis, ft
a = total radius of cylinder, ft
t = temperature in deg F, varying with r and θ
t_0 = initial uniform temperature
$P = k\theta/a^2$ = a dimensionless ratio; $P_1 = k\theta_1/a^2$

Bessel functions of x

$$J_0(x) = \left[1 - \frac{x^2}{2^2} + \frac{x^4}{2^2 4^2} - \frac{x^6}{2^2 4^2 6^2} + \dots\right]$$

and

$$-J_1(x) = \frac{d[J_0(x)]}{dx} = \left[\frac{x}{2} - \frac{x^3}{2^2 4} + \frac{x^5}{2^2 4^2 6} - \dots\right]$$

The B-function of r/a and P

$$B(r/a;\ P) = 2\sum_{n=1}^{\infty} \frac{1}{\beta_n^2}\left(\frac{J_0(\beta_n r/a)}{J_0(\beta_n)}\right) e^{-\beta_n^2 P}$$

in which β_n is defined by $J_1(\beta_n) = 0$.

General Conditions of the Problem

It is assumed that the cylinder is homogeneous and isotropic and that heat is being actually driven into the surface of the cylinder at the constant rate specified, no allowance being made for the heat capacity of the heating element, for heat leakage outward from the heating element or toward the ends of the cylinder. This latter condition implies that the ends of the cylinder are heat-insulated or that the cylinder is so long in comparison with its radius that axial heat flow is negligible. It is assumed that there is no surface resistance between the heating element and the surface of the cylinder.

The Integrated Equation

The integrated equation must satisfy all of the following five conditions:

(*a*) $$\frac{\partial t}{\partial \theta} = k\frac{\partial^2 t}{\partial r^2} + \frac{1}{r}\frac{\partial t}{\partial r}$$

This is the partial-differential equation of heat conduction in cylindrical coordinates, for strictly radial heat flow.

(*b*) $t - t_0 = 0$ when $\theta = 0$. This equation merely states that the initial temperature at all points in the cylinder is t_0.

(*c*) $\partial t/\partial r = q/K$ at $r = a$. At the heated surface, a constant rate of heating results in a constant temperature gradient, and the gradient is proportional to the heating rate but inversely proportional to the thermal conductivity.

(*d*) $\partial t/\partial r = 0$ at $r = 0$. At the axis, heat is coming in equally from all radial directions; therefore, no heat crosses the axis and there is no temperature gradient at the axis.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, N. Y., and will be accepted until November 11, 1935, for publication at a later date.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

(*e*) $\frac{1}{a}\int_0^a (t - t_0)C\rho r dr = q\theta$. The integrated value of the heat content of the cylinder above t_0 at any time must equal the total heat input up to that time.

An equation, all of the terms of which are dimensionless, and which satisfies all of these requirements is

$$\frac{(t - t_0K)}{qa} = 2P + \frac{1}{2}\left(\frac{r}{a}\right)^2 - \frac{1}{4} - B(r/a;\ P) \quad [1]$$

In this equation, β_n is defined by $J_1(\beta) = 0$. In explanation, it may be said that if one solves the $J_1(x)$ equation by substituting various values of x, and then plots $J_1(x)$ as ordinate against x as abscissa, a curve is obtained which resembles a sine curve, crossing the x-axis periodically. The value of x at the first, second, and third crossings, etc., are β_1, β_2, and β_3, etc. The first fifty values of β with the corresponding values of $J_0(\beta)$ are tabulated by Gray, Mathews, and MacRobert.[6]

Any one with a sufficient knowledge of the calculus to differentiate and integrate can test the validity of Equation [1] by solving it for $t - t_0$, differentiating once with respect to θ and twice with respect to r, and substituting the values so obtained in the equations expressing the first four conditions. Condition (*e*) is verified by substituting the value of $t - t_0$ under the integral and performing the integration. It is necessary to know the following properties of these Bessel functions in order to carry out the above operations.

For condition (*a*)

$$\frac{\partial}{\partial r}\left[J_0(\beta_n r/a)\right] = -\frac{\beta_n}{a} J_1(\beta_n r/a) \quad [2]$$

$$\frac{\partial}{\partial r}\left[J_1(\beta_n r/a)\right] = \frac{\beta_n}{a} J_0(\beta_n r/a) - \frac{1}{r} J_1(\beta_n r/a) \quad [3]$$

For condition (*b*)

$$B(r/a;\ 0) = 2\sum_{n=1}^{\infty} \frac{1}{\beta_n^2}\left(\frac{J_0(\beta_n r/a)}{J_0(\beta_n)}\right) = \frac{1}{2}\left(\frac{r}{a}\right)^2 - \frac{1}{4} \quad [4]$$

For condition (*e*)

$$\frac{\partial}{\partial x}\left[xJ_1(x)\right] = xJ_0(x), \quad \text{therefore,}$$

$$\int_0^a rJ_0(\beta_n r/a)dr = \frac{ar}{\beta_n}\left[J_1(\beta_n) - J_1(0)\right] = 0 \quad [5]$$

Integrated Equation for the Equalizing Period

If the constant-rate heating is suddenly discontinued, at $\theta = \theta_1$, and if no heat is allowed to escape from the cylindrical surface, the temperature at the axis will continue to rise and that at the surface will fall. Eventually, the temperature will become equalized throughout the cylinder. The temperature history at the surface and at the axis during this period may be traced by means of the equation

$$(t - t_0)K/qa = 2P_1 + B(r/a;\ P - P_1) - B(r/a;\ P) \quad [6]$$

When $\theta = \theta_1$, $P = P_1$ and Equation [6] must reduce to Equation [1]. This can be shown to be true by the aid of Equation [4]. When $\theta = \infty$

$$(t - t_0)K/qa = 2P_1$$

showing the final equalizing of temperature, independent of r.

[6] "A Treatise on Bessel Functions," by Gray, Mathews, and MacRobert. Second edition, Macmillan & Co., London, 1922, p. 301.

Numerical Solution of the Integrated Equation

All of the variables in the integrated equation are contained in the three dimensionless groups: $(t - t_0)K/qa$; r/a; and P. Each one of these groups may be treated as a variable and the equation may be handled as one of three variables. If one is interested in the temperature history of the heated surface ($r = a$), he may substitute $r/a = 1$ and obtain an equation in two variables. Obviously a curve may be plotted for such a case. If interested in the temperature history of the axis, the value $r/a = 0$ can be substituted, and another curve may be plotted for the other two variables. Table 1 gives the values of $B(r/a; P)$ for $r/a = 0$ and 1. The values of $(t - t_0)K/qa$ for a series of values of P for the cases $r/a = 0$ and $r/a = 1$ have been calculated by using Table 1 and are given in Table 2. For certain terminal values, it is convenient to know that

$$B(1;\ 0) = 2\sum_{n=1}^{\infty}\frac{1}{\beta_n^2} = \frac{1}{4};\quad B(0;\ 0) = 2\sum_{n=1}^{\infty}\frac{1}{\beta_n^2 J_0(\beta_n)} = -\frac{1}{4}.$$

For values of P equal to or greater than unity, the value of the series in the equation becomes negligible, and $(t - t_0)K/qa = 2P - 1/4$ for $r/a = 0$ or 1. The authors have not computed values for r/a other than 0 and 1. If desired, however, values for intermediate radii can be computed by the same methods.

In order to construct a table for the values of $(t - t_0)K/qa$ for Equation [6], one must first select a value for P_1. Ordinarily this value of P_1 is fixed approximately by the conditions of the practical problem, which will dictate a maximum value for the ratio of maximum temperature rise at the surface to the accom-

plished temperature rise at the axis. This ratio is plotted against P_1 in Fig. 1. In constructing this curve, the accomplished temperature rise at the axis is taken as the value of $t - t_0$ in $(t - t_0) K/qa = 2P_1$, implying the final temperature rise attained at complete equalization. Theoretically, this condition is not attained at finite times and in any practical case the value of P_1 selected will be based upon a somewhat lower temperature-rise ratio than the allowable maximum.

Numerical Example

A long solid cylinder of composition material $^5/_{16}$ in. diam, initially at the uniform temperature 70 F, is to be heated electrically all along its surface using a constant rate of heat input. The axis must be heated to 155 F, but the surface temperature must not exceed 255 F.

It is required to estimate the rate of heat input, to plot temperature-history curves for surface and axis, and to estimate the time of heating and the time elapsed before the axis reaches the required temperature.

Data:

K = 0.092 Btu per sq ft per hr per deg F
k = 0.0029 sq ft per hr
a = 0.013 ft

Solution:

Maximum rise at surface = 255 F — 70 F = 185 F
Required rise at axis = 155 F — 70 F = 85 F
Ratio = 185/85 = 2.18
Selecting a somewhat lower ratio = 2.10

Fig. 1 gives $P_1 = 0.1 = k\theta_1/a^2$. Substituting known values of k and a^2, $\theta_1 = (0.1)(0.013)^2/0.0029 = 0.00583$ hr or 21 sec.

At the heated surface $(t - t_0)K/qa = 0.418$ at the end of the heating period ($P_1 = 0.1$), from Table 2. Substituting known values, q = (185)(0.092)/(0.013)(0.418) = 3130 Btu per sq ft per hr = heating rate.

Fig. 2 was constructed from the data of this example, by using Tables 1 and 2. The upper and lower curves represent the temperature rise at the surface and at the axis, respectively. It is seen that the required rise at the axis (85 deg) is reached at θ = 78 sec.

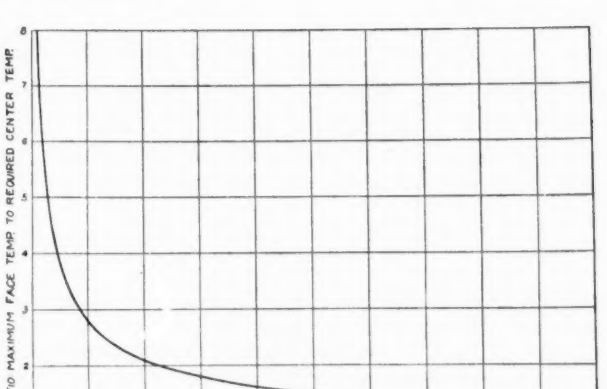

Fig. 1 Values of P_1 or $k\theta_1/a^2$ for Various Ratios of Maximum Temperature Rise at the Surface to Accomplished Temperature Rise at the Axis of Solid Circular Cylinders

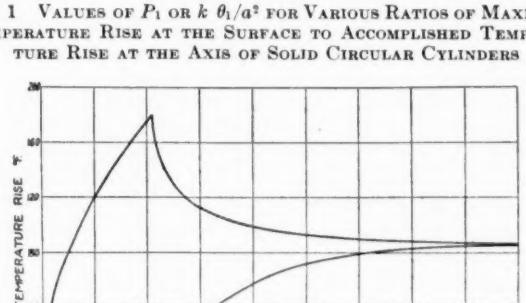

Fig. 2 Temperature Rise at the Surface (Upper Curve) and at the Axis (Lower Curve) of a Solid Circular Cylinder During Constant-Rate Heating

Summary:

Rate of heat input = 3130 Btu per sq ft per hr, or 75 watts per running ft.

Heating time = 21 sec.

Total elapsed time for center to reach required temperature = 78 sec.

An Application of the Interferometer Strain Gage in Photoelasticity

By R. W. VOSE,[1] CAMBRIDGE, MASS.

This paper was written at the suggestion of Mr. Mieth Maeser,[2] in response to numerous inquiries concerning the methods of photoelastic analysis in use at the Massachusetts Institute of Technology.

By the use of any of the usual photoelastic methods the difference of the principal stresses and their direction at any point in a suitable loaded specimen are determined, and through a knowledge of Poisson's ratio their sum is obtained (and a solution made possible) by a measurement of the lateral deformation of the specimen by means of an interferometer strain gage. This instrument, together with its accessories and their use, is illustrated and described in the paper. Examples of the problems solved by the use of the instrument show its accuracy and the consistency of the results obtained by the method.

UNDER the general name of photoelasticity the change in the index of refraction with change of the stress in certain transparent materials is utilized in determining the distribution of the stress in loaded specimens. A number of different methods of carrying out this type of determination are in use, each with its advantages and limitations.

The most direct method consists of determining the actual change of the index of refraction of the specimen (or the accompanying retardation of plane polarized light) along the two planes of principal stress at any point. For this determination Favre[3] uses a Mach-Zehnder interferometer, while Solakian[4] utilizes the two surfaces of the specimen itself for an interferometer as suggested by Fabry.

A second general method determines only the relative retardation of the light along the two principal planes, and hence the difference of the two principal stresses, by means of the interference pattern produced when the beams of plane polarized light from the two principal planes are analyzed in a common plane by means of a Nicol prism. Except at a free physical boundary of the specimen where one of the principal stresses is necessarily zero, additional means must be employed to determine the individual stresses. For this there are available the graphical-integration method of Filon,[5] an improved graphical method recently presented by Neuber,[6] the membrane analogy of Den Hartog[7] (all of which depend on free-boundary conditions), and the lateral-deformation methods of Frocht[8] and of Coker,[9] which are independent of boundary or other surrounding conditions.

For several years Filon's graphical-integration method has been used at the Massachusetts Institute of Technology, but the results obtained apparently have not been of the desired order of accuracy, and in addition the method could only be applied to cases in which good free-boundary conditions prevailed. These limitations led Mr. Maeser,[2] then in charge of photoelasticity, to suggest in the spring of 1933 that a sensitive lateral-strain gage should be devised for carrying out Coker's method. Accordingly, in October of 1933 the author built the interferometer strain gage described in the following paragraphs, and assisted in its experimental use on several specimens.

Interferometer Strain Gage

The strain gage is shown in Fig. 1 and the method of applying it in Fig. 2. At *A* are two rounded contact points held in contact with the specimen by the spring *B*. Any relative motion of the contacts is transmitted through the levers *C* which are pivoted at *D* by a crossed-plate fulcrum to a pair of small optical flats which form the interferometer at *E*. Three spring-opposed screws carry the mounting of one of the flats so that the parallelism and separation of the pair may be adjusted.

Mounting the strain gage is accomplished by supporting its weight on a string tied around the plate fulcrum and depending on the friction of the contacts with the specimen to retain its position, as shown in Fig. 2. This seemingly crude mounting has the advantage of easy adjustment and absolute freedom from the restraining forces accompanying a rigid mounting.

Since the interferometer flats measure their change of separation in terms of the wave length of light, which is in itself a standard of length, the only calibration of the instrument is that of its lever ratio. This is easily determined by direct measurement of the lever arms, and since these are 3 in. long an accuracy of better than 1 per cent may be obtained by use of a steel rule, or closer results by a measuring microscope. The fiducial point of the interferometer system is a set of cross "hairs" etched on the surface of one of the flats, and the measurement of the levers is taken to this point. A multiplication of unity has been found satisfactory for use on specimens from $^1/_4$ in. to $^1/_2$ in. in thickness.

Optical System

Interference fringes or bands may be observed very simply by placing two optical flats nearly in contact, as is done in optics shop practice. This type of fringe, similar to Newton's rings, becomes useful for accurate quantitative work only when observed with monochromatic light through a low-power microscope or telescope.

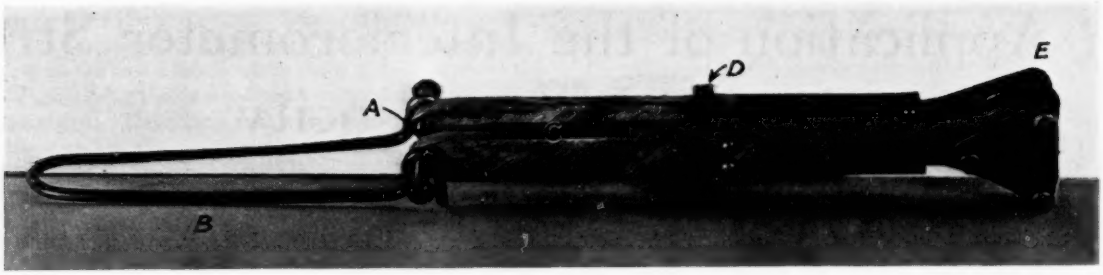

FIG. 1 INTERFEROMETER STRAIN GAGE

No. 62 filter gives a convenient and brilliant source of monochromatic light with a wave length of 5461 Å, and a corresponding band spacing of 0.00001075 in. This line is near the point of maximum sensitivity of the human eye, and an observer can count several thousand fringes per day without undue fatigue.

If the flats of the interferometer be illuminated by reflection from a plain glass mirror and observed through the mirror, as is shown in Fig. 2, a pattern of dark and light bands will be seen on the flats if the latter be adjusted so that there is a small air gap between them. These bands are due to the periodic changes in phase relationship between the light reflected from the front flat and that from the back flat as the air gap changes. This latter change in the air gap may be due either to a change in position over the flats, resulting in bands showing a contour map of the air-gap thickness, or to a change in separation of the flats, resulting in a movement of the set of contour bands across the flats. A count of the number of bands which pass a given point on the flats will thus indicate the change in the air-gap thickness at this point produced by a relative change in separation of the flats. Numerically this change will be equal to one-half the product of the number of bands counted, by the wave length of the light used.

Even with unfavorable conditions, fractions can be estimated to one-fifth of a band, or two millionths of an inch, and the author has made determinations with a similar strain gage in which the calculated probable error of a single setting on the center of a band was 0.009 band, or less than one ten-millionth of an inch. It will be noticed that the measurements are obtained without physical contact of the moving members at the measuring point, and hence the only possibility of friction or hysteresis comes in the flexing of the contact spring *B* and the plate fulcrum *D*, and is entirely negligible. With the usual photoelastic materials, however, this high sensitivity cannot be fully utilized because of plastic and thermal creep in the material.

METHOD OF USE

The difference of the principal stresses at any point in a loaded specimen may be determined by any of the usual photoelastic methods, such as the use of Coker's compensator,[9] or the comparison of fringes with those of a specimen of known stress.

To determine the sum of the principal stresses the strain gage is attached to the specimen at the point in question and the lateral deformation measured by counting the interferometer bands as the specimen is slowly loaded or unloaded. The solution is made from these readings by the use of Poisson's ratio and Young's modulus for the material. These latter properties, or more conveniently their product as a single constant, are usually determined on the compensator or comparator member used in the photoelastic work.

With the foregoing determinations of the sums and differences at points throughout the specimen the individual stresses may be separated by algebraic solution and the results plotted or tabulated.

ACCURACY

The accuracy of the method may be best illustrated by actual figures obtained in the calibration of a tension specimen. Here one photoelastic fringe used in determining the difference of the principal stresses was found to be equivalent to 90.4 lb per in., while the corresponding strain-gage interference fringe used in determining the sum of the principal stresses was equivalent to 18.46 lb per in. Thus the sensitivity of the strain gage is five times that of the photoelasticity apparatus, and in use is better adapted to the estimation of tenths. In addition, this calibration of 18.46 lb per in. was obtained with a calculated probable error of 0.06 per cent, which illustrates the accuracy with which the strain gage will repeat its indications.

In addition to the foregoing illustrations of instrumental accuracy, it is to be emphasized that the stress determination at any

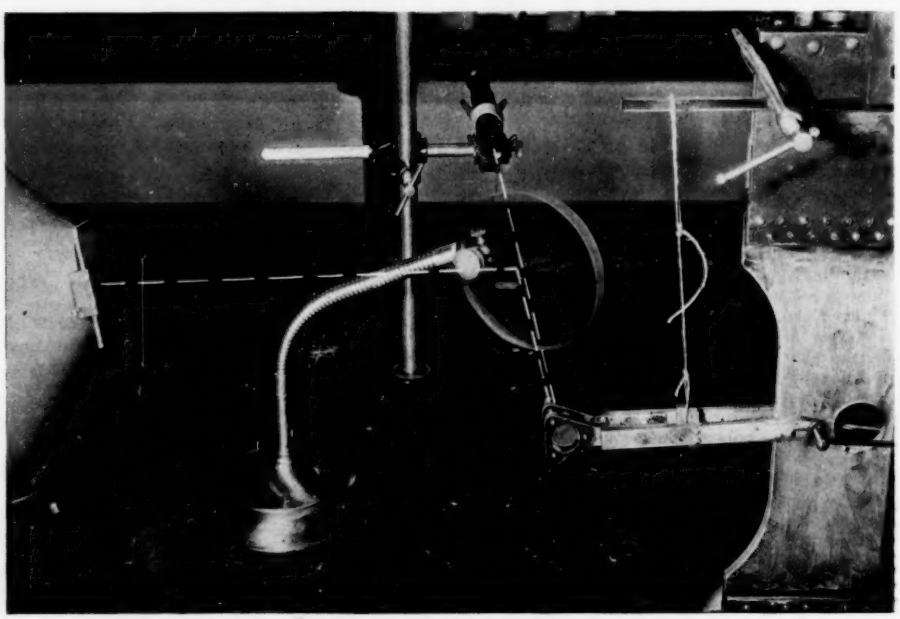

FIG. 2 THE APPLICATION AND METHOD OF READING THE STRAIN GAGE

given point in a specimen is independent of that made at any other point, so that small errors are not cumulative from point to point. A final plot of independent observations on consecutive points across a specimen gives an opportunity for "fairing" the curve and eliminating any accidental errors if such are found.

Limitations

To date the method outlined has been found applicable to all cases of plane stress. However, most plane models are constructed of material of considerable thickness in order to amplify the photoelastic effect, and in many cases the stress gradients are

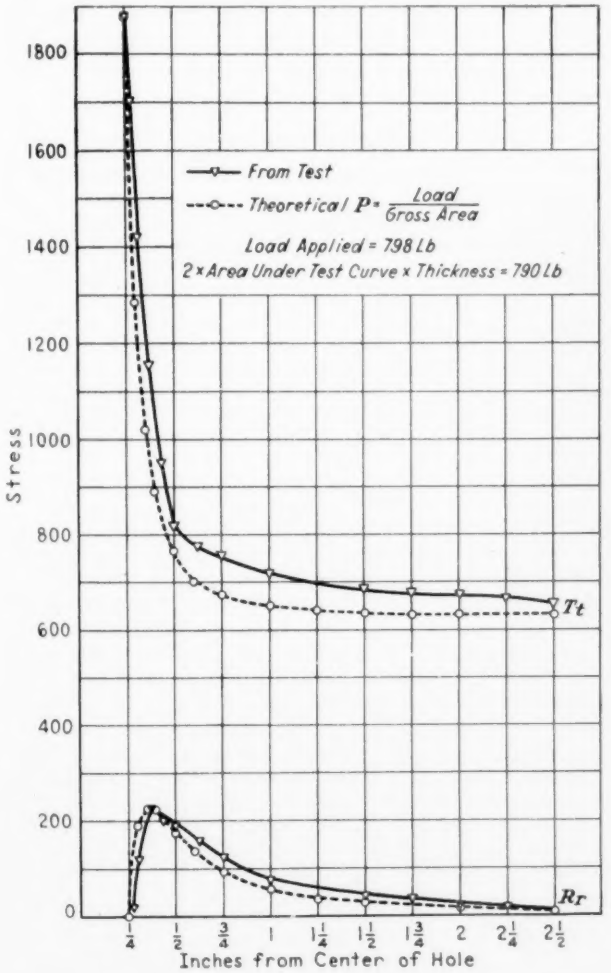

Fig. 3 Stress Distribution Across a Plate With a Central Hole

so large that a third dimensional restriction of deformation is apparent. Furthermore, if a boundary of the specimen is loaded (as in example 2, following) there is a further restriction of lateral deformation by the loading piece which is of detectable magnitude for a distance from the edge equal to one-half the thickness of the specimen, but is of importance for only a small fraction of this distance. While the lateral-deformation method particularly shows up these departures from the theoretical case because it measures them fairly directly, all other methods of photoelastic analysis are vitiated to an equal degree.

The errors here outlined are particularly prevalent at the boundaries of a specimen and, hence, any method of analysis which is dependent upon boundary stresses carries serious errors

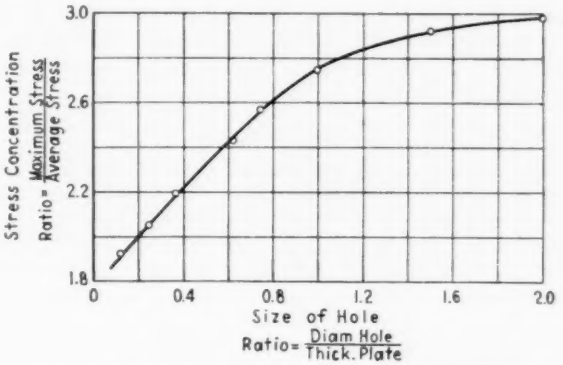

Fig. 4 Variation in Stress Concentration With Size of Central Hole in the Plate

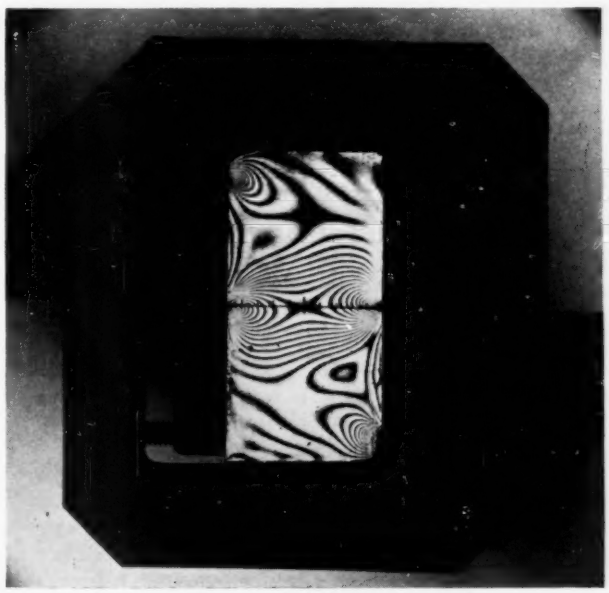

Fig. 5 Block in Direct Shear

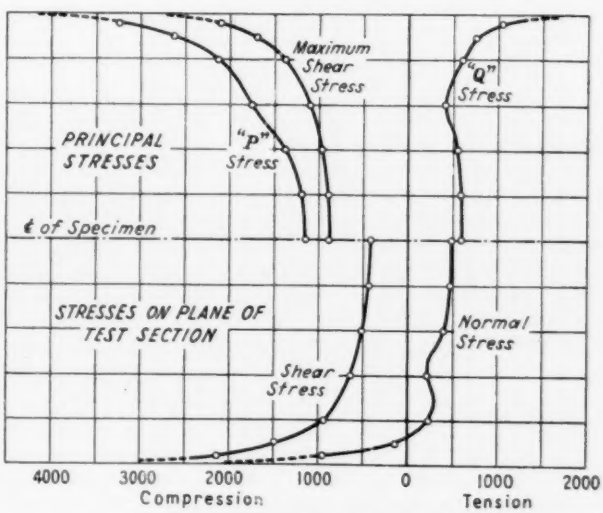

Fig. 6 Stresses in Shear Block

through the entire work. In contrast with this the lateral-deformation method gives accurate, independent results through the body of a specimen, and can be extrapolated to the extreme edge with fair accuracy.

Ease of Solution

While the amount of experimental work required in the application of this method may seem large, the desired results follow almost immediately from the experimental values without laborious calculations, graphical constructions, or auxiliary model making. In example 2, following, the entire problem was handled in about one day by a single observer. Attention may be concentrated on a few points of interest, in particular problems, and readings taken only at critical locations without covering areas of low stress.

Examples

Example 1. In Fig. 2 is shown a plate specimen with a central hole, which was investigated by the present method. The results were furnished by Mr. Maeser, and include the distribution of horizontal and vertical stresses on the cross-section at the hole as compared with theoretical values (Fig. 3) and the variation of the maximum stress with variations in the size of the hole (Fig. 4). This latter variation is due to a third-dimensional effect, since with a very small hole the stress distribution departs from that due to plane stress.

Example 2. Fig. 5 shows the photoelastic fringe distribution in a block of bakelite $\frac{1}{2}$ in. $\times$ $1\frac{1}{2}$ in. subjected to shear by the holders which are shown in silhouette. The stress distribution in this specimen is particularly difficult to determine by any method dependent on boundary stresses, since most of the boundary is restrained in an unknown manner. By the lateral-deformation method the principal stresses across the section of shear were determined, and from these and the usual isoclinics the normal and shearing stresses on the plane of the section were calculated. The results are shown in Fig. 6, and illustrate the uncertainty of the boundary conditions. As a check on the work the total shear on the section was found to differ from the applied load by less than 5 per cent.

Acknowledgments

The author is indebted to the staff of the Materials Testing Laboratory of the Massachusetts Institute of Technology, and particularly to Prof. A. F. Holmes for his support and advice; to Prof. I. H. Cowdrey for the photography; and to M. Maeser for the use of his results.

Recent Research Work in Vibration and Sound

By J. ORMONDROYD[1]

I—General

THE general field of vibrations, including the physical aspects of acoustics, was covered by some twelve books and about two hundred papers during 1934. Only those papers readily accessible to American engineers in publications usually available have been included in the following outline. The titles of all the papers listed have been translated into English for convenience in reference while the titles of the books are given in the language in which they were printed.

II—General Vibration Studies

Two general textbooks in English on all phases of vibration theory have appeared, a mathematical treatise built around actual technical problems, an advanced text by J. P. Den Hartog (1)[2] and an elementary textbook by E. B. Cole (2). The second volume of "Schwingungstechnik" by Ernst Lehr (3) appeared in 1934; the first volume of this book was published in 1930. The subject is also covered in the first part of volume 17 of the "Handbuch der Experimental Physik" (4), which was published in 1934, and (5) and (6) represent additional references.

III—Vibration Theory and Analysis

Special studies in the mathematical treatment of vibrations have appeared in numerous papers during 1934. On the energy method for critical speeds, a book on Rayleigh's principle by Temple and Bickley (7) gives a general résumé of the energy method of determining natural frequencies in engineering structures. An important paper bearing on the calculation of natural frequencies in undamped systems of many degrees of freedom by the direct use of matrices was published by Collar and Duncan (8). K. Klotter (9) gives a generalized outlook on the various physical forms of the matrix elements for characteristic equations of diversely coupled vibrating systems. Graphical methods of solving vibration problems received attention in three papers (10), (11), (12). Additional references are given under (13), (14), (15), (16), (17).

IV—Vibration Measurement

On the subject of vibration measurement only two papers are noted, (18) and (19).

V—Special Technical Problems

(*a*) *Vibration of Beams and Shafts, Rotor Balancing.* "Dynamik der Stabwerke" by Hohenemser and Prager (20), a book published in 1933, should be noted here since it gives a good generalized view of the modes of vibration in various combinations of beams common in structural engineering. See also (21). The old problem of shaft whirling still attracts attention in the technical literature (22), (23), (24), (25). The balancing of rotating machinery receives attention in papers describing a new automatic balancing machine (26), a new method of vector analysis from vibration amplitudes (27), and a new apparatus and associated method for field balancing (28). A paper by Galmiche (29) deals with the vibration of electrical machinery.

(*b*) *Torsional Vibrations.* Two books on torsional vibration have recently appeared, both in English and both published by John Wiley & Sons. A book containing practical methods for calculating vibration frequencies and amplitudes by Tuplin (30) gives a complete theoretical account of critical-speed calculations in systems of many degrees of freedom in unbranched and branched forms which are commonly met in practice. "Practical Solution of Torsional Vibration Problems" by W. Ker Wilson (31) as its name implies does not aim at the theoretical completeness displayed in (30). Four papers (32), (33), (34), (35) are devoted to torsional oscillations.

(*c*) *Damping of Vibrations and Spring Mounting.* The problem of vibrating systems operating at a critical speed gives great importance to the subject of damping and other means to limit the amplitudes of motion. Papers on damping in general appeared under the authorship of Spaeth (36), Miller (37), and Klein (38). Dynamic vibration absorbers received attention in four papers, respectively, by Inglis (39), Föppl and Knackstedt (40), Geislinger (41), and Koch (42). The paper by Koch (42) on "Mechanical Wave Filters" gives a generalized outlook on dynamic vibration absorption. The effect of transient conditions of vibration on spring-mounting design for electrical and reciprocating machinery was treated by Johnson (43) and the characteristics of rubber spring mountings was discussed by Thum and Oeser (44). Ghosh (45) discusses the impact effect on a damped string.

(*d*) *Maintained Oscillations.* The forced oscillations of simple systems at a natural frequency have been put to many uses. The pendulum clock is the oldest device which utilizes this principle. A book entitled "Pendules Électriques" by Granier (46) gives details of various electrical methods for maintaining and regulating the oscillations of clock pendulums. This little book contains information on the possible errors in frequency which can occur in pendulum designs. In (47) Sell discusses a mechanically controlled bolometer. Testing machines based on forced vibration at resonance and mechanical oscillators for other purposes are discussed by Spaeth in two papers (48) and (49). Stretched-wire vibrators, which have often been used as strain gages and thermometers by using the relationship between tension and natural frequency, are discussed by Stuart (50). Self-exciting tuning forks in radio circuits used as a standard of frequency form the subject of a paper by Dye and Essen (51). The natural vibrations of metallic reeds have been used frequently to determine the modulus of elasticity at room temperature and elevated temperatures. Davies and James discuss "An Electrically Maintained Vibrating Reed and Its Application to the Determination of Young's Modulus" (52). The paper is divided into two parts, theoretical and experimental.

(*e*) *The Vibration of Structures.* Two books appeared on this subject in 1934. C. E. Inglis discussed with great completeness the old problem of railway-bridge vibration in a book entitled "A Mathematical Treatise on Vibration in Railway Bridges" (53). Creskoff discusses the design of buildings to resist the destructive effects of earthquakes (54). Vibrations

---

[1] Experimental Division, Westinghouse Electric & Manufacturing Co., South Philadelphia, Pa. Mem. A.S.M.E.

[2] Numbers in parentheses refer to the bibliography at the end of the paper.

caused by moving vehicles are discussed in papers by Ramspeak (55) and Lürenbaum (56).

(*f*) *Transmission-Line Vibrations.* This subject was considered important enough in 1934 to give rise to seven papers (57), (58), (59), (60), (61), (62), and (63).

(*g*) *Ship Stabilization.* Although the Frahm tanks for stabilizing ships are almost as old as the present century, the theory underlying their action has been the subject of very recent controversy. O. Föppl clears up some of the questions in a paper on "The Theory of Frahm Ship Stabilizers" (64). The year 1934 saw the installation by a German firm of an activated Frahm tank in which the water in the stabilizing system does not create its own dynamical phase relationship to the ship's motion, but is artificially forced by pumps to take a more advantageous phase relationship. N. Minorsky, the inventor of an activated tank control, published a paper on the subject (65) which was the subject of editorial comment in the same issue. H. Hört gave a description of actual stabilizing installations (66) and E. G. Barillon prepared a new résumé of the whole theory of ship rolling (67).

(*h*) *Turbine-Blade Vibration.* When turbine blades break it is usually caused by "fatigue." The subject of turbine-blade vibration receives continuous attention from turbine designers. Papers by Peter (68) and Karas (69) appeared on this subject in 1934.

(*i*) *Hydrodynamic Oscillations.* This subject was treated in two papers by Hooker (70), (71).

(*j*) *Sound.* Since sound is produced by vibrating material bodies, books and papers on the physical aspects of sound are usually treatises on vibration and should be listed in this place.

Loud speakers, mechanical devices for pumping energy into the air, have been treated mathematically and structurally in two books by McLachlan (72) and (73). General treatises, in book form, on acoustic theory appeared under the authorship of Davis (74) and Olson and Massa (75). An article on acoustical measurements by Myer (76) appeared in 1934. Two other articles appear in the same issue, one on the application of sound waves in free media and the other on the theory of electro-acoustic transformers (telephones, microphones, loud speakers) (76).

Several papers on noise in electrical machines also appeared in 1934 (77), (78), (79). The noise meter as a shop tool for inspection is described by Johnson (80); and (81), (82), and (83) represent additional references on this subject.

Design Data

It is important that the data contained in technical papers be made readily available to designing engineers. In order to satisfy these needs of industry, this section of the Journal will include a concise presentation of data and information drawn chiefly from papers previously published by the Applied Mechanics Division of The American Society of Mechanical Engineers.

The data are prepared by a subcommittee of the Applied Mechanics Division on strength of materials (R. E. Peterson, chairman), under the guidance of S. Timoshenko.

Working Stresses[1]

By C. RICHARD SODERBERG,[2] PHILADELPHIA, PA.

I INTRODUCTION

THERE is a considerable number of variables, outside of magnitude of stress, involved in the problem of strength, but the following have been found to be of fundamental significance.

1 *Temperature.* While it is impossible to speak of any well-defined boundaries between the different regions, it is permissible, for practical purposes, to speak of (*a*) normal temperatures, where the problem of strength is based on elastic behavior, and (*b*) elevated temperatures, where the problem of strength must be based on plastic behavior. For steel and its alloys, the limit between these two regions is approximately 250 C.

2 *Ductility.* A definite classification of the materials with regard to ductility is equally difficult, because the term has meaning only when the state of stress is specified. Nevertheless, if tensile tests are made of soft steel and cast iron, the results differ so fundamentally that we can regard the former as ductile and the latter as brittle. It is on the basis of such a difference that the materials are classified as (*a*) ductile materials, giving a standard tensile test with more than 5 per cent elongation, and (*b*) brittle materials, giving less than 5 per cent elongation.

3 *Time-Mode of Stress Application.* The time element has been found to be of particular significance. It is possible to distinguish between (*a*) steady stress and (*b*) variable stress, for which the problem of failure must be considered separately.

At the present time only the following combinations of these variables can be treated with any degree of certainty: (*a*) ductile materials under steady stress at normal temperatures; (*b*) ductile materials under variable stress at normal temperatures; (*c*) brittle materials; and (*d*) ductile materials under steady stress at elevated temperatures.

[1] This paper was prepared for the Design Data section of the JOURNAL OF APPLIED MECHANICS and contains material published in "Factor of Safety and Working Stresses," by C. Richard Soderberg, Trans. A.S.M.E., vol. 52, part 1, 1930, paper APM-52-2, pp. 13–28.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until Nov. 11, 1935, for publication at a later date.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

II DUCTILE MATERIALS UNDER STEADY STRESS AT NORMAL TEMPERATURES

THE TENSILE TEST

There are many physical tests of importance, but for purposes of predicting failure the tensile test is practically the only source of information. Of the quantities furnished by the tensile test, only the yield strength σ_s has received general sanction as a measure of the strength. This is based on more than an arbitrary selection, because the usefulness of most engineering structures is impaired when the plastic deformation reaches a value which is large in comparison with the elastic deformation. For materials having no well-defined yield point, the stress corresponding to 0.2 per cent permanent deformation is often used as the yield strength.

Under the conditions of the tensile test, the working stress is now defined by the relation

$$\sigma = \sigma_s/n \quad [1]$$

where n is the factor of safety. (It is more convenient mathematically and also somewhat more logical to use a factor of utilization $u = 1/n$, however, because of the wide usage of the factor of safety, it was considered advisable to retain its use in these articles.[1])

The general treatment of the problem of strength is postulated on the assumption that it is always possible to find a certain limiting stress which for more complicated cases plays the role of the yield strength of the tensile test.

The object of the following rules is to define the factor of safety, rather than to give specific instructions as to its absolute value. This must remain the prerogative of the responsible designer for whom these rules furnish accepted methods of interpreting his experience. It has become customary to regard $n = 1.25$ to 1.33 as minimum values to be used under most favorable circumstances with reliable materials subjected to accurately known stresses. For the opposite extreme, maximum values of $n = 3$ to 4 are regarded appropriate. If practical experience indicates a need for still higher factors of safety, this should call for a more thorough analysis of the problem, either in the evaluation of the stresses or in interpreting the circumstances of failure. Most applications fall in the region where $n = 1.5$ to 3.

THEORIES OF STRENGTH

In order to extend the treatment to other forms of stress application, it is necessary to refer to a *theory of strength*, estab-

lishing in more detail the actual mechanism of failure. A considerable amount of experimental and theoretical material is now available and the practical choice has narrowed down to two theories: (*a*) the maximum-shear theory, and (*b*) the theory of constant energy of distortion.

The Maximum-Shear Theory. The condition for yielding, according to the maximum-shear theory, is based on the assumption that yielding starts in planes of maximum shearing stress, when the shearing stress in these planes reaches a certain limiting value. If the principal stresses are σ_1, σ_2, and σ_3 in algebraic order of magnitude, the maximum shearing stress occurs in the diagonal planes parallel with σ_2, Fig. 1, and has the value $(\sigma_1 - \sigma_3)/2$. The intermediate stress is assumed to be without influence, a fact, therefore, which has thrown doubt on the absolute correctness of this theory. When $\sigma_2 = \sigma_3 = 0$, the maximum shearing stress is $\sigma_1/2$, occurring in planes at 45 deg to σ_1. In the tensile test, therefore, failure takes place when the maximum shearing stress reaches the value $\sigma_s/2$, where σ_s is the yield strength in tension.

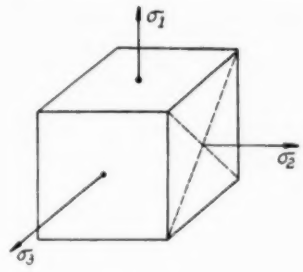

Fig 1

The Theory of Constant Energy of Distortion. The yielding of ductile materials has been found by careful experiments to obey the law

$$(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2 = 2\sigma_s^2 \ldots\ldots [2]$$

where σ_s again is the yield strength in straight tension. As far as the tensile test alone is concerned, the theory gives values identical with those obtained by the maximum-shear theory.

The greatest discrepancy occurs for the case of pure shear. This is obtained by making $\sigma_3 = -\sigma_1 = \tau$, $\sigma_2 = 0$, when Equation [2] becomes $\tau = (1/\sqrt{3})\sigma_s = 0.57\sigma_s$, as against $0.5\sigma_s$ on the basis of the maximum-shear theory.

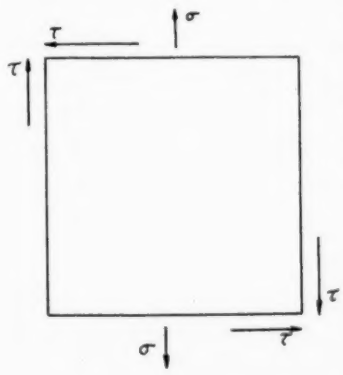

Fig 2

In the case of combined tensile stress σ and shearing stress τ, Fig. 2, the principal stresses are, in the order of magnitude:

$$\sigma_1 = 1/2[\sigma + \sqrt{(\sigma^2 + 4\tau^2)}]$$
$$\sigma_2 = 0$$
$$\sigma_3 = 1/2[\sigma - \sqrt{(\sigma^2 + 4\tau^2)}]$$

The condition of yielding then becomes $\sqrt{(\sigma^2 + 3\tau^2)} = \sigma_s$ instead of $\sqrt{(\sigma^2 + 4\tau^2)} = \sigma_s$ for the maximum-shear theory.

The experimental evidence is definitely in favor of the distortion energy theory, and if accuracy were the only guiding motive, the choice would certainly be in favor of this theory. The maximum-shear theory is so outstandingly simple, however, that it was considered advisable to use it as a basis for determination of working stresses.

Stress Concentration

Changes in shape of members, such as those due to fillets, holes, grooves, keyways, etc., cause local concentrations of stress. The stress-concentration factor k is defined as the ratio of maximum stress to nominal stress and is computed as $\sigma = P/a$ for tension-compression or $\sigma = M/(I/c)$ for bending. Values of k for various cases were given in the preceding article of the Design-Data series, in the June, 1935, issue of the Journal of Applied Mechanics, page A-67. For ductile materials, local concentrations of stress do not contribute to failure under steady stress, so that for this case stress concentration may be neglected.

Rules for Working Stresses for Ductile Materials Under Steady Stress at Normal Temperatures

1 Tension, compression, or bending, $n = \sigma_s/\sigma$ ..... [3]

2 Pure shear, $n = \sigma_s/2\tau$ ..... [4]

3 General case of combined stress, $n = \sigma_s/2\tau_{max}$ ..... [5]

4 Tension σ and shear τ, $n = \sigma_s/\sqrt{(\sigma^2 + 4\tau^2)}$ ..... [6]

The stresses are evaluated in each case without reference to local concentrations of stress.

III DUCTILE MATERIALS UNDER VARIABLE STRESS AT NORMAL TEMPERATURES

The Simple Fatigue Test

The general case of variable stress involves the combination of a steady stress σ_0 and a variable stress σ_v, Fig. 3. The strength properties under the influence of the steady component have been discussed in the preceding section. The property of strength is embodied, for practical purposes, in the yield strength σ_s. When the stress is alternating with the amplitude σ_v, the criterion of failure is the endurance limit,[3] denoted as σ_e.

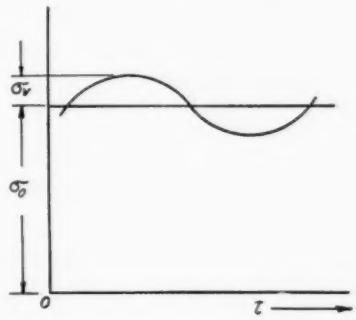

Fig 3

The most significant difference from the conditions for steady stress concerns the influence of stress concentration. Under variable stress both the average stress and the local maximum of the stress at any point influence the failure. The actual conditions depend on the sharpness of the stress concentration and the nature of the material.

Of equal significance is the dependence of the endurance limit upon other factors such as corrosive conditions, temperature of the atmosphere surrounding the specimen, and finish and surface treatment of the specimen. These create points of utmost importance which must be taken care of in each individual case. It is possible in many cases to conduct the tests so that the results include the effect of stress concentration. For the present purpose, it will be assumed that the true value of the endurance limit σ_e and the appropriate factor of stress concentration $k > 1$ have been established for the conditions of the problem in question.

Superposition of Steady and Variable Stress

Assuming the conditions for the separately acting stresses σ_0 and $k\sigma_v$ to be fully determinate, the case of simultaneous application of these stresses still raises an important problem. The experimental material is fairly extensive and does permit certain conclusions. Plotted in the manner shown in Fig. 4, the relation

[3] "The Fatigue of Metals," by H. F. Moore and J. B. Kommers, McGraw-Hill Book Company, New York, first edition 1927, p. 119.

between σ_0 and σ_v, corresponding to failure, is generally a curve going through (O, σ_e) but almost always falling outside the straight line connecting (O, σ_e) and (σ_s, O). In view of the uncertainty of the available material, it appears reasonable to treat the problem on the basis that this straight line is the actual line of failure, particularly since this is almost always on the safe side. The equation of this line is $\sigma_0/\sigma_s + k\sigma_v/\sigma_e = 1$, which thus expresses the combinations of σ_v and σ_0 which will cause failure. In order to obtain a factor of safety n, the stresses must follow the relation

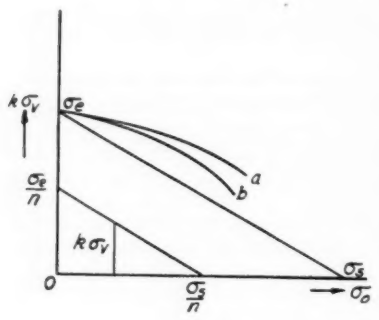

Fig 4

$$\sigma_0/\sigma_s + k\sigma_v/\sigma_e = 1/n \quad [7]$$

representing a straight line connecting the points $(O, \sigma_e/n)$ and $(\sigma_s/n, O)$. It is evident that $\sigma_e/k\sigma_v = n_v$ and $\sigma_s/\sigma_0 = n_0$ represent the factors of safety when the stresses are acting alone and hence this result may be written

$$1/n_x + 1/n_0 = 1/n \quad [8]$$

Equation [8] may also be written

$$1/n = [\sigma_0 + k\sigma_v(\sigma_s/\sigma_e)]/\sigma_s \quad [9]$$

in which form it expresses the fact that the variable stress can be added to the steady stress by "weighting" it with the factor $k(\sigma_s/\sigma_e)$.

Combined Stresses

The difficulties become greater when cases of combined stresses are considered, because very little in the way of experimental material is available on this point. Gough's work[4] on the fatigue of single crystals shows that fatigue failure is generally preceded by slip on planes having maximum-resolved-shear stress. Tests of low-carbon steel subjected to combined alternating torsion and alternating bending[4] have produced results agreeing closely with the distortion-energy theory. The ratio of endurance limits obtained from torsion tests and from bending-test averages somewhat greater than one-half for steels.[5,6] Taking the foregoing results into consideration it seems reasonable, for the present, to use the maximum-shear theory for variable stresses also.

Failure is thus defined by the relation

$$2\tau_0/\sigma_s + 2k_\tau\tau_v/\sigma_e = 1 \quad [10]$$

between the constant component τ_0 and the variable component $k_\tau\tau_v$ of the shearing stresses in the plane of failure. The factor of safety is found from the relation

$$1/n = 2\tau_0/\sigma_s + 2k_\tau\tau_v/\sigma_e \quad [11]$$

The method may be criticized on the basis that great care has to be exercised in selecting the appropriate combination. The steady components may cause failure in one plane, while the variable components may cause failure in another plane. Equation [10] should apply to the plane which makes n a minimum.

The conditions are best illustrated by applying this result to the common case of combined tension $\sigma_0 \pm k\sigma_v$ and shear $\tau_0 \pm k\tau_v$, Fig. 5. The combined shearing stress in the plane PP is made up of the constant component $(\sigma_0/2)\sin 2\alpha - \tau_0 \cos 2\alpha$ and a variable component $(k_\sigma\sigma_v/2)\sin 2\alpha - k_\tau\tau_v \cos 2\alpha$.

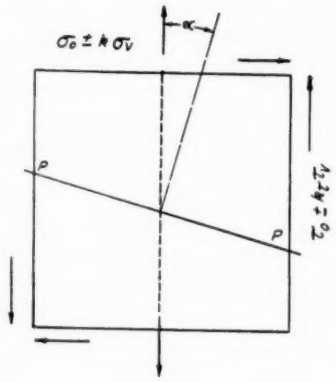

Fig 5

The value $1/n$ in this plane may thus be obtained by applying Equation [11] to

$$\frac{1}{n} = \frac{\sigma_0 \sin 2\alpha + 2\tau_0 \cos 2\alpha}{\sigma_s} + \frac{k_\sigma\sigma_v \sin 2\alpha + 2k_\tau\tau_v \cos 2\alpha}{\sigma_e} \quad [12]$$

The minimum value of n occurs when

$$\tan 2\alpha = -[\sigma_0 - k_\sigma\sigma_v(\sigma_s/\sigma_e)]/2[\tau_0 - k_\tau\tau_v(\sigma_s/\sigma_e)] \quad [13]$$

When $\sigma_s = \sigma_e$ this is the plane of maximum shear. The absolute value of the factor of safety in the plane is

$$n = \frac{\sigma_s}{\sqrt{[\{\sigma_0 + k_\sigma\sigma_v(\sigma_s/\sigma_e)\}^2 + 4\{\tau_0 + k_\tau\tau_v(\sigma_s/\sigma e)\}^2]}} \quad [14]$$

which thus establishes the working stresses for this case.

When the variable components of the stresses exist as a small addition to the steady stresses, it is sometimes convenient to introduce the "weighting" factors

$$k_\sigma = 1 + k_\sigma(\sigma_v/\sigma_0)(\sigma_s/\sigma_e) \text{ and } k_\tau = 1 + k_\tau(\tau_v/\tau_0)(\sigma_s/\sigma_e) \quad [15]$$

whence the expression for maximum factor of safety

$$n = \sigma_s/\sqrt{[(k_\sigma\sigma_0)^2 + 4(k_\tau\tau_0)^2]} \quad [16]$$

This method was in practical use before the derivation was known.

Rules for Working Stresses for Ductile Materials Under Variable Stress at Normal Temperature

The following rules may be formulated for working stresses:

1 Alternating stress in tension, compression or bending

$$n = \sigma_e/k\sigma_v \quad [17]$$

2 Alternating stress in shear

$$n = \sigma_e/2k\tau_{v\,\max} \quad [18]$$

3 Combinations of steady and alternating stress

$$1/n = \sigma_0/\sigma_s + k\sigma_v/\sigma_e$$

$$n = \sigma_s/[\sigma_0 + k(\sigma_s/\sigma_e)\sigma_v] \quad [19]$$

4 General case of combined variable stress. Evaluate the constant component τ_0 and the variable component $k\tau_v$ of the shearing stress in the plane of minimum n, where

$$1/n = 2[(\tau_0/\sigma_s) + (k\tau_v/\sigma_e)] \quad [20]$$

5 Special case of combined variable tension stress and variable shearing stress

$$n = \frac{\sigma_s}{\sqrt{[\{\sigma_0 + k_\sigma\sigma_v(\sigma_s/\sigma_e)\}^2 + 4\{\tau_0 + k_\tau\tau_v(\sigma_s/\sigma_e)\}^2]}} \quad [21]$$

Discussion

Ordinate Systems for Quadratures Similar to Tchebycheff's Ordinates[1]

L. T. Fleming.[2] Professor Karelitz' paper is an interesting application of approximate-quadrature theory to a specific type of problem. The author compares the method he has developed with that of Tchebycheff, but not with Gauss's formula nor with those using a rational integral polynomial of high-degree and equidistant ordinates.

The accuracies of approximate quadrature formulas depend not only on the number of ordinates used, but also on the goodness of fit of the function that is substituted for the given curve or function. Good practice ordinarily requires that the error in computation should, at most, not exceed that due to scaling measurements or the inaccuracies of fabrication. It is this writer's opinion that, in a majority of cases, formulas employing equidistant ordinates will give a better fit than those in which the ordinates are not equidistant.

As an example, consider, for shapes such as these water lines, the tenth-degree polynomial with intervals between ordinates of $(2L/10)$. The coefficients for computing the moments and the whole and half areas above the x-axis of such a curve follow. As the formulas are equally applicable when the end ordinates are not zero, coefficients for y_5 and y_{-5} are given. The author's notation is followed except that the symbol L, for the half length, replaces the letter l.

Whole area, from $x = -L$ to $x = L$:

$$A_1 = (2L/10)\ (0.268341\,(y_{-5} + y_5) + 1.775359\ (y_{-4} + y_4) - 0.810436\ (y_{-3} + y_3) + 4.549463\ (y_{-2} + y_2) - 4.351551\ (y_{-1} + y_1) + 7.137646\ y_0)$$

Half area, from $x = 0$ to $x = L$ (reverse the ordinates for area from $x = -L$ to $x = 0$):

$$A_2 = (2L/10)\ (-0.006001\ y_{-5} + 0.066988\ y_{-4} - 0.341276\ y_{-3} + 1.050153\ y_{-2} - 2.184818\ y_{-1} + 3.568823\ y_0 - 2.166733\ y_1 + 3.499310\ y_2 - 0.469159\ y_3 + 1.708371\ y_4 + 0.274343\ y_5)$$

Moment about y_0 of whole area, from $x = -L$ to $x = L$:

$$M_1 = (2L/10)^2\ [1.341707\ (y_5 - y_{-5}) + 7.101438\ (y_4 - y_{-4}) - 2.431307\ (y_3 - y_{-3}) + 9.098926\ (y_2 - y_{-2}) - 4.351551\ (y_1 - y_{-1})]$$

Moment about y_0 of half area, from $x = 0$ to $x = L$ (reverse the ordinates and multiply by (-1) for moment about y_0 of area from $x = -L$ to $x = 0$):

$$M_2 = (2L/10)^2\ [-0.027986\ y_{-5} + 0.311971\ y_{-4} - 1.585828\ y_{-3} + 4.858778\ y_{-2} - 9.993580\ y_{-1} + 14.614977\ y_0 - 14.345131\ y_1 + 13.957704\ y_2 - 4.017135\ y_3 + 7.413408\ y_4 + 1.313721\ y_5]$$

The areas and moments of the curves a and b, Fig. 5 of the paper, used by the author as examples, computed by the above formulas, differ by the following per cents from the exact values: curve a, area, —0.13 per cent, moment, —0.30 per cent; curve b, area, +0.0017 per cent, moment, +0.0041 per cent. It will be noted that these errors are appreciably smaller than those reported by the author in his Table 9.

The statement in the text that "...Tchebycheff ordinates do not give... (the) moment with satisfactory accuracy," might be misleading; the moment being the area under a curve, can of course be computed by these ordinates to any reasonable degree of accuracy. The Tchebycheff ordinates used for the area computation, multiplied by their respective abscissas, should give the moment of the whole figure, from $x = -L$ to $x = L$, with, usually, but slightly less accuracy for an unsymmetrical figure than that obtained for the area. But from geometrical considerations rather than for the reason cited in the text, we cannot expect to obtain a satisfactory moment of the half area by use of ordinates taken at the same points as used for the area of the whole figure, as the moment curve then has a sharp break at $x = 0$ and is not the smooth curve required by the Tchebycheff polynomial.

This difficulty is admirably overcome by the ordinates proposed by the author, but it should be noted that they do not give an exact moment for curves which are exactly integrated as to area, a possible defect not inherent in the equidistant-ordinate formulas. It will require considerable experience with these ordinates to give convincing proof that the polynomial which they integrate gives as good a fit to the general run of curves as a polynomial with no terms missing and no restrictions on the parameters.

S. J. Mikina.[3] The appearance of Professor Karelitz' paper with its elaboration on Tchebycheff's work of 70 years ago, prompts the writer in turn to resurrect a little-known quadrature formula of even more ancient antecedents. A good and sufficient reason for this is that the formula in question is superior in point of simplicity of application and accuracy of results to anything of the kind in present-day literature on mensuration and well deserves to be brought to light and given recognition. Reference is made to the formula in the book, "The Calculus of Finite Differences," by George Boole (the first edition of which appeared in 1860), who attributes it to an English mathematician of an earlier date named Weddle. Weddle's rule for obtaining an approximate expression for the area under a curve requires that the given area be divided into six portions bounded by seven equidistant ordinates, as shown in Fig. 1 of this discussion. If the common distance between these ordinates is h, the area is given by

$$S = \frac{3h}{10}\left[y_0 + y_2 + y_4 + y_6 + 5(y_1 + y_3) + 6y_3\right]$$

This practical rule, which ought to find a place in every engineer's note-book, may be conveniently kept in mind by the following mnemonic:

The proposed area being divided into six portions by seven equidistant ordinates, add into one sum the even ordinates, 5 times the odd ordinates, and the middle ordinate, and multiply the result by $^3/_{10}$ of the common distance of the ordinates.

The theoretical basis for the rule was laid by evaluating the area integral of a sixth-degree polynomial passing through the

seven ordinates. The remarkable simplicity of the numerical constants in the rule is due to the application of the calculus of finite differences to the evaluation of the area integral in question. By expressing the polynomial in terms of successive finite

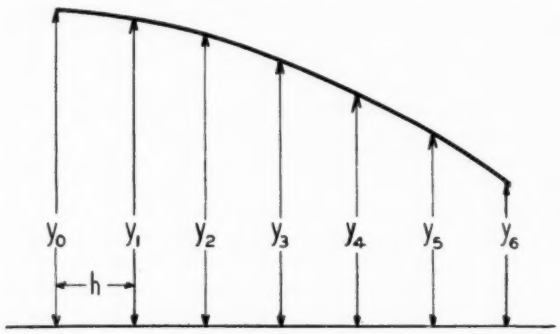

FIG. 1

differences in a manner analogous to the representation of a function by Taylor's series in terms of its successive differential coefficients, it was found possible to gage accurately the error committed in neglecting certain terms and in this way to simplify the final expression by purging it of all arithmetically complex, but demonstrably negligible, factors.

The application of Weddle's rule to Professor Karelitz' clinical curves $y = 0.7\ (1 - X^3) + 0.3\ (1 - X^6)^2$, designated by him as curve *a* in Fig. 5 of the paper, and $y = 0.935 \cos\ (\pi\ x/2) + 0.065 \cos\ (3\pi x/2)$, designated as curve *b* in Fig. 5 of the paper, gives the results shown in Table 1 of this discussion for the region $X = 0$ to $X = 1$.

The value of the area under curve *b* was given by Weddle's rule as being equal to 0.5814, correct to four places. The somewhat unfavorable comparison of this value with the value of 0.584, given as exact in Professor Karelitz' paper, provided the incentive for a recalculation of the exact value. This was found to be 0.5814, thus checking Weddle's value. For both curves, Weddle's-rule values are consistently better than those determined with the formulas considered in the paper.

The differences in error between Weddle's rule and Professor Karelitz' proposed rules are hardly great enough to argue about, however, and any preference for one or the other on the basis of minimum error must be a matter of personal taste. From the point of view of ease of application, however, Weddle's rule with its equidistant ordinates has the advantage over the peculiar ordinate spacing required by Professor Karelitz' rules. Just as a matter of simple drafting it is apparent that it is much easier, and more conducive to accuracy in the final result, to divide a line into six equal parts by the usual geometrical construction than to lay off such abscissas as 0.27047, 0.41791, or 0.65263 times the length of the line.

Weddle's rule will be found particularly useful in such applications as the determination of moments of inertia of irregular shapes, such as propeller- or turbine-blade sections, in the evaluation of indicator-card areas, and in the evaluation of definite integrals which cannot be integrated in terms of elementary functions. In the case of indicator-card areas it is suggested that the diagram be divided up so as to avoid applying the formula over regions of too sharp a variation in ordinate heights. This may be done in any case where extreme accuracy is desired.

AUTHOR'S CLOSURE

The principal value of Tchebycheff's coefficients, or those proposed in the paper, is the possibility of obtaining the area and moment of curves with a small number of ordinates and without multipliers. As mentioned, it is of primary use for practical shipbuilders when they compute the stability elements of a ship's hull. Certainly, there are numerous other formulas which give the area with a satisfactory accuracy, but the Tchebycheff method involves the least amount of labor.

The ship's lines are, with our present knowledge, empirical lines, and it is hardly possible to determine which member of the polynomial series would be the most important. In fact, there is no reason why the powers of the polynom should be integral numbers, or why the water-lines would not be represented better by a sum of trigonometric functions. Experience has shown that Tchebycheff's formula with 9 ordinates (four sections fore and four sections aft) gives results of sufficient accuracy for practical ship calculations.

The author takes this opportunity to thank Mr. Mikina for calling attention to the arithmetical error in the example *b*. It seems that the half-length of the "clinical" lines was divided into six parts for the application of Weddle's formula. This would require 13 ordinates for the application to a ship's water line instead of 9, as with Tchebycheff's or the author's ordinates.

Pitting Due to Rolling Contact[1]

GEORGE W. ALLAN.[2] The author is to be congratulated for his interesting paper which clears up many of the obscurities regarding the surface failure of metals under rolling stresses. He has been successful in obtaining experimental results free from the troubles encountered by other experimenters in the same line of work. He has also most ingeniously analyzed the effect of lubricant on the rolling stresses.

There are a few minor matters on which the writer would like to have Mr. Way's opinion. In the pictures of the damaged rolls, the pitting or fine scoring, depending on the running conditions, appears to be heaviest at the center of the surface, there being a narrow band of surface at the ends which shows practically no damage. This may be due, in the writer's opinion, to either of two causes: The metal in the immediate vicinity of the edge, being less constrained than that in the middle, may not experience as much contact pressure. The second cause might arise from a type of error which the writer thinks would not be easy to adjust or measure in the author's machine. If the axes of the two rolls while lying in parallel horizontal planes were not parallel with each other so that those lines on the two rolls, which under correct conditions when the rolls were just making contact formed the common line of contact, crossed each other instead at a slight angle, we would get point contact. Under load, this would become an elliptical contact area so that the pressure at the center would be greater than that at the ends.

The author mentions that no slip took place between his rolls. His method of proving this seems to have been to turn the rolls around once and to ascertain that the spacing of two dents on one roll caused by one protuberance on the other was equal to the circumference of the other. This was hardly running conditions and it would have been interesting to attach counters on each

roll shaft to ascertain whether any slow creep took place over a period of running time.

The writer would like to know whether any oxide of iron such as the author found after a dry test was present in the oil after a test with lubricated surfaces. Manufacturers of friction drives ap-

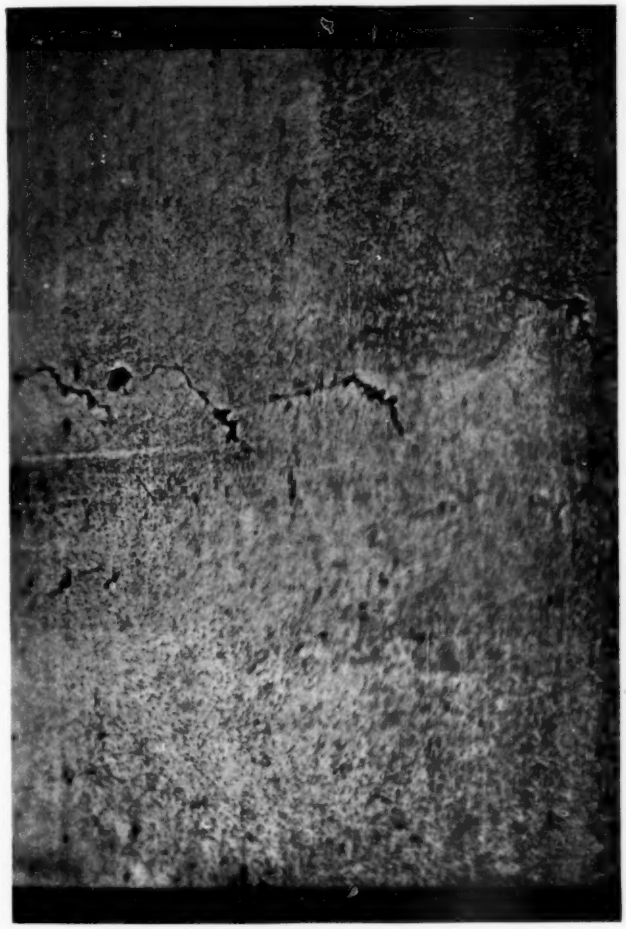

FIG. 1 (× 100)

pear to have found that this oxide formed even with lubricant present. Of course this may be due to the fact that a friction drive using steel disks experiences sliding abrasion to a great extent whereas in the author's tests, this was practically absent.

The writer notes that in the photographs showing the development of a pit that the crack, which was the first visible stage of its development was a short isolated and comparatively straight one. In the tests on which the writer is at present engaged and in which he uses smaller and harder rolls, the cracks are spread over the surface generally before the failure becomes general. The accompanying photomicrograph, Fig. 1 (100 magnifications), shows the type of crack which the writer has found.

The author's analysis of pressure forces due to the oil affords an interesting picture of the forces produced by oil in very high-speed gear teeth and other fast moving machinery. Has the author considered the boundary film properties of his lubricant in determining the point at which metal-to-metal contact takes place? With boundary lubrication, a heavier load would have to be applied to make metal-to-metal contact than if there were none.

Finally the writer would like to know whether the surface temperature of the rolls rose much while running.

E. LEONARD MARMONT.[3] Many theories have been advanced in connection with pitting of cylindrical surfaces when in rolling contact under load. Mr. Way's paper shows that he has devoted much thought to the subject and as far as his experimenting goes his conclusions are justified.

Those men engaged in the rolling of sheet and tin plate who constantly give their attention to pitting (or spalling) of mill rolls may first turn to the theory that spalling is the result of creeping. For the sake of explanation we may study the action of a plain (unthreaded) rubber tire when subjected to load and in rolling motion. As shown in Fig. 2 of this discussion, the rubber

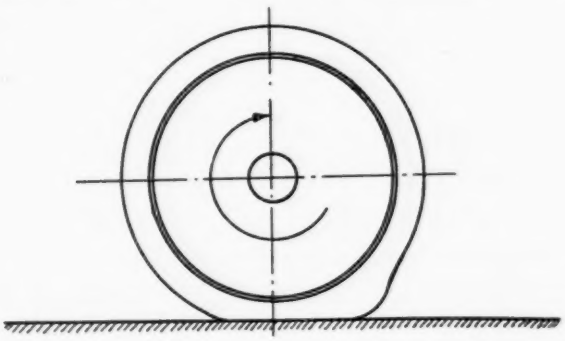

FIG. 2 CREEPING OF TIRE TREAD DUE TO LOAD AND ROLLING MOTION

is being compressed with the result that creeping takes place in front of the vertical center line in the direction of rolling. This creeping is continuous except when load or road conditions cause that part to snap back with the result that excessive wear takes place at this point. It is for this reason a smooth rubber tire does not wear evenly but develops cavities. For the purpose of relieving this creeping action and to provide better traction, tires are made with a thread design which allows a free displacement. According to the theory, a similar creeping action takes place in a mill roll and eventually causes spalling.

A second theory maintains that spalling is caused by an unequal stress distribution set up in the roll at the time of its manufacture combined with the stress produced when rolling under heavy load. There seem to be certain similarities between this theory of spalling and our equally uncertain knowledge concerning the cause of earthquakes. It is a well known fact that in the cooling of a solid, non-homogeneous body such as the earth, unequal stresses must necessarily be set up in the outer regions. To these stresses present in the crust of the earth must be added frictional stresses caused by the earth's contact with the surrounding atmosphere. Some scientists say that because of the earth's high velocity of over 1000 mph, this friction is influential in connection with earthquakes. In the manufacture of mill rolls high stresses are similarly set up in the outer parts of the rolls due to cooling. According to the theory, we add to these stresses those resulting from more or less impure rolling contact. Even though a comparatively long period may elapse before spalling occurs the roll will finally spall because the stresses are accumulative. It is thought that if the mill rolls were heat-treated correctly to relieve the accumulated stresses, the spalling problem would be overcome. The correctness of these or any other theories can be settled only by scientific research.

It seems appropriate to mention a mill incident, of recent date. It was observed that the strip on a four-high cold mill was being marked by a spalled roll. The mill was stopped immediately, the spalled roll exchanged for another and placed on the floor.

[3] Engineer-Draftsman, American Sheet and Tin Plate Co., Gary, Ind. Jun. A.S.M.E.

Examination of the roll showed a spalled part approximately equal to the cross-sectional area of an ordinary pencil. A few minutes elapsed when suddenly a 35- or 40-sq in. piece disengaged itself from the surface of the spalled roll and shot 20 ft into the air. Luckily, no one was hurt. Such occurrences are, fortunately very infrequent. But some mills provide a pit in which rolls are put immediately upon removal from the mills. The rolls remain in the pit until they have acquired room temperature.

Cold-rolling of tin plate is being done both with and without the use of oil on the rolls and spalling occurs in both cases. Oil is used as a cooling medium on mills working under screw-down pressures of about 70,000 lb per in. of roll face but it is not used on so-called skin-pass mills where the highest pressures are about 20,000 to 25,000 lb per in. of roll face. To say that the presence or absence of oil has no effect on spalling would be a hasty statement since the fact remains that mills using oil suffer more lost time due to spalled rolls than mills operating dry; although that could be attributed to higher screw down pressures.

Opinions as to the cause of spalling are more diversified than this discussion shows. Thus, in one article which appeared in *Blast Furnace and Steel Plant*, August, 1925, Harold Harris makes the following statement: "To avoid spalling, a plate-mill roller should carry water on the working surfaces of his rolls at all times." Evidently this implies that the temperature of the roll is a factor in spalling.

The elimination of the present confusion in regard to spalling would be of immense value. It is, therefore, hoped that more experimentation will be undertaken with full understanding of the complexity of the problem.

HAAKON STYRI.[4] The results obtained by Dr. Way are very interesting but it seems that the conclusions he has drawn are much too sweeping. It is possible that publication of more detailed data will show a better foundation for his conclusions but objections can be raised to most of them, even if applied only to the test conditions used by Dr. Way. Still greater objection can be raised against applying the conclusions to antifriction bearings.

The authors experiments consistently showed that there was no pitting when the rollers were run without lubricant. It would be desirable to learn how much the rollers lost in diameter during these tests due to oxidation of the contact surfaces and also if there was any measurable small slip between the rollers due to friction in the journal bearings. Since only one roller was driven, it seems that precautions should have been taken to mount the idle roller in ball bearings to reduce the friction. It is then possible that a different result would have been obtained. At least one fact observed in practical operation suggests this, namely, that locomotive tires which run without lubrication on the rail can pit or spall as shown in Fig. 3 of this discussion, in which case the spalling has progressed further than recorded by Dr. Way. His experiments have shown that under the conditions used in the tests, apparently all pitting starts from the surface and that it occurs only when a lubricant is used. It is not permissible to conclude that this also will be the case in other applications. If the initial crack starts at a point below the surface of cylindrical rollers and progresses to the surface along the direction of an obtuse cone it may break through and appear on the surface as a lip extending in the direction of the rolling. Fig. 4 of this discussion shows the beginning of a crack below the surface of a ball bearing where no crack was visible in the ball path even by etching. Fig. 5 shows the results of plastic deformation in a ball-bearing race due to running under heavy load. The structure is developed by etching in nitric acid and alcohol and is magnified 1000 times. Ball and roller bearings have, of course, highly polished rolling surfaces, and a hardness over 60 Rockwell, recorded on the *C*-scale.

In all kinds of endurance tests on ball and roller bearings, the dispersion in life before failure of an adequate number of specimens at any given load is very great, frequently of the order of 1 to 10. The dispersion in life before flaking or pitting in ball and roller bearings is of this order or even greater under all test conditions, including test conditions for roller bearings similar in nature to those used by Dr. Way for rollers. It seems reasonable, therefore, to expect that Dr. Way should obtain very

FIG. 3 SPALLING OF A LOCOMOTIVE TIRE

FIG. 4 BEGINNING OF A CRACK BELOW THE SURFACE OF A BALL BEARING

[4] Director of Research, SKF Research Laboratories, SKF Industries Inc., Philadelphia, Pa. Mem. A.S.M.E.

great dispersion in life before pitting is observed under any given test condition. He states that the number of cycles necessary for the beginning of pitting is practically independent of the hardness, although he observes that a harder surface resists pitting better. In roller-bearing practice, the relationship between load and average life before failure due to pitting or flaking has been quite well established and can be expressed mathematically by an empirical formula

$$P = C/n^{0.3}$$

where P is load, n is the life in cycles, and C is a constant depending on the material and construction of the bearing. In

FIG. 5 RESULTS OF PLASTIC DEFORMATION IN A BALL-BEARING RACE

this connection it would be of interest to record the lives before pitting for the loads used in Dr. Way's Fig. 6. The life under any given load condition does depend greatly on the hardness of the material but there is no direct relationship. There is a distinct and sharp drop in life with decrease in hardness value from about 59 Rockwell, C-scale, down to lower values. Very few test data are available for ball or roller bearings with a hardness below 55 Rockwell, C-scale, because the life is so much reduced that the bearings would be considered defective. In order to obtain fair average values at least 20 tests must be run for each load condition.

We have never been able to find any relationship between failure due to pitting and viscosity of lubricant, although a great number of tests have been run with widely different oils, under conditions varying from flood lubrication to insufficient quantities of oil to operate the bearings properly.

It is possible that Dr. Way has been successful in identifying a special phenomenon entering into the complex mechanism of fatigue failure. However, it is not safe to generalize results which were obtained under a particular set of conditions. As stated previously by the writer, established facts relating to the development of flaking or fatigue in antifriction bearings are at variance with the results revealed by Dr. Way's tests. The fatigue failure due to surface flaking in antifriction bearings is a matter of great practical interest, and we are forced to conclude that the action described by Dr. Way is in this instance entirely subordinated to other influences which are of controlling importance.

AUTHOR'S CLOSURE

Considering Mr. Styri's question on the necessity of lubrication for pitting, the pitting of the locomotive tire shown in Fig. 3 of the discussion may have been promoted by water on the rails acting as the lubricant. As to tangential traction in the pitting tests affecting the results, it can be stated that this effect was minimized by mounting all rollers in antifriction bearings. The rate of wear of the dry tested rollers was sometimes small and sometimes large. In one case, a roller of 250-VPN hardness run dry for 12 million cycles at a load of 2500 lb per in. decreased only 0.0003 in. in diameter.

Another open question is, "Exactly where do the pitting cracks start?" Figs. 6 and 7 of this discussion show pitting cracks in

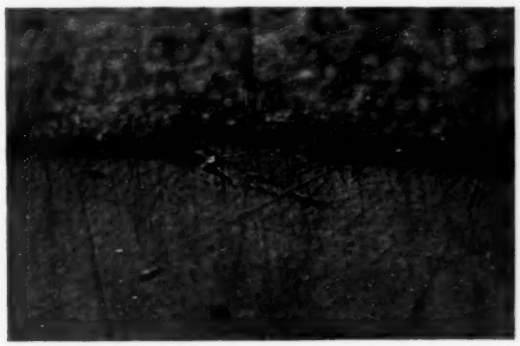

FIG. 6 CROSS-SECTION OF PITTING CRACK (× 300)

FIG. 7 CROSS-SECTION OF PITTING CRACK (× 300)

cross-section which are not more than 0.0008 and 0.002 in. deep, respectively. The depth of the point of Hertz' maximum-shear stress is 0.007 in. Other minute cracks have also been observed in section. Therefore, we can say that in the case of rolling cylinders (the stress system is different for ball bearings) pitting cracks start somewhere in a surface layer of material which is thin compared to the depth of the point of Hertz' maximum shear. It is very interesting that Mr. Styri has obtained illustrations of cracks in ball bearings beneath the surface. Can we be sure these cracks are prepitting cracks?

The antifriction-bearing manufacturer is interested in relations of average life to load and hardness. The gear manufacturer, on the other hand, wants to be sure that his gear will not fail by pitting. The present pitting studies have been made more from the standpoint of the needs of the gear industry. Therefore, it has not been the author's object to conduct an investigation of the average life of the test rollers at different loads and hardnesses, but rather to find conditions of load, hardness, viscosity and other factors which will insure against pitting.

Since preparing the paper, the author has had an opportunity

to study the effects of hardness variation on load-carrying capacity. One lubricant was used in these tests, and the same steel was used with the same treatment in all cases, except that drawing temperatures were varied to secure different hardnesses. If different types of heat-treatment are used giving different structures, there is evidence that the relation of load and hardness will vary. Fig. 8 of this discussion shows the results of a group of tests. From this series it appears that if the maximum

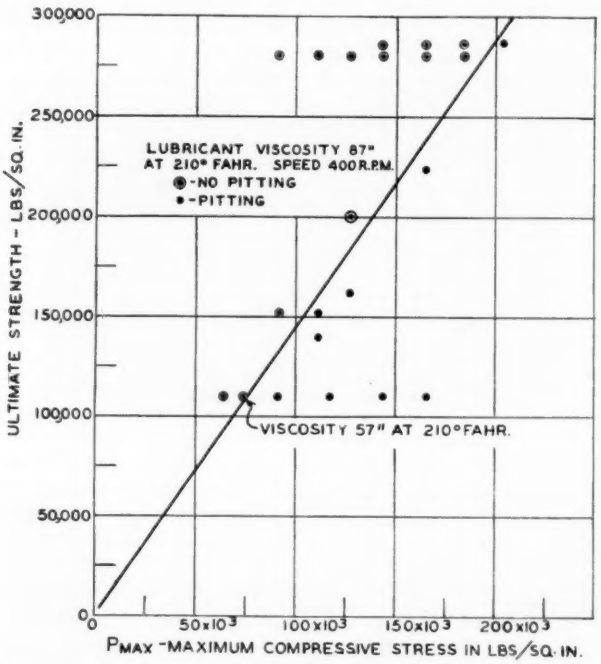

FIG. 8 LOADS THAT CAUSE PITTING OF QUENCHED AND TEMPERED 0.40-C STEEL ROLLERS

compressive stress is less than 0.7 of the ultimate strength, pitting will not occur.

If p_{max} is 0.7 of the ultimate strength, the maximum range of shear stress is only ± 0.175 of the ultimate strength, whereas the shear endurance limit is of the order of ± 0.25 to ± 0.28 of the ultimate. (The maximum range of shear stress rather than the maximum shear stress should be considered when determining the cause of fatigue cracks.) Furthermore, the point where the range of the shear stress is a maximum is 0.005 in. below the surface for a load of 2500 lb per in. Thus, it is apparent that the formation of pitting cracks in the very beginning cannot be due to repetitions of the theoretical Hertz stress system for rollers that are perfectly cylindrical. It is quite likely that these cracks are produced by the highly localized stresses near the surface caused by surface irregularities.

Mr. Styri remarks that variations in oil viscosity have little effect on bearing life even at a given load. It is possible that if the viscosity were increased far above any practical value, the effect would be noticed. It seems that only in the case of relatively soft materials such as gear steels, it is practical to attempt to eliminate pitting by increasing the oil viscosity. To get a clear conception of this situation, one must look at a three-dimensional diagram of the critical values of load, hardness and viscosity. Such a diagram is at present being constructed as rapidly as data can be obtained.

The pit on the locomotive tire shown in Fig. 3 of this discussion resembles those the writer has seen on ball bearings, one of which is shown in Fig. 9 of this discussion. There is a summit in the middle of the pit, the surface of which is the original surface of the ball. The pit appears to have grown radially from this central summit. Such a radial structure is also suggested in the pit in Fig. 3 of this discussion. There is evidently a characteristic structure for pits on spherical or ellipsoidal surfaces of contact

FIG. 9 PIT ON A BALL BEARING (× 8)

different from that for pits on cylinders. This presents a field for further study. A study of the pit in Fig. 9 strongly suggests that the crack which precedes the pit results from tensile stresses at the boundary of the contact area.

Mr. Allan asks about several details of the tests. The wear is confined to the middle portion of the upper roller because the face width of the upper roller is greater than that of the lower. Counting the revolutions shows that there is no slip between the rollers. A chemical analysis was not made of the steel dust which collects in the oil, but all of it was found to be magnetic. The tests Mr. Allan made were conducted on rollers that were quite hard, inasmuch as the pitting cracks obtained by him were quite irregular. This irregularity has also been found to exist by the author to a more marked degree on harder rollers.

The question of "oiliness" is one about which very little is known. We can be quite sure of one thing, however, and that is that the thickness of the film of molecules associated with the term "oiliness" is very much smaller than the height of surface irregularities on the test rollers or on gear teeth in general. I believe it is justifiable to neglect the adhesive forces binding the oil molecules to the surface in calculating the load necessary to bring the surface irregularities into contact.

The temperature of the lubricant was found to increase from 20 C to 40 C above room temperature, depending on the viscosity.

Mr. Marmont raises the important subject of the spalling of mill rolls. It is perhaps in order to rule out of the discussion failures of a more or less explosive character due in whole or in part to thermal causes and consider only surface failures due to the rolling forces. It is questionable whether spalling due to rolling forces is a failure of the same nature as pitting on gear teeth or on test rollers, so different are the conditions of operation. The main differences that might be mentioned are (1) the plastic condition of the rolled material, (2) the presence of high tangential traction, (3) high temperatures in the case of hot mills. The "creeping" explanation of spalling would not account for pitting under conditions where there is negligible tangential traction. Also, one feels periodic slipping or "creeping" would produce gradual wear rather than pitting cracks. Residual stresses cannot play an important part in mechanical pitting, as is shown by the occurrence of pitting on untreated gears and rollers.

REVIEWED BY A. NADAI[1]

DISTORTION OF METAL CRYSTALS

IT is now about 15 years since a small group of young scientists, among whom the names of M. Polanyi, Miss C. F. Elam, and E. Schmid may be mentioned as well as those of H. C. H. Carpenter, G. I. Taylor, T. Czochralski, and others, became interested in the plastic deformation of large crystals. Until that time the subject was known to only a few mineralogists. Among these D. Mügge was probably the first to discover that rock-salt crystals, which at ordinary temperature fracture as a brittle material, may easily be bent permanently to a considerable extent without fracturing if heated, and that under a polarizing microscope beautiful curved lines (slip lines) become visible after permanent bending. The salt crystals had been permanently deformed along numerous regularly curved packages of layers. Similar but straight "slip bands" were subsequently described by W. Rosenhain and G. Tammann in most of the polycrystalline ductile metals after these metals had been plastically deformed. It is probable that comparatively large metallic crystals have been produced accidentally in many cases prior to systematic studies of these crystals. The enormous softness and ductility which became apparent as soon as the first single-crystal wires of metals were stretched and the most regular manner according to which these crystals deform were some of the astonishing facts which led to further investigation. X-ray analysis of these materials contributed much to the structural discussion of deformed metals and crystals.

Mrs. G. H. Tipper, well known for her pioneer testing work on the distortion of metallic single crystals and for her joint investigations with H. C. H. Carpenter and G. I. Taylor in Cambridge, England, has undertaken to present briefly some of the most important general results of the extended investigations by herself and by a few physicists and engineers. During the last 15 years this work has greatly helped to establish the laws of the plastic deformation of single crystals of the ductile metals. Mrs. Tipper states in the preface of the volume that it was decided to limit the scope of the book to an account of the changes in structure and in physical and mechanical properties accompanying plastic deformation of metallic single crystals and to the effect of temperature. The corresponding phenomena in polycrystalline metals are not treated in detail.

Fifteen chapters are devoted to the following subjects: Preparation of metal crystals, deformation of metal crystals, calculation of forces required to produce deformation, deformation by twinning, deformation of polycrystalline metal, deformation of alloys, deformation under repeated stresses, fracture, effect of temperature, duration of test, rate of application of load, alteration in the X-ray reflections accompanying deformation, relation between work done and energy absorbed during deformation, changes in physical properties, plasticity, effect of heat on deformed metal, and a summary and theoretical discussion.

The aim of the book is to avoid unnecessary details, and to lay stress on the experimental methods and to furnish an account of their principal results as well as of theoretical considerations without entering into a mathematical discussion. The little book accomplishes these aims satisfactorily and will be appreciated by many engineers and by those who wish to learn about the numerous interesting and practically important phenomena relating to the permanent deformation of crystals. The book is lucidly written, and the simplest language is used to describe physical or geometrical facts that are not simple. Reading is therefore delightful.

CRYSTAL PLASTICITY

The circle o freaders to whom this book will appeal is perhaps larger than that for which Mrs. Tipper's was probably written. E. Schmid is a professor at the University of Freiburg (Switzerland) and is also one of the pioneers in this field who has contributed considerably through his own exact and careful experimental investigations to a knowledge of the laws of the plastic deformation of single crystals. The book has chapters devoted to the following subjects: Crystallographic fundamentals crystal-elasticity, production of single crystals, methods of finding the orientation of axes in crystals, geometry of the mechanism of plastic deformation, plasticity and strength of metal crystals and of ionic crystals (rock salt), theories and behavior of polycrystalline metals. In the two short introductory chapters the notation by indexes used by the mineralogists is explained, the crystal systems are discussed and the linear equations expressing Hooke's law of elasticity between the six stress and strain components for crystals treated. Among the various methods for production of single crystals the methods by recrystallization after a critical strain hardening, by local crystallization of a powdered metal (tungsten), by growing from the molten state, by pulling out of the liquid metal, and by sublimation are described. A long chapter is devoted to crystal lattices and to the various methods of structural analysis by means of X-rays. The mechanism of simple and double slip and of twinning in single crystals is then described in detail, illustrated by a large number of beautiful photographs of slip bands and of the strange local necking phenomena characteristic for the last stage of deformation of certain metal crystals. An instructive addition consists in the numerous photographic illustrations of model surfaces made of plaster of Paris representing the shearing stress at the yield point (*Fliessgefahrkoerper*) or the modulus of elasticity or the tensile strength of single crystals in a kind of a vector diagram (surface) in space. Even for the regular system of crystals some of these surfaces show unexpectedly large variations in the corresponding variable

[1] Research Laboratories, Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

quantity. The effect of temperature and time is studied. Space is devoted to phenomena related to recrystallization and to heat-treatment. A chapter is devoted to the theories of the solid state of matter and of strain-hardening and one deals with the so-called *fiber* structure in polycrystalline materials due to severe cold-working. The book is well illustrated and contains an accurate description of the most important phenomena related to the deformations of single crystals. For a better understanding of the fundamental properties of metals upon which their ductility, strength, and other mechanical properties depend, this book will be a welcome source of useful information.

Solid State of Matter

Some 200 distinguished physicists attended the international conference on physics, held in London in 1934 at the Royal Society and at the Royal Institution of Great Britain.

The deviations of the numerical values for certain mechanical and strength properties actually determined by tests on real crystals from the values predicted by the theory of lattices of ideal crystals occupy today the center of discussion in connection with the theory of the solid state of matter. It was therefore thought that it might be of some interest to engineers to have a brief summary of some of the papers and discussions, which were presented at the London conference in 1934 and are now available in print in the second volume devoted to this conference. It has been said, and it does not appear improbable, that engineers will some day utilize one or the other of the remarkable observations which seem to indicate that the natural strength of crystalline or amorphous solid bodies under certain conditions can be substantially increased. For the writer of this review, as one of those who can observe these recent advances only from a distance, it seems after glancing over the conference reports that the conceptions upon which the computations of strength of crystals rest are at the present time in a highly controversial and unsettled state.

The following papers were presented at the conference: "The Mosaic Texture of Rock Salt," by P. P. Ewald and M. Renninger; "Experimental Evidences of Group Phenomena in the Solid Metallic State," by A. Goetz; "On the Cause of the Low Value of Mechanical Strength," by A. Joffe; "On the Mechanism of Brittle Rupture," by A. Joffe; "The Rupture of Plastic Crystals," by E. Orowan; "The Structure-Sensitive Properties of Salt Crystals," by A. Smekal; "Shear Hardening and Recrystallization of Aluminum Single Crystals," by W. G. Burgers; "On Plasticity, Crystallographic and Non-crystallographic," by E. Schmid. The conference report is introduced by a short article by Sir W. H. Bragg in which he points out rightly, that this was by no means the first conference to discuss the problem of the solid state. One of the most striking facts revealed by the X-ray analysis is the prevalence of the regularity of arrangement of the elements in the solid state of bodies. On the other hand there are important phenomena which are not revealed in X-ray patterns or are not dependent on the few atoms of the unit cell in a crystal; strength, stresses at rupture and at plastic limit, and strain-hardening, are only a few of them. The papers are devoted to these important and unknown conditions that affect the properties of solids above the regular arrangement of the ideal lattices.

P. P. Ewald and M. Renninger (Stuttgart) report that when investigating rock-salt crystals they could not find traces of a mosaic structure (that is, of blocks at most 10^{-4} cm) in carefully grown artificial samples, while natural salt crystals, freshly cleaved or polished were not free of such structural disturbances of this magnitude. They conclude that in perfect artificial crystals no trace of the mosaic structure of the order of 10^{-4} cm can be detected by X-ray reflections contrary to the predictions by Darwin, Zwicky, and others, according to which a mosaic or block structure should exist in every real crystal. The experiments of A. Goetz (Pasadena), however, point in favor of the secondary structure and to the fact that the orientation of a crystal persists even beyond the process of fusion, so that on subsequent solidification the same structure reappears.

A. Joffe summarizes his well-known experiments with rock salt in the conclusion that the practical weakness (against rupture) consists principally of sharp discontinuities along *the surface of the body* and cannot be ascribed to small *internal* faults (Griffith), *Lockerstellen* (Smekal), mosaic structure, or the like. His experiments with Jurkov furnished them new evidence that the weakness of glass or quartz should be due to irregularities on the surface of filaments, while the same kind of small faults when distributed throughout the bulk would not act so. From his experiments with *mica* E. Orawan believes that trivial cracks in cut edges are the cause of the lowering of the strength of this material, while if precautions are taken to avoid cut surfaces so that no free edges are present in the region where stresses are high, the tensile strength is considerably raised. According to him the assumption of a secondary (mosaic) structure in crystals is also unnecessary and it leads to impossible conclusions.

A. Smekal (Halle) critically reviewed the following subjects: Stability of lattices, instability of the ideal crystal, laws of crystal growth, primary and secondary flaws, and experiments with rock salt. Space does not permit the abstracting of the various discussions which strengthen further the impression, already given, that agreement with regard to the existence or the absence of a mosaic, block, or secondary group structure within the lattice of a crystal could not be reached by the speakers of the conference. Two very instructive papers by W. G. Burgers (Eindhoven) and E. Schmid (Freiburg, Switzerland) on shear-hardening and recrystallization of aluminum single crystals and on crystal plasticity terminate the volume.

New Pathways in Science

New Pathways in Science. By Sir Arthur Eddington, M.A., D.Sc., LL.D., F.R.S. Plumian Professor of Astronomy and Experimental Philosophy in the University of Cambridge. Messenger Lectures, 1934. The Macmillan Company, New York, N. Y. University Press, Cambridge, 1935. Cloth, $5^3/_4 \times 8^1/_2$ in., 326 pp., and index, 4 plates, $3.

Reviewed by J. Ormondroyd[2]

THE Messenger lectures delivered in the spring of 1934 by Sir Arthur Eddington at Cornell University are collected and published in this book. The author considers this collection as a disjointed addendum to his previously published popular scientific treatises, "Stars and Atoms" (1927), "The Nature of the Physical World" (1928), and "Science and the Unseen World" (1929). Reference to, and comparisons with, previous statements made in these books are given frequently in this volume. Under these circumstances no attempt is made in "New Pathways in Science" to provide a systematic introduction to modern scientific ideas. Atomic physics provides the background almost exclusively and, except for inevitable allusions, the theory of relativity is not discussed. Enough on this subject is given to indicate to the reader that the two branches of modern physics, atomic theory and relativity, have developed along independent paths which are just beginning to converge to a unified road.

Chapter 1 gives the philosophical outlook of modern science, and attempts to relate the scientific picture of the world to the "familiar story" in our minds. Chapter 2 is a summary of the present outlook on atomic physics. Chapters 3 to 6 deal mainly

[2] Experimental Division, Westinghouse Electric and Manufacturing Company, South Philadelphia, Pa. Mem. A.S.M.E.

with laws of the statistical type, with a complete discussion of the position of determinacy and casual connections in the new physics. The last chapter in this group treats the subject of probability which is naturally the mathematical foundation of all statistical law making. Chapters 7 to 10 outline the latest knowledge in astro-physics. The discussion on the "Cosmical Constant" in Chapter 10 leads naturally to a consideration of the most fundamental conceptions of physics which are fully treated in Chapter 11 under the heading of "The Constants of Nature." Eddington himself feels that this chapter is a little too severe and difficult for the surroundings in which it finds itself. However, its inclusion was inevitable since this subject forms the core of Eddington's intellectual activity of the last five years. Chapter 12 introduces the ideas of the Theory of Groups, a subject which touches the very keynote of scientific philosophy.

An active thinker who happens to have a pungent tongue is certain to stir up discussion. Chapter 13, on "Criticisms and Controversies," gives Eddington's answers to some of the philosophical obstacles which have been put in the path of his reasoning in the last few years.

Chapter 14, the "Epilogue" which closes the spirited tale, is written in a religious and penitent mood. The ordinary man in Eddington concludes, with evident relief, that physical science has at last so definitely delimited itself that the esthetic and religious aspects of life may emerge from the threatening shadows and blossom in any direction which satisfies the human soul. The last words of the book constitute an "amend honorable" to Newton, who must have turned over in his grave under the scathing and heartless satire heaped upon his famous three axioms in "The Nature of the Physical World." After all, the present needed a past to provide its roots and Newton still stands, a Titanic figure, looming up in that misty darkness which is swiftly enveloping the older gods.

To sum up the book with perfect honesty the reviewer usually does not know what Eddington is talking about but he always likes the way in which it is said.

Engineers who read this book will enjoy it much in the same manner as they enjoy a performance by any clever prestidigitator. The logical sequence of events which bring about the effects remains hidden but the effects themselves are more than marvelous and Eddington provides that continuous stream of epigrammatic, brilliantly humorous patter so necessary to the business of public entertainment.

Many philosophical physicists, Planck, Bohr, Jeans, as well as Eddington, have attempted to stoop low enough to lift the layman up to a level where he can have a bowing acquaintance with modern physics. They succeed only in making a formal introduction followed by interpretative eulogies without ever producing the "thing itself." They cannot produce it for us because it consists only of "symbols connected by mathematical equations." It is the product of mathematicians for the consumption of mathematicians. As at the Academy in ancient Athens only those who know mathematics are admitted to the actual presence. Pictures are no longer possible and scientific model making has become worse than a crime—a meaningless blunder. But by the very nature of our profession we are hopelessly model-minded. Perhaps Lord Kelvin was the last great physicist whom we could expect to understand. Eddington, somewhere in his book, has called the classical physicists engineers, simply because he could imagine nothing worse to fling at them.

"Mass is equivalent to energy." "Mass (energy) is a curvature in space-time." "Force is the difference between an assumed geometry and the real geometry of a space." "Electrons are waves of probability." "The position and velocity of an electron cannot both be measured with the same high accuracy at the same instant, therefore, the principle of causality vanishes." These, and many other phrases, undoubtedly stick in the minds of readers of popular scientific treatises, mainly because they strike the sense of the bizarre. But, after all, they are meaningless phrases waiting to receive solid content.

Perhaps the reviewer paints the picture too darkly. Many of the ideas of modern physics find our minds prepared for acquiescence. That all we know physically reduces to "pointer readings" is a familiar fact of engineering. That only "intervals" can be measured seems natural enough, although our stubborn belief that there is something absolute about rotation indicates that we really miss the point here. That the process of measurement can profoundly influence the magnitude of the quantity measured is a commonplace in engineering experimentation. Under these circumstances functional relationships between the measured quantities cease to be useful. Indeterminacy and its philosophical consequences are almost within the grasp of our usual mental outlook.

The popular treatises do hint at the road to complete understanding. All that we require in order to turn modern physics from a series of empty phrases to something functionally real is a knowledge of partial-differential equations, transformation of coordinates, calculus of variations, probability, non-Euclidean geometry, matrix theory, tensor analysis, and the theory of groups. Here time alone stands in the way, not lack of intellectual ability. One wonders why mathematics has escaped attempts at popularization in these days when all the other sancta have been thrown open to the public.

From the philosophical standpoint we are somewhat handicapped in our consideration of this third revolution in physical outlook by having remained blissfully ignorant of the philosophies of the first two modern scientific upheavals. When Galileo, Newton, and their contemporaries were turning Greek mechanics from a mass of meaningless words into a body of effective results they used and expressed an underlying philosophy which would be understood by the modern engineer if he ever took the trouble to become aware of its existence. Similarly the "age of coordination" which produced the generalized principle of the conservation of energy and the theory of thermodynamics gave rise to philosophical interpretations which remain a closed book to most of us.

As long as engineering is defined as a technical trade, and not as an intellectual profession, those who practice it will be doomed to read such books as "New Pathways in Science" merely for mystified amusement.

Theory of Functions

THEORY OF FUNCTIONS AS APPLIED TO ENGINEERING PROBLEMS. By R. Rothe, F. Ollendorff and K. Pohlhausen. Technology Press, Cambridge, Mass. 1933. Cloth, 6 × 9½ in., 184 pp., 108 figs., $3.50.

REVIEWED BY J. C. HUNSAKER[3]

THIS little book of 184 pages is the authorized translation by Alfred Herzenberg of "Funktonien theorie und Ihre Anwendung inder Technik," published in Germany in 1931 by Julius Springer. The material was first presented by the Ausseninstitute of the Berlin Institute of Technology in 1929–1930, jointly with the Berlin Electrical Engineering Society, in an effort to present together the mathematical theory of functions and its applications. R. Rothe, in the first 83 pages, develops the general mathematical theory and the principal theorems and principles necessary for the practical use of function theory. This is followed by five sections on applications: (*a*) the con-

[3] Head of Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Mass. Mem. A.S.M.E.

struction of electric and magnetic fields by means of source-line potentials; (*b*) two-dimensional fields of flow; (*c*) field distribution in the neighborhood of edges; (*d*) complex treatment of electric and thermal transient phenomena; (*e*) spreading of electric waves along the earth.

The material on applications is naturally very largely in the field of electrical engineering, with the exception of Pohlhausen's chapter on fluid mechanics. However, the great value of the book lies in its compact and straightforward development of the mathematical tools obtained from function theory with their use illustrated by examples. The mechanical engineer might prefer to see the applications made to problems in elasticity, vibration, acoustics, and heat flow. However, the applications that are given cover a wide range of problems from the electric, magnetic, thermal, hydrodynamic and aerodynamic fields.

The exposition, in the opinion of a mathematical colleague, is "simple, sufficiently thorough, and should be followed without undue difficulty by any one familiar with calculus." An engineering colleague, on the other hand, finds the treatment highly compressed and demanding a comprehensive familiarity, if not facility, with advanced calculus. The fundamental conceptions of line and hook integrals, Heaviside operational calculus, conformal mapping of Riemann surfaces, etc., are developed in a few paragraphs each, and in W. Schottky's chapter a vectorial notation is employed in discussing the properties of potential fields.

The book may be considered both as an introduction to function theory and as a reference text for engineers concerned with the theoretical analysis of fluid flow, wave propagation, and the configuration of fields of force. As such, it should prove stimulating and useful to mechanical engineers interested in learning the use of some of the tools and methods very generally employed in physics.

Hydro- and Aeromechanics

FUNDAMENTALS OF HYDRO- AND AEROMECHANICS, VOL. 1 AND APPLIED HYDRO- AND AEROMECHANICS, VOL. 2. Based on lectures by L. Prandtl of Göttingen. By O. G. Tietjens with English translation of vol. 1 by L. Rosenhead and vol. 2 by J. P. Den Hartog. Engineering Monograph Series. McGraw-Hill, New York, 1934. Cloth, $5^3/_4 \times 9$ in., vol. 1, 270 pp., 186 figs., $4; vol. 2, 275 pp., 311 figs. including 226 figs. in text and 68 on supp. plates, $4.

REVIEWED BY F. WATTENDORF[4]

THIS book, one of the Engineering Societies Monograph Series, is an English translation of the book "Hydro- und Aeromechanik," based on lectures by Prof. L. Prandtl of Göttingen, by Dr. O. G. Tietjens, one of his former assistants.

The book appears in two volumes. Volume 1, translated from the German by Dr. L. Rosenhead, is entitled "Fundamentals of Hydro- and Aeromechanics," and presents the basic theories of fluid statics, as well as perfect and viscous fluid motion. Volume 2, translated by Dr. J. P. Den Hartog, is entitled "Applied Hydro- and Aeromechanics," and deals with the mechanics of real fluids with technical applications. The material is presented in such a way that each volume can be used independently of the other.

In keeping with the spirit of Professor Prandtl's lectures, the book gives the reader a clear physical picture of the fundamental principles underlying the various theories, unobscured by masses of detail. In most cases one or two practical examples are given for the purpose of illustrating each principle, information of a statistical nature being avoided as much as possible.

[4] Research Fellow in Aeronautics, California Institute of Technology, Pasadena, Calif.

The first volume is divided into three parts. Part 1, "The Statics of Liquids and Gases," presents classical hydrostatic theory, with application to the equilibrium and stability of the atmosphere, and to the static equilibrium and stability of balloons. A short section on surface tension is also included in Part 1. Part 2, "Kinematics of Liquids and Gases," deals largely with the Eulerian and Lagrangian methods of describing perfect fluid flow and includes a section on vectorial representation of fields of flow. Part 3, "The Dynamics of Non-Viscous Fluids, gives the fundamental concepts and theorems of potential flow, including conformal transformation and vortex motion. One short section is devoted to the influence of compressibility on potential flow and another to energy and momentum theorems, with a discussion of the impulse propeller. The final chapter of the volume treats the derivation of the Navier-Stokes equation for viscous flow. In this one case the American edition differs from the German in that this chapter was a part of Volume 2 in the German edition.

Volume 2 deals with the application of hydrodynamic theory to the flow of real fluids. It begins with a physical interpretation of viscosity, and the relationship between viscous and inertia forces, on which the law of similarity is based. After this introduction there follows a section on flow in pipes and channels. This is a well-organized treatment of the subject, beginning with the early experiment of Hagen and Poiseuille, the classical work of Osborne Reynolds on the transition between laminar and turbulent flow, and extending through the work of Nikuradse and Dönch on convergent and divergent channels.

There follows a section on boundary layers, which is in close accordance with Prandtl's well-known lectures on the subject.

The next topic considered is the resistance of bodies moving through fluids. A clear picture is given of the various physical components of drag, and their relative importance for various bodies and flows.

This is followed by a well-presented treatment of airfoil theory, including both two-dimensional and three-dimensional theory, with application to multiplanes, and a short discussion of wind-tunnel interference.

The concluding chapter, a well-written summary of experimental methods and apparatus as used in modern aerodynamic laboratories, is not based on Prandtl's lectures, but has been added by Dr. Tietjens. The book closes in a fitting manner with a series of interesting flow photographs.

The translations into English have been made in an excellent manner by Dr. Rosenhead and Dr. Den Hartog. Much credit is due Dr. Den Hartog for his choice of suitable words for difficult and hitherto untranslated technical expressions of recent origin.

Photoelasticity

FESTIGKEITSLEHRE MITTELS SPANNUNGSOPTIK. By Ludwig Föppl and Heinz Neuber. R. Oldenbourg, Munich and Berlin, 1935. Board, $5^1/_2 \times 8^1/_2$ in., 115 pp., 80 figs., 6.60 rm.

REVIEWED BY E. E. WEIBEL[5]

THE possibilities of the photoelastic method are being increasingly realized both as an aid to the practical designer and for the more detailed study of stress distribution in problems for which mathematical methods are insufficient. Until now the "Treatise on Photo-Elasticity" by E. G. Coker and L. N. G. Filon, published by the Cambridge University Press, 1931, has been the only textbook for reference on the subject. Although not to be compared in size with the English work, the present volume contains the essentials of the photoelastic theory as well

[5] Engineering Mechanics, University of Michigan, Ann Arbor, Mich.

as a few sections of heretofore unpublished material. The authors who are capable exponents of the theory of elasticity have drawn upon the results of their photoelastic experiments extending over a period of six years in the Mechanical-Technical Laboratory at Munich.

The book is divided into four chapters, the first of which covers fundamentals of the photoelastic method. The use of glass models and of compensation methods of measuring maximum shear stress at many separate points are current practice in Germany and are described. Some reference is also made to the use of more active optical materials such as bakelite and phenolite as used in this country.

The second chapter, on the complete determination of stresses, describes the lateral-extensometer method and Filon's graphical-integration method of determining principal stress values, and then presents the theory underlying Neuber's new graphical method which was discussed in his recent paper. (See Trans. A.S.M.E., 1934, paper APM-56-17, p. 733.) The membrane analogy also is presented as a supplement to the photoelastic method for the complete determination of stresses.

In the third chapter three special problems in photoelasticity are given mathematical treatment. The course of principal stress trajectories is derived for the region around a singular point or points at which the principal stresses are equal. The second problem is that of the effect of Poisson's ratio in the interpretation of photoelastic results. It is known that for most cases the stresses are independent of the elastic constants, but that for certain types of loading of multiply connected bodies a correction is necessary. The authors show that in problems which are important enough to warrant the extra work the correction stresses can be found by making supplementary photoelastic experiments on models which have been slit from outer to inner boundary and which have had known displacements applied at the slit. The third study considers those stress cases for which the stress trajectories satisfy the equations for stream lines in fluid motion. A limited number of simple problems would appear to meet these conditions.

In the fourth and last chapter a number of applications of the photoelastic method are discussed and illustrated. The authors include a few fringe photographs, the models for which were made of trolon, a synthetic resin available in Germany, with satisfactory optical properties but mechanically inferior to bakelite and phenolite.

Conjugate Functions for Engineers

CONJUGATE FUNCTIONS FOR ENGINEERS. By Miles Walker, M.A. (Cantab.), D.Sc. Eng. (London), F.R.S. Sometime Professor of Electrical Engineering in the Faculty of Technology, University of Manchester. Oxford University Press, London, 1933. Cloth, 116 pp., 92 figs., $4.75.

REVIEWED BY J. C. HUNSAKER[5]

DR. WALKER is an electrical engineer who has undertaken to develop in this little book the details of conformal transformation, and to give what is essentially a mathematical manipulation an appearance of physical reality. In this, the author has shown great ingenuity and patience in following through a series of simple steps to establish a procedure which is then applied to the solution of a series of problems.

The first 31 pages consist of a consideration of a two-dimensional field of force (magnetic, electric, pressure, thermal) simplified to a pattern of lines of force and of flux which are continuous and without vortices. Consequently, only a steady-state potential field is involved. The fundamental conceptions of potential are developed by use of the line integral, and it is shown that the equipotential lines are at right angles to the stream lines and that the force at any point is the space gradient of the potential.

This orthogonal system of lines is then shown to be identical in pattern with the system of lines that results from plotting certain functions of a complex variable known as conjugate functions. This analogy is very properly taken as merely a fortunate property of the mathematical tool available. A brief résumé is then given of complex algebra and the plane of numbers in which the imaginary square root of minus one, or j, is treated, by definition, as an operator, which rotates a vector 90 deg. De Moivre's theorem is quoted in order to permit the use of complex exponents. The conditions that a complex function may be "analytic" and its real and imaginary parts "conjugate," are deduced mathematically and illustrated graphically. The point is made that where $w = f(z) = \phi + j\psi$, the transformation of a pattern on a z-plane (coordinates x and $j\,y$) to a truly corresponding pattern in the w-plane (coordinates ϕ and $j\,\psi$) requires that $\frac{dw}{dz}$ be independent of the slope of dz or of $\frac{dy}{dx}$. This is precisely the requirement that ϕ and ψ must satisfy to be classed as "conjugate functions." Consequently a plot of conjugate functions is shown to represent on the w-plane the pattern of potential and flux on the z-plane.

Up to this point, the reader has followed a clear path of reasoning but now he must make a leap in the dark and accept as an historical event (Schwarz in 1869 and Christoffel in 1867) a differential equation stating the nature of the change in a function of z, bounded by any straight-sided figure, in order that this boundary may be transformed into one straight line in the w-plane. It is possible that this acceptance of the Schwarz-Christoffel theorem saves the engineering reader time and difficulty if his only object is to learn a practical procedure for working out flow patterns, but he may resent the publishers statement: "This book explains the method in such simple language that even the author can understand it." However, the "method" to be used is very clearly illustrated in a series of thirteen problems whose detailed solutions make up the balance of the book.

These problems are all in the field of electrical engineering, such as: Current fed into one point of a thin conducting sheet; current between cylinders standing in a solution; current flow around corners; magnetic flux across an air gap; dynamo slots, etc. Similar solutions can be worked out for corresponding ideal two-dimensional problems in elasticity, hydromechanics and heat flow, but the mechanical engineer rarely has reason to attack such idealized problems. Had the worked examples been chosen more liberally and included the classical fields of force and flow in applied mechanics, interest in a very skillfully contrived exposition would be more general.

Practical Solution of Torsional Vibration Problems

PRACTICAL SOLUTION OF TORSIONAL VIBRATION PROBLEMS. By W. Ker Wilson, M.Sc. John Wiley & Sons, Inc. New York, 1935. Cloth, 5 1/2 × 8 1/2 in., 438 pp., 106 figs., $7.

REVIEWED BY R. EKSERGIAN[6]

THE increasing applications of internal-combustion engines and their peculiar susceptibility to critical torsional vibrations has brought forward the analysis of torsional vibrations as a major problem in design. The theory of torsional vibrations for engine installations is by no means a simple problem, and for

[6] Edward G. Budd Manufacturing Co., Philadelphia, Pa. Mem. A.S.M.E.

this reason approximations and simple computation methods assume importance in practical design.

Mr. Wilson's book is particularly commendable from this latter point of view. Chapters 1 and 2 are devoted to natural-frequency calculations of typical engine installations as well as their approximations to two- and three-mass systems. In the tabulation method for multi-mass systems for one- and two-mode vibrations, the author introduces a column for stresses per degree of deflection at the end mass. These data are later used in the determination of forced oscillation stresses.

In Chapter 4, Mr. Wilson gives a method for determining stresses at non-resonance conditions on the basis of "equilibrium amplitudes" and amplified by a "dynamic-magnifier factor." While it is difficult to accept his proof for a multi-mass system by the simple system he uses, the subsequent formula and applications, using the equilibrium factor and dynamic magnifier, really suggest the theory of normal coordinates to practical applications in the calculation of non-resonance stresses in torsional-vibration problems.

In estimating the effect of the exciting forces, the author apparently deals singly with individual modes; whereas, actually in estimating the resultant amplitudes and total stresses it is necessary to consider the relative excitation of the several modes of oscillation of the system and their phase relations. Due to the proximity of the forced frequency with the primary natural frequency for a system with heavy fly-wheel and distributed crank masses, Mr. Wilson's numerical calculation shows good agreement with the tabulated method for forced oscillations.

Frequently in multi-mass systems for good approximations it is only necessary to consider the first and second modes due to the rapid convergence of the higher modes, and sometimes only the first mode alone. This is true because of the relative importance of this mode, particularly when the excitation is powerful with respect to it and the higher modes are far removed from it.

In Chapter 5, resonance stresses are obtained by the usual method of equating the work of the exciting forces to those of the damping forces. Where these stresses are at resonance with a given mode, simplification is effected due to the quadrant phase relation between the excitation forces and displacement amplitudes. This chapter offers much interesting detail in various damping components.

The remaining chapters are devoted to the measurement of torsional-vibration amplitudes and stresses with various types of torsiographs, and a discussion of torsional-vibration damping devices. A welcome feature is the interpretation and investigation of actual torsiograph records and some detail discussion on flexible couplings.

In the final chapter which is of an elementary nature a brief discussion is given on electrical generating sets direct coupled to internal-combustion engines.

On the whole, the work is a valuable contribution to the literature. Not only are clear-cut and well-balanced discussions given to the various factors on torsional-vibration analysis with illuminating examples and worked-out data, but the author introduces an ingenious method of analysis as well.

The Story of Energy

THE STORY OF ENERGY. By Morton Mott-Smith, Ph.D. Appleton New World of Science Series. D. Appleton-Century Company, Inc., New York, 1934. Cloth, 5 × 7½ in., 290 pp., 33 figs., $2.

REVIEWED BY J. ORMONDROYD[2]

THIS little book should hold great interest for engineers since it tells a half-familiar tale. It outlines the history of prime-mover development including the practical, theoretical, and philosophical aspects of the subject. The subject matter divides itself into three sections.

Chapters 1 to 6 consider the development of steam engines from Hero to the work of James Watt and includes the advances made by some of the lesser contemporaneous successors of that great inventor. This section ends with a detailed account of the analysis of the motive power of heat which Sadi Carnot published in 1824. Carnot saw the problem so clearly that he prophesied correctly the future steps needed to improve the performance of heat engines. But he was limited in his achievements by the caloric theory of heat and by early death. The complete theoretical outlook used today was fashioned by other and later hands as is outlined in the next section.

Chapters 7 to 17 trace the rise of the generalized doctrine of the conservation of energy and consequent formation of the theory of thermodynamics. These chapters give the tragic story of Mayer's labors in this field and outline the happier parts which Joule and Helmholtz played in the same drama. Chapter 15 shows the idea of energy conservation growing inevitably from human experience; slowly gathered first in the guise of animism, then in religious form and finally through magic to the modern scientific outlook. Chapter 16 describes the reconciliation of the apparently contradictory principles of Carnot and Joule by Clausius, and the creation of modern thermodynamics from this by Clausius and Thompson. The last chapter of this section is dedicated to that mysterious and exciting "arrow of time," entropy.

Chapters 18 to 20 describe various cycles and engines which have actually been developed to transform heat into mechanical work in the last seventy years. Air engines, steam turbines, and internal-combustion engines are reviewed historically. The book ends with a description of mechanical refrigeration.

In carrying out the program outlined in the title, the author gives an understandable statement of the philosophy of classical physics interwoven with the evolution of thermodynamic theory and practice. The historical parts are unusually complete. Important passages from the papers of Carnot, Mayer, and others are quoted in extenso. A rather complete bibliography of the original publications in the field treated is given in the footnotes and at the end of the book.

A few factual errors must be noted. Heat engineers will be surprised to find the critical temperature and pressure of water noted respectively as 689 F and 2947 lb per sq in. on page 40 and in Fig. 8. This surprise may turn to amazement as they read that impulse and Rateau turbines are now practically obsolete having been completely displaced by Parson's reaction turbine (page 256) and that the maximum inlet pressure for reaction turbines is 250 lb per sq in. (page 257). Isolated facts, however, are only incidental to the purposes of the book, which does not pretend to be a technical text, and these slips would seem to arise from the use of somewhat obsolete reference material on the part of the author.

Historians of science certainly would not connect Descartes' theory that the quantity of motion in the universal remains constant with the impact experiments of Wallis and Huygens (page 81) who published their findings on this subject some nineteen years after the great philosopher's death. Descartes, according to his own lights, found a more satisfactory basis for this theory in the infinite wisdom of God rather than in mere experimental results.

In a popular work these defects have minor importance. Engineers who read this book will agree with the reviewer that it is entertaining and highly instructive.

Journal Bearing Performance

By R. BAUDRY[1] and L. M. TICHVINSKY,[2] EAST PITTSBURGH, PA.

This paper contains an application of the hydrodynamical theory of lubrication to the practical design of journal bearings. In a simplified method satisfactory for most engineering applications the authors consider the journal bearing as a plane bearing. Then correction factors make allowance for (1) the type of the journal bearing, (2) the shape of the oil film and width-length ratio of the bearing, and (3) the losses in the nonactive parts of the bearing.

In a more accurate method, the same correction factors are applied to the rather complete data published on journal bearings of infinite width. It is also shown that the clearance of the bearing can vary between rather large values and still maintain closely optimum conditions of performance of the bearing. Results of tests are shown to be in close agreement with these methods of calculation.

Introduction

ALTHOUGH the hydrodynamical theory of lubrication was developed a long time ago, the design of modern bearings is still based to a great extent upon empirical data. Theoretical analysis considers only an ideal bearing which is never realized in practice. Even for this ideal bearing the analysis is very complicated, particularly for the case of journal bearings.

Furthermore, deformation of the bearing produced by load and nonuniform temperature distribution, accuracy of machining, and degree of finish are important factors which cannot be well introduced in any theoretical analysis.

Although many laboratory tests of bearings verify satisfactorily the hydrodynamical theory, these tests are only of small help in the design of large bearings. Improvements in the design of bearings can only be made by means of tests duplicating as much as possible the normal conditions of operation and manufacturing. Much useful information may also be gathered from tests on bearings of machines in normal operation in order to verify the losses and temperature distribution.

Bearing Operation

The operation of a journal bearing is better understood by considering first the operation of the plane bearing such as shown in Fig. 3 (1).[3] The simplest theory usually assumes that (*a*) the bearing is of infinite width, (*b*) the lubricant is of uniform viscosity throughout the oil film, and (*c*) the inlet and outlet pressures are both equal to atmospheric pressure. In Fig. 4 are given the coefficient of friction, oil-film thickness, oil flow and temperature rise of the oil going through the oil film, for various ratios of h_i/h_o. In this ideal case, the line of action of the load can be located at a certain distance back of the center of the bearing which will give either the maximum oil-film thickness or the minimum coefficient of friction.

The assumption of infinite width is obviously never met in practice. Michell (2) has given a theoretical solution of the rectangular-plane bearing for uniform viscosity through the oil film and uniform pressure at the edges. In this case the flow of oil is two-dimensional; the effect of the side leakage increases the coefficient of friction and decreases the oil-film thickness as shown in Fig. 5. The increase in temperature rise of the oil and the change in flow of oil at the inlet and outlet are given in Fig. 6.

The viscosity of the oil decreases with the increase in temperature as shown in Fig. 7. R. O. Boswall (1) has shown by assuming a simple law of viscosity variation with temperature that it was permissible to consider only the average temperature of the oil through the film.

Bearings are made also with a rounded edge or sometimes with a small chamfer at the inlet so that due to the momentum (4) of the oil, the pressure at the beginning of the film is not equal to the pressure at the outlet as assumed. This, together with the variation of viscosity, produces a displacement of the line of action of the load toward the center as shown by tests (3, 5). Experience also shows that a centrally loaded plane bearing operates satisfactorily. This simplifies manufacturing and permits operation of a machine in any direction of rotation.

A. Kingsbury (6), also assuming a journal bearing of infinite width, uniform viscosity and boundary pressure, has given a complete analysis of the optimum conditions of operation of journal bearings. He shows how the different elements of a bearing can be determined so as to have either a minimum coefficient of friction or a maximum load which can be carried on the basis of a given minimum oil-film thickness. The curves shown in Fig. 8 give the minimum coefficient of friction and corresponding oil-film thickness which can be obtained from a journal bearing of correct proportions as compared with a plane bearing operating under the same conditions.

S. J. Needs (7), by the use of an electrical analogy, has made a theoretical analysis of the 120-deg central partial bearing of finite width. In a discussion of his paper (8) it was shown that the values of leakage factors so obtained were in close agreement with the assumptions previously made, thus showing that the leakage factors calculated for plane bearings can be applied with sufficient accuracy to journal bearings. Many authors are applying to the journal bearing the leakage factors calculated by Michell, Boswall, and others for the plane bearing. In this case it is assumed, as is usually done for the plane bearing, that the inlet-outlet ratio of the oil film is constant and equal to 2.5, and the length of the oil film is equal to the developed length of the bearing arc.

In Fig. 8 it is seen that particularly for small angles the operation of a journal and of a plane bearing are nearly the same. Boswall (3) has also made tests showing that journal bearings behave in the same way as plane bearings. For example, a fitted bearing (smaller than 90 deg and with round, beveled, inlet edge) can be operated satisfactorily with a central load contrary to the simplified theory. No complete theoretical analysis of the side leakage for the journal bearings has yet been made on account of its complexity as compared with a plane bearing. Actually, the shape of the oil film, i.e., the inlet-outlet ratio and the active

Contributed by the Applied Mechanics Division and presented at the Annual Meeting, New York, N. Y., December 3 to 7, 1934, of The American Society of Mechanical Engineers.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until February 10, 1936, for publication at a later date.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

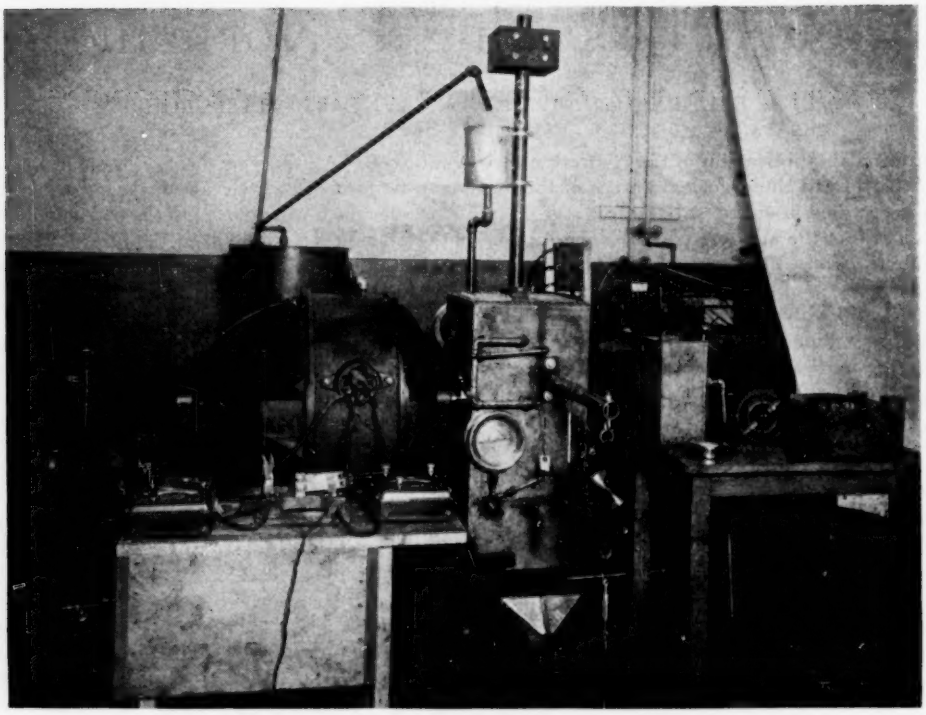

FIG. 1 THE TEST SET-UP OF THE 6-IN. × 12-IN. JOURNAL BEARING

(Left to right are the high-pressure pump for loading the bearing, the driving motor, oil water cooler, and electrical meters. The bearing shell and housing are overhung on the journal. The lever arm and scale for torque measurement, thermocouple distributor, and potentiometer are seen on the right.)

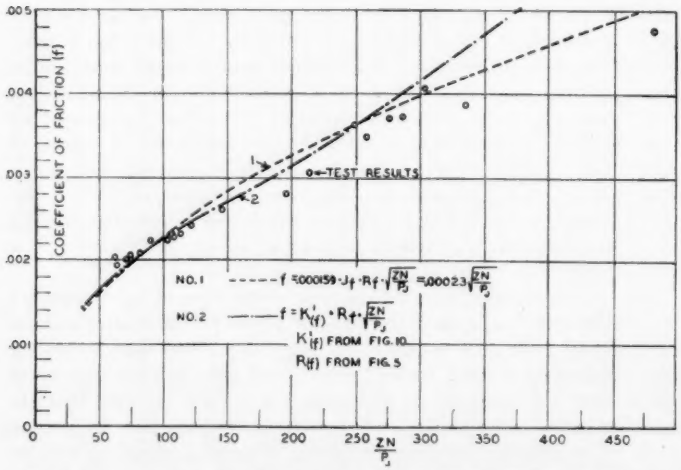

FIG. 2 COEFFICIENT OF FRICTION OF 6 IN. × 12 IN. 90-DEG CENTRAL PARTIAL JOURNAL BEARING, $\eta/r = 0.0015$

(For curve No. 1 it is assumed that the journal bearing operates similarly to a plane bearing. Allowance is made for the J_f type of journal bearing, curves for which are shown in Fig. 8. The constant leakage factor is the same as for a plane bearing having a length equal to the developed bearing arc and a ratio $h_i/h_o = 2.5$. The coefficient of friction is proportional to $\sqrt{(ZN/P_j)}$. Curve No. 2 is obtained from theoretical analysis for a journal bearing of infinite width given in Fig. 10. The active length of the oil film, the shape of the oil film h_i/h_o, and the corresponding value of leakage factor R_f change with load, speed, and viscosity ZN/P_j.)

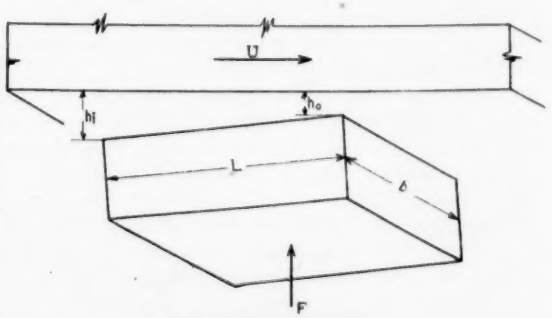

FIG. 3 PLANE BEARING

length, change with the speed, load, and viscosity (ZN/P_j). The position of the journal relative to the bearing is determined by the eccentricity and the angle between the line of centers and the direction of the load as shown in Fig. 9.

Rather complete data are available (6, 9, 10) for different kinds of journal bearings of infinite width.

In Figs. 10, 11 and 12 are given characteristics of central clearance partial bearings 90-deg, 120-deg, and 180-deg angle. In these figures the coefficient $K'(\eta/r) = (\eta/r)/\sqrt{(ZN/P_j)}$ determines the eccentricity of a bearing having a clearance ratio η/r and a characteristic number ZN/P_j. From this value of the eccentricity can be found:

1 The coefficient of friction $f = K'_f \sqrt{ZN/P_j}$
2 The minimum oil-film thickness $h_o = K'_{h_o} \sqrt{ZN/P_j}$
3 The position of the center of the journal α
4 The ratio h_i/h_o

With this knowledge of the shape of the oil film (α and h_i/h_o), it is possible to determine more accurately the leakage factor for friction and oil-film thickness.

The length of the bearing should be taken equal to the zone of positive pressure of the oil film. In partial bearings of a small angle, this zone extends from the beginning of the bearing arc in the direction of rotation to a point approximately half way between the point of nearest approach and the end of the bearing arc.

The curves in Figs. 10, 11, and 12 show very clearly the optimum condition for operation of a bearing. They show also

that the coefficient of friction and the minimum oil-film thickness do not change appreciably with a rather large variation of the clearance ratio, showing that a bearing with a given clearance ratio will operate near the optimum condition over a wide range of loads and speeds. For example, for a range of ZN/P_j be-

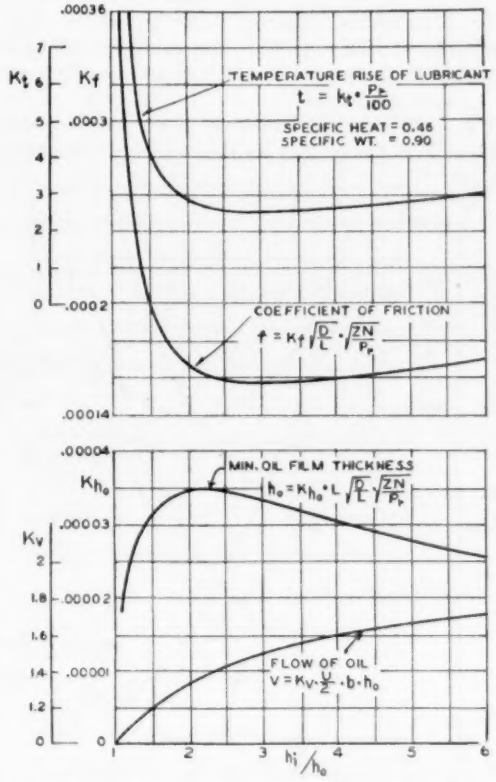

FIG. 4 CHARACTERISTICS OF A PLANE BEARING OF INFINITE WIDTH

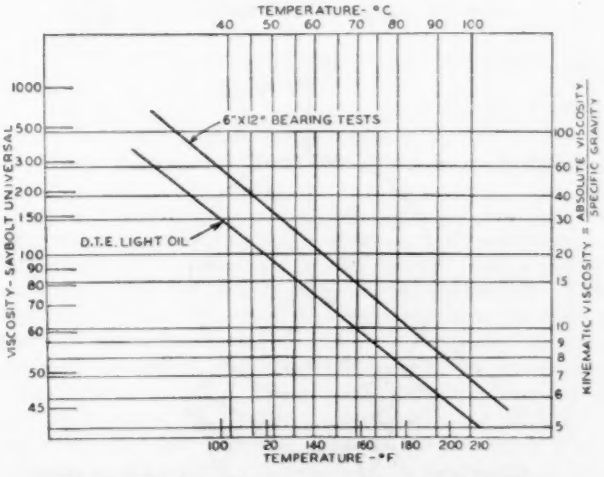

FIG. 7 VISCOSITY-TEMPERATURE CHART OF OILS USED DURING TESTS

tween 80 and 300, the coefficient of friction of a 90-deg bearing will not vary more than 2 per cent and the oil-film thickness more than 1 per cent from the possible theoretical minimum. This small variation of the coefficient of friction and minimum oil-film thickness with a rather large change of the clearance ratio has a very practical aspect from the manufacturing and operation standpoint. It makes possible the use of a constant clearance ratio over a large range of operation while still remaining near the optimum condition of friction and oil-film thickness. In Fig. 13 are shown the optimum clearance ratios for 90-deg, 120-deg and 180-deg central partial clearance bearings. They agree very well with existing practice for electrical machines ($ZN/P_j <$ 100) and for high-speed steam turbines ($ZN/P_j >$ 100) where

clearance ratios of 0.001 in. per in. and 0.002 in. per in., respectively, have been used for many years.

A sufficiently accurate value of the losses in the nonactive parts of the bearings (upper half, oil throwers, etc.) can be obtained by assuming that the clearance of these points is uniform and filled with oil. The losses can then be calculated by considering a uniform shear as shown in Table 1. It was shown by the authors when this paper was presented in more complete form at the Annual Meeting, 1934, of The American Society of Mechanical Engineers, that in a 30-in. × 60-in. journal bearing, the losses in the nonactive parts amounted to approximately 10 per cent of the total bearing losses.

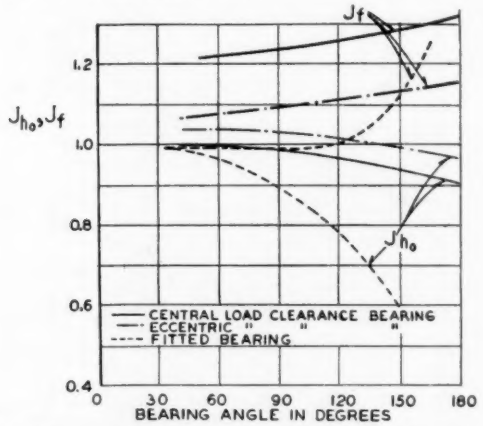

FIG. 8 MINIMUM COEFFICIENT OF FRICTION AND CORRESPONDING OIL-FILM THICKNESS IN BEARINGS OF INFINITE WIDTH (6)

(1) Plane bearing

$$f = 0.000159\sqrt{\frac{D}{L}}\sqrt{\frac{ZN}{P_r}};\quad h_0 = 0.0000345\,L\sqrt{\frac{D}{L}}\sqrt{\frac{ZN}{P_r}}$$

(2) Journal bearing

$$f = 0.000159\,J_f\sqrt{\frac{d}{l}}\sqrt{\frac{ZN}{P_r}};\quad h_0 = 0.0000345\,J_h l\sqrt{\frac{d}{l}}\sqrt{\frac{ZN}{P_r}}$$

where P_r is the unit pressure on the developed bearing surface. Usually for journal bearings the unit pressure is referred to the projected area on the diameter, in that case the following formulas should be used:

$$f = 0.000159\,J_f\sqrt{\frac{ZN}{P_j}};\quad h_0 = 0.0000345\,J_h\,\frac{\pi r}{180}\,\theta\sqrt{\frac{ZN}{P_j}}$$

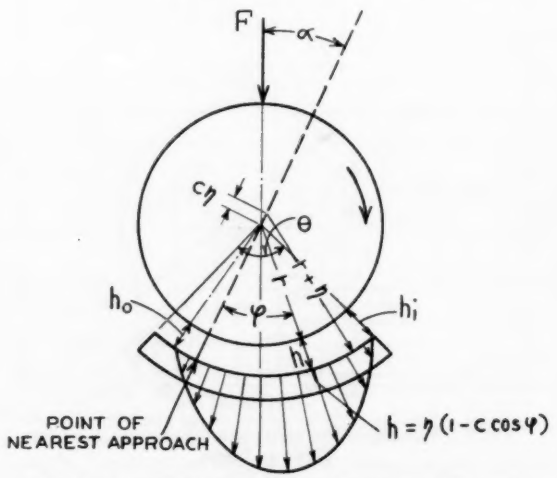

FIG. 9 CENTRAL LOAD PARTIAL CLEARANCE BEARING

TEMPERATURE CONDITIONS

The satisfactory operation of a bearing is usually determined by its maximum temperature. In connection with electrical apparatus it is limited to 80 C in the oil well or a 40-deg rise above 40 C ambient.

Due to friction, the temperature of the oil film increases between the inlet and outlet. Boswall (1) has shown that in the calculation of the bearing performance the average temperature of the oil film can be used with a fair degree of accuracy.

In Fig. 4, t gives the temperature rise through the oil film for a plane bearing of infinite width. This curve has been calculated for an oil having a specific heat of 0.46 and specific weight γ of 0.9.

In Fig. 6, R_t gives the correction factor for the temperature rise of the oil in the oil film for the case of a rectangular plane

(Solid line for 90-deg bearings. Dash line for 120-deg and 180-deg bearings.)

bearing. For journal bearings calculated as plane bearings, allowance must also be made for the higher coefficient of friction and the smaller oil-film thickness as compared with plane bearings. In this case, with additional correction factors used (see Figs. 4 and 10) the temperature rise through the oil film of a journal bearing is

$$t_1 = 0.00658\,\frac{K'_f}{K'_{h_o}}\,\frac{R_f}{R_{h_o}}\,\frac{P_j}{K_v\gamma\rho}$$

The average temperature of the oil film is equal to the temperature of the inlet oil plus $t/2$. It is to be noted that the temperature of the inlet oil film is not equal to the temperature of the oil supplied to the bearing. There is a film of hot oil which adheres to the shaft and is continuously recirculated. This film is cooled outside the active oil film, the make-up for the oil leakage being added at the inlet.

It should be noted that for a given bearing the temperature rise of the oil is a function only of the unit pressure and independent of speed and of viscosity of the oil.

The average temperature of the oil film in bearings cooled by means of circulating oil is usually only slightly higher than the temperature of the bearing shell. It can be easily seen that the heat-transfer rate between the oil film and the bearing shell is much higher than between the latter and the ambient air. This is particularly true when the area of contact between the bearing shell and bearing housing is very small. A. Kingsbury has given an exact method of calculating the temperature distribution through the oil film (11). A simpler approximate method can be used to determine the average temperature of the oil film by considering the flow of heat through the oil film which is assumed to be of a uniform thickness equal to the average as in a guide bearing. In a guide bearing where there is a uniform clearance, the shear of the oil is uniform throughout (assuming uniform viscosity which is approximately true for small temperature variation). The same quantity of heat Q flows from the oil film to the bearing shell and from the latter to the ambient air by convection or radiation. Knowing the temperatures of the shell and ambient air, the quantity of heat Q flowing from the shell can be calculated with the use of known heat-transfer data (12, 13). In most bearings the flow of heat through the shaft is negligible (12) and the latter's temperature usually can be taken equal to that of the oil film. For such cases, the temperature distribution through the oil-film thickness can be calculated from the known equation of the steady flow of heat through a body such as the oil film where heat is being uniformly generated. This temperature distribution is parabolic and the

average value of the temperature rise of the oil film above the bearing shell is

$$t_f = Qh/3K = 80\,Qh$$

for ordinary lubricating oils.[4]

This method of calculation will still hold when heat is carried away by means of circulating oil since t_f applies only to the flow of heat through the bearing shell which is a function only of its temperature rise above ambient air.

This method has been applied to determine the average temperature rise of the oil film above the measured temperature of the bearing shell in the described test of 6-in. × 12-in. bearing.

Oil Flow

The supply of oil in any bearing must always be sufficient to maintain a perfect oil film, otherwise, a much higher temperature of operation is to be expected. In some properly designed bearings it is sufficient to supply an amount of oil equal to the side leakage, but it is usually much safer to have a supply equal to the flow of oil at the inlet.

The flow of oil in a plane bearing of infinite width is

$$V = K_v h_o b(U/2)$$

where K_v is as given in Fig. 4.

For a plane rectangular bearing, due to side leakage, the flow of oil is increased at the inlet and decreased at the outlet, as shown in Fig. 6.

The flow of oil at the inlet is

$$V_i = R_{vi} K_v h_o b(U/2)$$

The flow of oil at the outlet is

$$V_o = R_{vo} K_v h_o b(U/2)$$

The side leakage is

$$V_L = V_i - V_o = (R_{vi} - R_{vo}) K_v h_o b(U/2)$$

The flow of oil in a journal bearing of finite width is nearly the same as for a plane rectangular bearing. This method gives results very close to the ones obtained by S. J. Needs (7) by means of an electrical analogy, and also with tests made at the Research Laboratories of the Westinghouse Electric and Manufacturing Company (14).

Application of Data

The application of curves given in this paper is illustrated by an example. The bearing, 6 in. in diameter and 12 in. long, tested in the laboratories (Figs. 1 and 2) was taken for this purpose. The active length of the bearing = 9¾ in., the radial clearance = 0.0045 in., the clearance ratio = 0.0015 in. per in., the load = 10,000 lb, the speed = 1600 rpm, the oil-film temperature = 70 C, and the peripheral velocity = 500 in. per sec. The unit pressure on the projected area P_j = 171 lb per sq in., and the characteristic number of the bearing ZN/P_j = 10.67.

Referring to Fig. 10, the characteristics of the bearing are: $K'(\eta/r)$ = 0.00014, K'_f = 0.000195, K'_{h_o} = 0.000052, α = 27 deg, and h_i/h_o = 2.15. The active length l of the 81-deg oil film = 4.25 in., and the length-width ratio l/b = 0.435.

Leakage factors for the coefficient of friction, oil-film thickness, oil flow, and temperature rise from Figs. 4, 5, and 6 are: R_f = 1.12, R_{h_o} = 0.86, R_{vi} = 1.13, R_{vo} = 0.95, K_v = 1.36, R_i = 1.25, and K_i = 2.7.

[4] Taking K = 0.0042 watt per sq in. per deg C per in. from W. J. King (13).

Coefficient of friction

$$f = R_f K'_f \sqrt{(ZN/P_j)} = 1.12 \times 0.00195 \times 10.67 = 0.00234$$

Minimum oil-film thickness

$$h_o = R_{h_o} K'_{h_o} r \sqrt{(ZN/P_j)} = 0.86 \times 0.000052 \times 3 \times 10.67 = 0.00143 \text{ in.}$$

Inlet oil flow

$$V_i = R_{vi} K_v h_o b(U/2) = 1.13 \times 1.36 \times 0.00143 \times 9.75 \times 250 = 5.36 \text{ cu in. per sec}$$

Outlet oil flow

$$V_o = R_{vo} K_v h_o b(U/2) = 0.95 \times 1.36 \times 0.00143 \times 9.75 \times 250 = 4.5 \text{ cu in. per sec}$$

Oil leakage

$$V_L = V_i - V_o = 0.86 \text{ cu in. per sec}$$

Temperature rise through the oil film

$$t_1 = 0.00658 \frac{K'_f R_f}{K'_{h_o} R_{h_o}} \frac{P_j}{K_v \gamma \rho} = 9.75 \text{ C}$$

Conclusions

Tests were made recently on the apparatus shown in Fig. 1 by the Westinghouse Electric and Manufacturing Company on a journal bearing 6-in. diameter × 12-in. long of standard manufacture. A rather close agreement was found to exist between the results of these tests and theoretical analysis made available in recent years.

In Fig. 2 are shown theoretical and experimental values of the coefficient of friction for varying conditions of load and speeds. It is given as a function of the characteristic number ZN/P_j.

The theoretical curves agree very well with the test results in the range of normal operation of the bearing, that is, for values of ZN/P_j between 80 and 300. Below ZN/P_j = 80, conditions are such that the hydrodynamical theory is no longer valid since this is the region of semifluid lubrication. For large values of ZN/P_j above 300, the momentum effect of the oil at the oil-film inlet becomes of great importance; this effect is not considered in the theoretical analysis in common use and some discrepancy with tests can, therefore, be expected.

In Table 1 the data are summarized for the calculation of the performance of bearings of various types under conditions described in the paper.

Nomenclature

- A = area of a guide bearing, sq in.
- b = width of the bearing surface (axial length of bearing perpendicular to direction of motion), in.
- c = eccentricity of journal bearing
- D = mean diameter of plane bearing, in.
- d = journal bearing diameter, in.
- F = total load acting on bearing, lb
- f = coefficient of friction
- h = oil-film thickness, in.
- h_o = oil-film thickness at outlet, in.
- h_i = oil-film thickness at inlet, in.
- J_f, J_h = type factors for journal bearings
- K_f, K_h, K_t, K_v = coefficients for plane bearing of infinite width
- K = heat-transfer coefficient, watts per sq in. per deg C per in.
- L = length of plane bearing in direction of motion, in.

l = length of the active oil film in journal bearing, in.
N = speed, rpm
P_j = F/bd = unit bearing pressure projected on journal diameter, lb per sq in.
P_r = F/bL = actual unit bearing pressure for rectangular plane bearing, lb per sq in.
Q = flow of heat through bearing surface, watts per sq in.
R_f, R_h, R_v, R_v = leakage factors for plane rectangular bearing
r = $d/2$ = radius of journal bearing, in.
S = shearing force, lb
t_1 = average temperature rise through the oil film, C
t_f = average temperature rise of oil film above bearing shell, C
U = peripheral velocity of journal, in. per sec
V_i = flow of oil at the inlet of the oil film, cu in. per sec
V_o = flow of oil at the outlet of the oil film, cu in. per sec
V_L = volume of oil leaking on the sides of the bearing = $V_i - V_o$, cu in. per sec
Z = oil viscosity, centipoise
α = angle for location of minimum oil-film thickness in journal bearing, deg
γ = specific weight, lb per cu in.
η = radial clearance, in.
ρ = specific weight of oil.

Effect of Surface Rolling on the Fatigue Strength of Steel[1]

By O. J. HORGER,[2] CANTON, OHIO

The investigation discussed in this paper was made to determine the effect of cold-working on the endurance limit and other related physical properties of steel. This cold-working was of a surface nature resulting in an almost negligible reduction in area. The preliminary work conducted in this field, for the most part, has been a laboratory development in so far as the technical and mechanical details of the surface-rolling process is concerned, but it has been sufficient to show the advantageous effect of this process on the endurance limit of steel, thereby justifying further study. Therefore, the investigation discussed in this paper was inaugurated to determine the various factors involved in the immediate application of this surface-rolling process in practice. As a result this paper is in the nature of a progress report covering principally tests made on 0.3-in. and 1-in. diameter cold-worked specimens without stress concentration. Further fatigue tests are being conducted on 1-in. and 2-in. diameter surface-rolled specimens with and without stress concentration and on 0.080-in. diameter fatigue specimens machined from various layers of 2-in. diameter surface-rolled specimens.

Introduction

THE failure of machine parts in fatigue which suggested the investigation reported in this paper usually occurs at points of local weakness. A few of the typical failures found in practice occur at the wheel or gear seat of locomotive and railroad-car axles, at the wheel or bearing seats of automobile axles, at automobile rear-axle housings adjoining the differential, at the pressed or fitted bits of long drill rods used in oil-well and rock-drilling operations, and at grooves and holes in axles. In general, many cases of fitted members subjected to reversed bending action have been a constant source of failure. Some means of reducing the effect of the local stress concentrations causing such failures is very desirable.

As a result of a development made in German laboratories it was shown that cold-working of the surface of the steel in the region of the stress concentration improved its fatigue strength. On the basis of such promising preliminary investigations as have already been made both in Germany and the United States, it appeared worth while to learn more about the phenomena of this surface-rolling process.

Development of the Surface-Rolling Process. At the Wöhler-Institute in Braunschweig, Germany (1),[3] the importance of this method was first recognized in 1928. It was observed in studies on surface conditions, that the effect of hammer and chisel marks did not decrease fatigue strength as did filing or grinding. The fact that failure did not occur in these compressed areas led to further tests.

O. Föppl (2) made fatigue-bending tests on specimens having surfaces prepared under certain rolling pressures and found that the endurance limit was increased 5 to 30 per cent. P. Behrens made torsion-fatigue tests and found an increase in fatigue strength between 6 and 29 per cent. An increase in fatigue strength was indicated by torsion tests conducted by Heydekampf (4) and also by bending tests conducted by Döring (5).

More recently, surface-rolling investigations have been devoted to practical problems of design where severe stress concentration exists. Kühnel (6) studied railroad-axle failures occurring at the wheel fit and found the fatigue strength was reduced one-half due to the press fit of the wheel, and Thum (7) continued this study by surface-rolling the axle wheel seat. He found that rolling the axle surface gave about the same strength as the axle without the press fit or an improvement of 69 per cent.

The effect of compressing plastically the surface area surrounding various forms of stress-concentration systems such as holes and grooves in machine parts were studied at the Darmstadt materials-testing laboratory (8, 9, 10) and an improvement of as much as 38 per cent was obtained. Staedel (11) extended the rolling process to cut threads on bolts, reporting an increased fatigue strength of as much as 100 per cent. Also, Koch (12) studied keyways and reported a small improvement in fatigue strength. A synopsis[4] of various forms of cold-work investigations was given by Thum and Wunderlich (13) in 1934.

In the United States, Peterson and Wahl (14) and Buckwalter (15) have published papers contributing substantiating data on the beneficial effect of cold-working $1^{5}/_{8}$-in. and 2-in. diameter axles at wheel and bearing seats. While the German laboratories have confined their tests to specimens with a maximum diameter of about $^{9}/_{16}$ in., it was indicated that this same improvement may be extended to the larger diameters more frequently met in practice.

While there is no difference of opinion as to the favorable effect of cold-working, there is no uniformity of opinion as to the explanation of why the fatigue strength is increased. There are two schools of thought, and the controversy arising therefrom is represented by Thum and Föppl (16).[4] Briefly, Föppl contends that the change which takes place in the metal structure is largely responsible for this improvement in fatigue strength, while Thum insists that residual stresses is the contributing factor. At the present time there is no direct evidence available to support conclusively either opinion.

Materials, Tests, Testing Equipment, and Test Specimens

Materials Tested. An S.A.E. 1045 open-hearth steel was

Presented at the National Applied Mechanics Meeting of The American Society of Mechanical Engineers, Ann Arbor, Mich., June 18–19, 1935.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until February 10, 1936, for publication at a later date.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[4] After this paper was written, Thum and Bautz published an article in *Forschung auf dem Gebiete des Ingenieurwesens*, vol. 6, May–June, 1935, p. 121, in which it was stated that four-fifths of the increased fatigue strength in reversed bending was due to residual stresses and one-fifth was due to hardening, while increased torsional-fatigue strength was all due to strain-hardening.

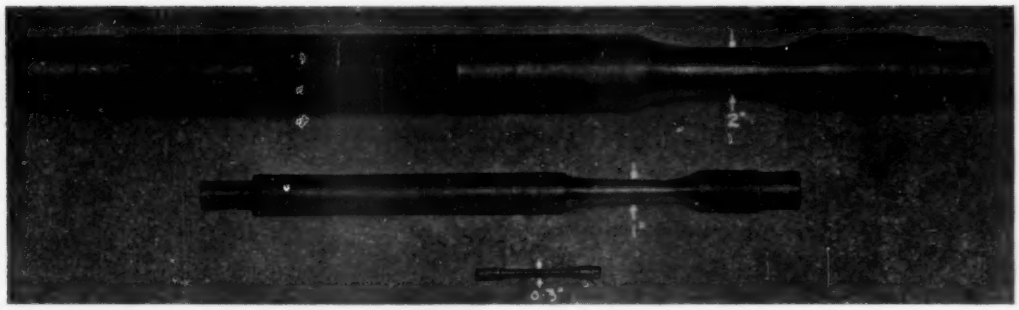

FIG. 1 FATIGUE SPECIMENS TESTED

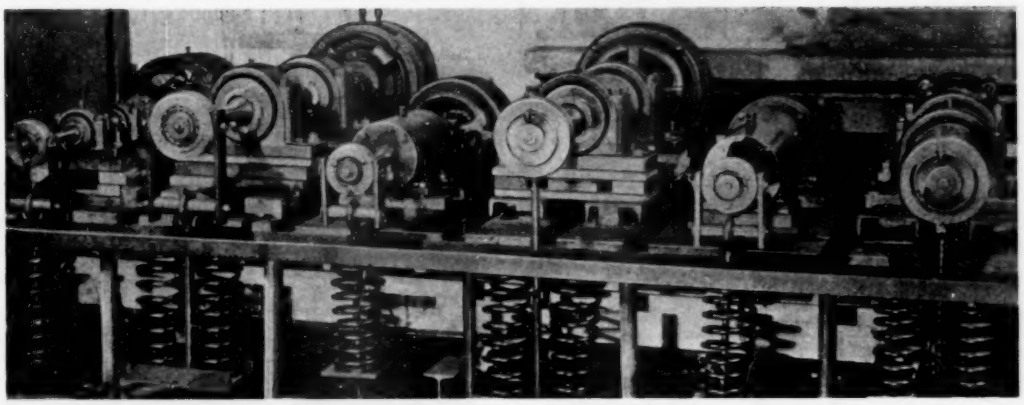

FIG. 2 CANTILEVER-TYPE FATIGUE MACHINES USED TO TEST THE 1-IN. AND 2-IN. DIAMETER SPECIMENS

used in all the tests discussed in this paper. The chemical analysis of each bar tested is shown in Table 1. The physical properties of the bars are given in Table 2. All specimens were normalized at 1620 F and drawn at 1115 F before machining.

Fatigue Tests. The three different diameters of fatigue specimens tested in rotating bending are shown in Figs. 1 and 3. The fatigue machines used to test the 0.3-in. diameter specimens were of the conventional Farmer type, but the 1-in. and 2-in. diameter specimens were tested in cantilever-type machines shown in Fig. 2. Pillow blocks of the selfaligning type with Timken bearings were fitted to the specimen by means of a taper sleeve between the bearing cone and specimen. The load was applied on the end of the 1-in. and 2-in. specimens by the action of compression springs, which had a low constant of about 300 to 400 lb per in. of travel, permitting very close adjustment to the proper load.

Tensile Tests. The 0.3-in. diameter specimen shown in Fig. 4 was used so that the tensile data obtained on surface-rolled specimens would be comparable with fatigue-test data obtained on surface-rolled specimens of the same diameter.

Two Martens mirror extensometers with 100-mm gage length (3.937 in.) were used on all the tensile-test specimens.

Hardness Tests. The Vickers pyramidal diamond test was used to investigate the hardness of the surface-rolled specimens shown in Fig. 5. The Bierbaum scratch-hardness test was used on a transverse section.

Surface Finish of Specimens. The machined surface of the test section of all fatigue specimens was polished with 000 emery cloth previous to the surface-rolling operation. A profilograph (17, 18) was used to measure the surface irregularities along the length of the specimens before rolling and after rolling under various conditions of roller shapes, feeds, and pressures. Briefly, the principle of this instrument consists of (*a*) tracing over the surface with a very sharp diamond point (*b*) magnifying the movements of this tracer point through an optical system, and (*c*) recording them on sensitized paper.

Description of Rolling Equipment. A diagrammatic arrangement of the device used to roll the surface of the specimens is shown in Fig. 6. An engine lathe was adapted for this rolling operation by supporting the specimen in lathe centers and the rolling device in a transverse slide fixed to the lathe carriage. This setup is shown in Figs. 7, 8, and 9, while the various proportions of rollers which were used are shown in Fig. 10. The roller load was applied through calibrated springs with long travel to permit

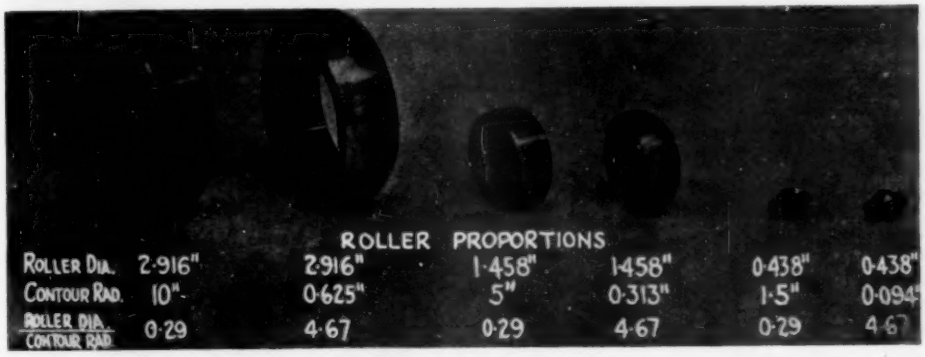

FIG. 10 ROLLER PROPORTIONS

endurance limits[5] established on the various diameter specimens are summarized in Table 3. The values of endurance limit are used as a base from which any improvement due to cold working is calculated.

Lines 3 and 6 of Table 3 indicate that there is a change in fatigue strength in going from the 0.3-in. to 1-in. diameter. This effect of variation of fatigue strength with size of specimen is in accordance with that reported in the literature (19, 20) for specimens without stress concentration.

Effect on Endurance Limit of Surface Rolling. The results of the tests on 0.3-in. diameter surface-rolled specimens are given in Table 4 and shown graphically in Figs. 11 and 12.

[b] Roller has a diameter of 7/16 in. and a contour radius of 1 1/2 in.

shapes of rollers differ only in contour radius, their diameters being the same. The effect of roller shape is given in Table 5, where it is observed that under constant roller pressure there results a change of only 5 per cent in endurance limit. Considering the same endurance limit with both types of rollers, it is seen in Table 6 that the flat roller of 1 1/2-in. contour radius requires considerable more pressure than the sharp roller of 3/32-in. contour radius to obtain this differential of 5 per cent. The effect of roller shape is discussed later in the paper.

The fatigue studies discussed, on 0.3-in. diameter specimens, have been extended to include 1-in. and 2-in. diameter specimens. A portion of this program has been completed and

h	Cast-iron cylinder bore with another tool		

the data obtained to date on 1-in. specimens is given in Table 7. Referring to Fig. 10, it is seen that the $^7/_{16}$-in. × $^3/_{32}$-in. rollers and 0.3-in. specimen are geometrically similar to the 1.46-in. × 0.31-in. rollers and 1-in. specimen. It may then be expected that the percentage increase in endurance limit would be the same with both 0.3-in. and 1-in. specimens rolled at pressures in the ratio of the squares of the diameters of the two specimens. In this respect the test results shown in Table 8 and Fig. 12 indicate that the percentage of increase in fatigue strength for the 1-in. rolled specimens approaches that for the 0.3-in.

TABLE 9 EFFECT OF ROLLER FEED ON ENDURANCE LIMIT

Roller feed — Equiv. threads per in.	In.	Endurance limit — Lb per sq in.	Per cent	Ratio of roller contact width[a] to roller feed in.
0	0	39800	100	0
20	0.050	44500	112	1.01
40	0.025	45900	115	2.02
80	0.0125	46200	116	4.03
224	0.00446	46500	117	11.3

[a] Actual contact width between roller and length of specimen = 0.0505 in. A discussion of static indentation tests is given later in the paper under the heading "Effect of Roller Shape."
NOTE: The roller used had a diameter of $^7/_{16}$ in. and a contour radius of $1^1/_2$ in. The normal pressure per roller was 130 lb.

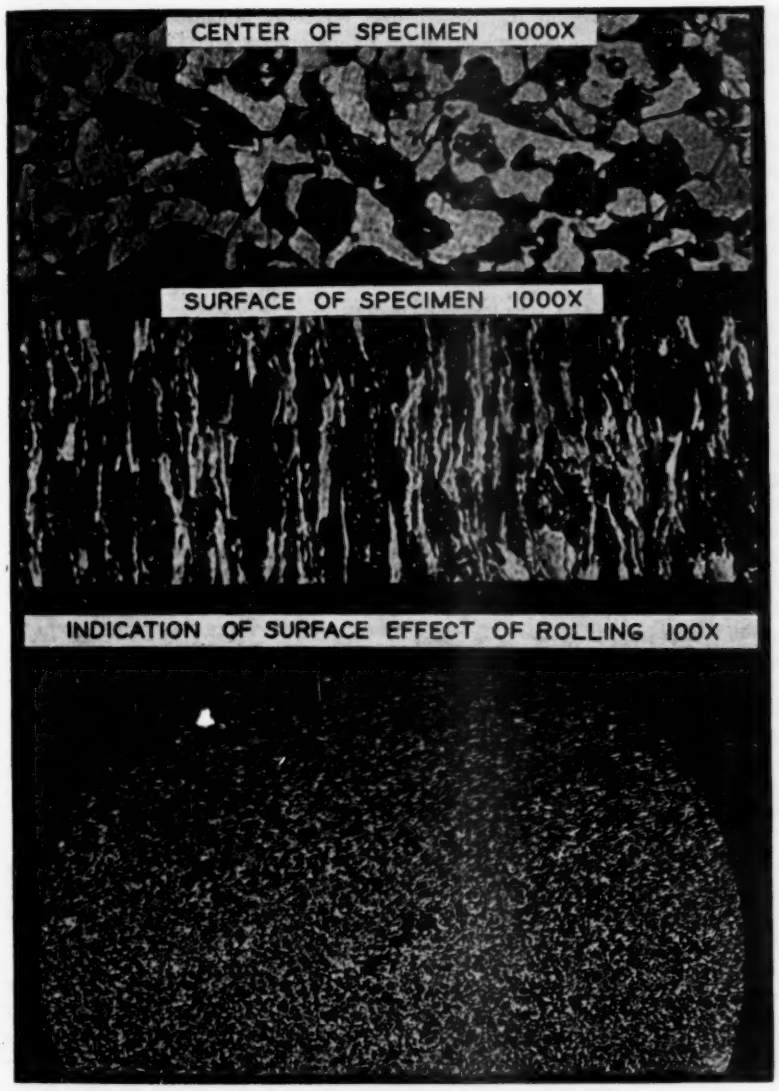

FIG. 16 PHOTOMICROGRAPHS OF SPECIMEN 4-1 THROUGH A TRANSVERSE SECTION
(The surface of the specimen was rolled with a normal pressure of 250 lb per roller with rollers of $^{7}/_{16}$-in. diameter and $1^{1}/_{2}$-in. contour radius fed at a speed equivalent to 224 threads per in.)

In this comparison, the 0.3-in. specimens were selected from the region of negligible bending stress of the drive-coupling end of a 1-in. specimen after it was tested in reversed bending. In this manner the same material and heat-treatment were used and there was no effect of prestressing. Also the 0.3-in. specimens were cut from the region of the larger specimen at $^{1}/_{2}$-in. radius so as to present material in the same surface layer.

TABLE 11 DEPTH OF PENETRATION OF COLD-WORKING ON 0.3-IN. SPECIMENS

Normal pressure per roller, lb	Depth of penetration, in. $^{7}/_{16} \times {}^{3}/_{32}$-in. roller	Depth of penetration, in. $^{7}/_{16} \times 1^{1}/_{2}$-in. roller
183	0.0075[a]	0.006
250	0.0150	0.011

[a] Specimen given a mild heat-treatment after rolling.

Effect of Roller Feed on Endurance Limit. A study of the effect of the roller feed on the endurance limit is given in Table 9. It may be concluded from the values given in this table that very little increase in fatigue strength results with feeds above 40 equivalent threads per inch for the particular shape of roller and pressure used. This is readily apparent from the endurance feed curve in Fig. 13.

The manner in which the roller feed affects the endurance limit is believed to be due to the degree of uniformity to which the surface of the specimen is cold-worked. As an expression of this uniformity we may use the ratio

$$\frac{\text{Actual contact width between roller and length of specimen}}{\text{Equivalent thread pitch of roller feed}}$$

It would be desirable to know the proper feed for other pressures using the same roller and to extend this still further to apply to rollers of different contours and other materials. This determination could be made by a large number of fatigue tests, but it is believed that this ratio equal to 2 would be suitable for calculating the proper feed.

Effect on Endurance Limit of Machining Specimen After Rolling. The rolled surface was machined off a number of 0.3-in. diameter specimens rolled under the same conditions with the results shown in Table 10 and Fig. 14. The conclusions to be derived from this work would indicate that the first 0.0056 in. removed from the diameter reduces the endurance limit by 7 per cent or by an amount equal to one-half of the total increase due to rolling. The removal of this surface layer on small parts would be important, but the decrease in endurance limit would become less as the parts become larger.[6]

Surface Profiles of Rolled Specimens. A comparison of surface irregularities of specimens which were surface-rolled with machined surfaces is given in Fig. 15. It will be observed that the rolled surfaces are more irregular than a 000-emery finish and yet the fatigue strength is higher as given by Table 4.

Effect of Mild Heat-Treatment After Rolling. A mild heat-treatment at 525 F for 1 hour with a furnace cool after rolling of the specimen effected an increase in the fatigue strength of 6 per cent over the specimen not heat-treated.

The effect of aging and mild heat-treatment in increasing the low proportional limit of materials subjected to cold-working has been known for a long time (21). The phenomena underlying this action are not known. Several theories have been advanced of which one indicates that mild heat-treatment causes a release of internal stress (21) while another indicates that the slip planes present in the cold-worked material are healed by the mild heat-treatment (22, 23).

The way in which this low proportional limit was effective was displayed by many cases of the bending of the rolled specimens, instead of resulting in fracture in the fatigue tests. The specimens and testing machines were checked for eccentricity and the load applied slowly after the machine had reached its operating speed. The vibration of the specimen would not begin immediately but after a period of operation at load. This period was from several minutes to several hours, depending on the magnitude of the stress above the endurance limit. It should be mentioned that this vibration has apparently no effect on the values of endurance limit established, since no vibration took

[6] This statement assumes that the larger parts will be rolled at proportional rolling pressures.

place at the endurance limit or below it. A difference of about 400 lb per sq in. bending stress exists between the fatigue strength of two specimens that will both run 10 million cycles, but with one specimen there is no perceptible vibration and with the other specimen the vibration builds up at the beginning of the test, but then does not increase as for specimens under higher stress.

Stress-strain curves were made from static-bending tests and hysteresis loops formed at 2000 lb per sq in. below the endurance limit for the rolled specimens. No hysteresis could be measured for either the specimens given a mild heat-treatment after rolling or specimens not rolled when both were tested at 2000 lb per sq in. above the endurance limit. This checks with the fatigue tests where practically no difficulty with vibration was experienced.

It is believed that the static-bending tests are good reasons for the vibration phenomenon encountered. Kimball (24, 25) has shown that internal friction, as for instance elastic hysteresis, may cause a shaft to whirl.

It should be mentioned that when the rolling process is used to strengthen local regions of a machine part instead of the whole this difficulty with vibration may not be much of a factor. In any event a mild heat-treatment will remedy the situation.

Microstructure of Surface-Rolled Specimens. Typical structural conditions after rolling, shown in Fig. 16, indicate that the stretching and elongation of the crystals with parallel fibers tend to improve the quality of the steel. The depth of penetration of cold-working was measured from photomicrographs at 1000 magnification. The results obtained are shown in Table 11. The depth given was measured at the point where the fibrous structure begins to merge into the normal structure. With this type of steel, the proportions of ferrite and pearlite make it difficult to determine the depth of penetration, and for this reason these measured depths are of a qualitative rather than a quantitative value.

Hardness of Surface-Rolled Specimens. The hardness of a rolled specimen as determined by the Bierbaum scratch test and Vickers pyramidal diamond test gives different results as shown in Fig. 17. The pyramidal diamond test indicates that the surface hardness is 25 per cent greater than the core, while the scratch test shows a difference of 100 per cent. This divergence may be attributed to the different nature of the two types of hardness tests.

It is interesting that cold-stretched and rolled specimens which gave pyramidal diamond measurements of about the same surface hardness also exhibited a fatigue strength of practically the same value.

Tensile Tests of Rolled and Cold-Stretched Specimens. From the summary data shown in Tables 2, 4, and 15, it may be concluded that the degree of cold-working used by surface-rolling, cold-stretching, and rolling in accordance with steel-mill practice, affects the physical properties of the $^1/_2$-in. diameter cold-rolled S.A.E. 1045 normalized-and-drawn steel as given in Table 12. In general, Table 12 indicates the desirable high fatigue strength of surface-rolled specimens which is obtained with small loss of ductility measured by per cent elongation, reduction in area, and area under tensile-test diagram. The mill-rolling and cold-stretching operations are more uniform in their action throughout the section and considerably reduce the ductility. A measure of this ductility is taken from the elongation, reduction in area, and area under the tensile-test diagram of Table 15.

Effect of Roller Shape.[7] It was thought that a measure of the pressure distribution over the roller indentations made on the fatigue specimens in the rolling process would give some relation to the fatigue strength through the strain hardening produced. Static indentation tests were therefore made using the rollers as an indentor. The indentations were made on 0.3-in. and 1-in. diameter specimens covered with a thin film of smoke. The size of the recovered indentation was determined with a micrometer microscope. There may be a very small difference between the recovered and unrecovered area of indentation but its determination would require considerable refinement of equipment. Table 16 summarizes the calculated and actual indentation characteristics.

TABLE 12 EFFECT OF COLD WORKING ON PHYSICAL PROPERTIES OF SPECIMENS[a]

[a] All values given in per cent.

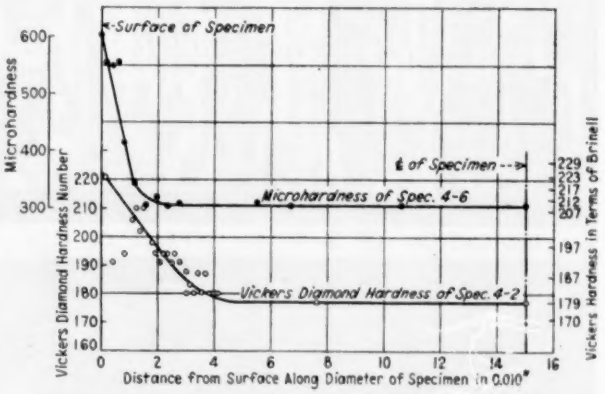

FIG. 17 COMPARISON ON SURFACE-ROLLED SPECIMENS OF HARDNESS OVER A CROSS SECTION BY TWO DIFFERENT METHODS

(Hardness comparisons made by the Bierbaum diamond-point scratch test using a 3-g load and by the Vickers pyramidal diamond test using a 30-kg load. The specimens were rolled with a normal pressure of 250 lb per roller with rollers of $^7/_{16}$-in. diameter and $1^1/_2$-in. contour radius fed at a speed equivalent to 224 threads per in. The specimen design is shown in Fig. 3*d*.)

The calculated values[8] assume elastic conditions and the actual values are based on the measured indentations. In both cases an ellipsoidal pressure distribution similar to the Hertz theory is used to determine q_o, the maximum pressure at the center line of ellipsoid of contact between the roller and specimen.

Fig. 18 shows the value of q_o determined from the static indentation tests plotted against per cent increase in endurance limit determined from the fatigue tests on rolled specimens. It may be noted that q_o reaches a limiting value and then drops off when the fatigue strength becomes a maximum. It would also seem as though the fatigue strength for the 1-in. diameter specimen would continue to increase with higher rolling pressures, but the increase would be small compared to the pressure.

Fatigue Strength of Cold-Stretched Specimens. The results of these tests are given in Table 13 with a comparison of similar tests made by Moore and Kommers (29) on a different steel. The

[7] The effect of roller shape on the endurance limit was considered by Thum and Bautz (8). They proposed a relation between roller pressure and favorable roller shape to produce "the desired increase in fatigue strength." The application of their relation to the tests outlined in this paper on 0.3-in. diameter specimens gives a minimum roller pressure of 600 lb as compared to 200 lb actually used to obtain maximum fatigue strength. Their relation is not satisfactory, and since they do not give the reason or derivation of their proposed relation, no further discussion can be made.

[8] Calculations showing how these values were derived are too lengthy to include in this paper but the procedure may be found in the literature (26, 27, 28).

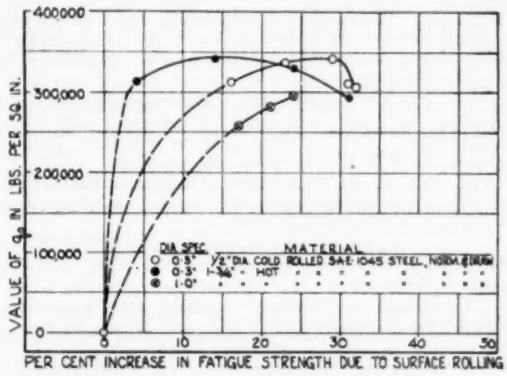

FIG. 18 VARIATION OF q_0 WITH INCREASE IN FATIGUE STRENGTH

data presented in Table 13 indicate that strain hardening[9] in the absence of residual stresses was directly responsible for the large increase in fatigue strength. In all these tests it has been found that an increase in hardness is associated with higher fatigue strength. While it is too early to state definitely, the results of these tests seem to indicate that the strain-hardening phenomena rather than the residual stresses are largely responsible for the increased fatigue strength found with rolled specimens.

[9] A discussion of strain hardening and residual stresses may be found in the literature (27).

TABLE 14 EFFECT OF SURFACE-ROLLING ON COLD-WORKED SPECIMENS

Effect of Surface Rolling of Previously Cold-Worked Specimens. In these tests, the surface rolling of specimens which had already been cold-worked showed a much smaller percentage of increase in endurance limit than found on the normalized-and-drawn steel. The results of these tests are summarized in Table 14. It has been shown by O'Neill (30) that an increase in indentation hard-

[a] $2a$ = the major axis of the area of contact.
[b] $2b$ = the minor axis of the area of contact.
[c] $q_0 = 3/2 \times ab$ = maximum pressure at the center line of ellipsoid of contact between the roller and specimen.
[d] This specimen machined from 1/2-in. diameter cold-rolled S.A.E. 1045 steel, normalized and drawn; endurance limit = 39800 lb per sq. in. The specimen was rolled with rollers of 7/16 in. diameter and 3/32-in. contour radius.
[e] This specimen machined from 1 3/4-in. hot-rolled S.A.E. 1045 steel, normalized and drawn; endurance limit = 39800 lb per sq in. The specimen was rolled with rollers of 7/16 in. diameter and 3/32-in. contour radius.
[f] This specimen was machined from 1 3/4-in. hot-rolled S.A.E. 1045 steel, normalized and drawn; endurance limit = 36000 lb per sq in. The specimen was rolled with rollers of 1.46 in. diameter and 0.31-in. contour radius.
NOTE: The 7/16-in. diameter by 3/32-in. contour-radius rollers were slightly worn at the contour radius due to therolling of a large number of specimens. At the time these indentation tests were made, the 3/32-in. contour radius measured about 1/8 in. The calculated values given in the table are based on the 3/32-in. radius.

ness due to cold-working is accompanied by a decrease in the work-hardening capacity. This would explain the results obtained in Table 14.

Conclusion

The conclusions to be derived from this work, based on the limitations imposed by the nature of the materials, tests, and size of specimens tested, may be summarized as follows:

1 Fatigue strength may be increased from 24 to 32 per cent as shown in Figs. 11 and 12.

2 Roller shape has little effect on the increased fatigue strength as shown by Tables 5 and 7.

3 The minimum roller feed for about maximum fatigue strength may be expressed by a ratio of roller contact width to roller feed equal to 2 or greater.

4 The irregularity of the surface finish obtained by rolling may be controlled by proper feed as shown by Fig. 14.

5 Mild heat-treatment after rolling gives 6 per cent additional fatigue strength.

6 Cold-stretching of fatigue specimens in tension increased fatigue strength as much as 35 per cent as shown in Table 13.

7 Surface rolling of previously cold-worked steel does not give as great an increase in fatigue strength as the annealed steel.

Acknowledgments

Much credit is due Prof. S. Timoshenko of the University of Michigan for his invaluable suggestions during the progress of this work. The interest of T. V. Buckwalter, vice-president of Timken Roller Bearing Company, has been of primary importance in furthering this research. The assistance of Dr. J. L. Maulbetsch has been of great value in these tests.

A Method of Harmonic Analysis

By FRANK M. LEWIS,[1] NEW YORK, N. Y.

The method of harmonic analysis described in this paper is of the selected ordinate type. It is similar to the Fischer Hinnen analysis in that a different spacing of ordinates is used for each harmonic component to be determined, and no multiplications are necessary. The basis of derivation is the assumption that the curve to be analyzed can be replaced by a parabola passing through certain ordinates in each half period of the harmonic component. A spacing of these ordinates is then found such that the sum of the ordinates is proportional to the harmonic component of the parabolas replacing the original curve.

Spacings have been determined for 3, 5, and 7 ordinates per half period, corresponding to parabolas of second, fourth, and sixth orders. In the five and seven ordinate rules it is necessary to use a multiplying factor of $^1/_2$ for the end ordinates.

In use a set of transparent charts with the ordinates for each component are constructed. Laid over the curve to be analyzed, the ordinates can be quickly summed on a strip of paper.

The accuracy of the method is relatively high and in use it is of the utmost simplicity, so that with a set of charts once prepared, correct results can be obtained by the most unskilled computer.

METHODS of harmonic analysis by selected ordinates are of two types: Analyses in which the identical spacing of ordinates is used to determine all the components; and analyses in which a different spacing of ordinates is used to determine each harmonic component.

Methods of harmonic analysis by identical ordinates have been devised by several writers.[2] In general, the procedure is to divide the period into a number of equidistant intervals, enter the ordinates at these points in tabular forms, multiply each ordinate by a set of constants, and by proper combinations and additions of the products the harmonic coefficients can be determined up to an order number which depends upon the number of intervals into which the period is divided. The tedious multiplications are an undesirable feature in this procedure, and the use of the tabular forms requires considerable skill and care on the part of the computer.

The Fischer Hinnen analysis and the method to be presented in this paper are examples of the second type.

The Fischer Hinnen analysis,[3] in which a different spacing of ordinates is used for each of the harmonic components avoids the multiplications of the identical ordinate methods. It may be stated as follows:

"If starting at $x = 0$, we measure $2n$ ordinates at intervals $l/2n$, where l is the periodic length, the average of these ordinates, taken alternately plus and minus, is equal to the sum of the amplitudes of the nth, $3n$th, $5n$th, etc., cosine components."

A similar rule holds for the sine components.

If the higher components are small or absent, or a high degree of accuracy is not necessary, this rule is particularly simple and rapid in application. It is desirable to lay down the curves to a standard length and construct a set of ruled transparent charts with the ordinate spacing, one for each of the components.

If higher components are present and accuracy is desired, it is first necessary to determine a number of the higher components, and use these to correct the lower, and the rule loses somewhat in simplicity.

The method of analysis to be described in this paper is similar to the Fischer Hinnen analysis in that a different spacing of ordinates is used for each of the harmonic components and multiplications are avoided, but it has an entirely different basis of derivation. It is particularly useful in those cases where higher components are present and accuracy is wanted. Any particular component is determined independently of the others.

The three-ordinate rule will be described first.

Referring to Fig. 1 the period AB is divided into $2n$ equal intervals, where n is the order number of the harmonic coefficient to be determined. For sine components the intervals will all be equal, while for cosine components there will be half intervals at the ends. Taking an origin at the center of any one of these intervals any harmonic coefficient, sine or cosine, will be given by

$$A_n = \Sigma \frac{1}{nh} \int_{-h/2}^{h/2} f(x) \cos \frac{\pi x}{h}\, dx \qquad [1]$$

Σ meaning the sum of the contributions from the separate intervals.

It is assumed that in each interval the arbitrary curve $y = f(x)$ can be replaced by a parabola of the form

$$y = a_0 + a_1 x + a_2 x^2 \qquad [2]$$

The spacing of three ordinates will be determined so that if in any interval, $f(x)$ is replaced by the parabola passing through these ordinates, the integral in Equation [1] will be proportional to the sum of the ordinates.

This procedure is suggested by Tchebycheff's rule for areas. In Tchebycheff's rule an ordinate spacing is found so that the area is proportional to the sum of the ordinates. In this paper a harmonic coefficient is made proportional.

It will be assumed that one of the ordinates is at the center of the interval and that the others are equidistant x_1 to left and right of the center.

Then

A_n (CD contribution)

$$= \frac{1}{nh} \int_{-h/2}^{h/2} (a_0 + a_1 x + a_2 x^2) \cos \frac{\pi x}{h}\, dx$$

$$= M \begin{bmatrix} a_0 \\ + a_0 + a_1 x_1 + a_2 x_1^2 \\ + a_0 - a_1 x_1 + a_2 x_1^2 \end{bmatrix}$$

$$= M(3a_0 + 2a_2 x_1^2)$$

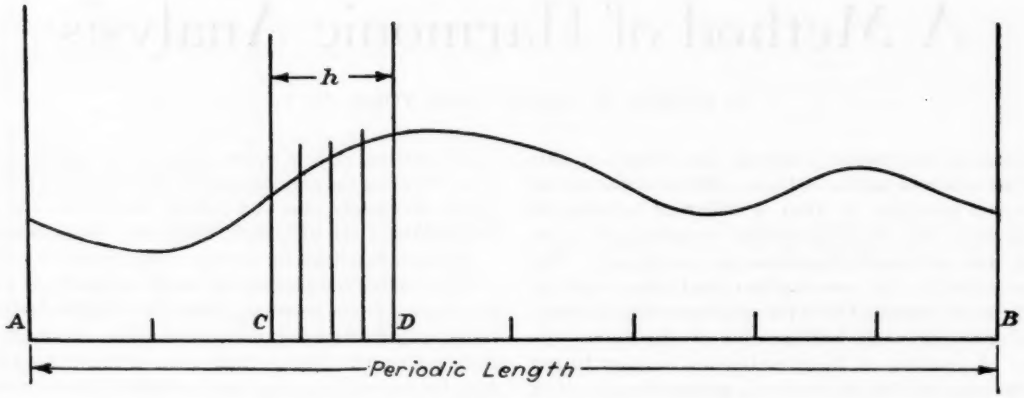

FIG. 1

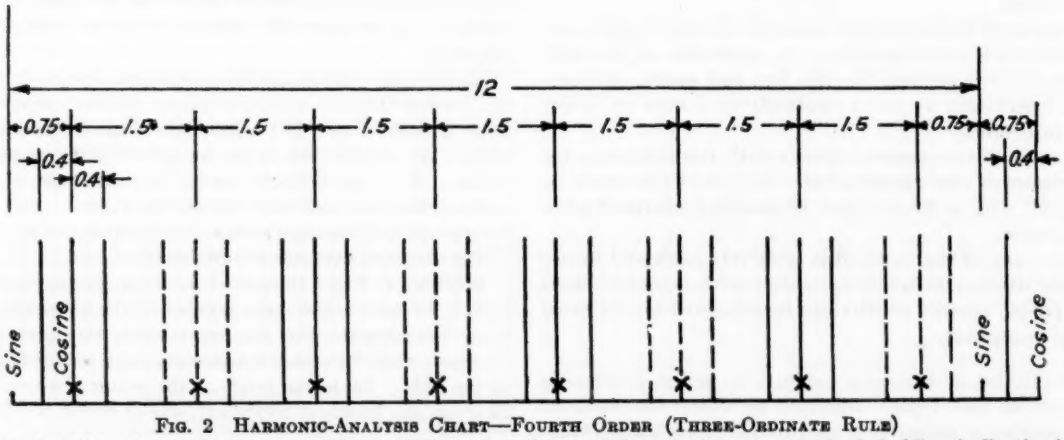

FIG. 2 HARMONIC-ANALYSIS CHART—FOURTH ORDER (THREE-ORDINATE RULE)

(a_4 or $\beta_4 = [1/8\pi]$[sum of the ordinates represented by solid lines minus the sum of the ordinates represented by dashed lines.] For the shorter Fischer Hinnen rule, a_4 or $\beta_4 = [1/8]$ [sum of the ordinates represented by the solid lines minus the sum of the ordinates represented by the dashed lines], taking only the ordinates marked x.)

Evaluating the integral and equating the coefficients of a_1 and a_2 there is obtained

$$M = (4\pi)(1/6n)$$

$$a_1 = (\sqrt{3}/2\pi)[\sqrt{(\pi^2/2) - 4}]h = 0.26652\,h$$

Fig. 2 illustrates the spacing of ordinates for a complete chart as prepared for the fourth-order components. The period is taken as 12 in. This is divided into eight intervals of $1^1/_2$ in. each. Ordinates are laid off to the right and left of the center of each of these a distance 0.26652×1.5 in. $= 0.399$ in.

The curve to be analyzed is laid down to a periodic length of 12 in. To determine the fourth-order sine coefficient, the fourth-order chart is laid over the curve so that the termini marked "sine" are at the termini of the curve, and the sums of the ordinates under the ruled lines determined, the full lines being taken as positive and the dashed lines as negative. The sum of these ordinates multiplied by $M = 1/6\pi$ will be an approximation to the fourth-order coefficient given by the integral in Equation [1]. How close an approximation is obtained depends upon how close the individual sections of the actual curve approximate to parabolas.

To obtain the cosine coefficient, the chart is shifted until the termini marked "cosine" terminate the period and exactly the same procedure is followed. The end ordinates must be added only once.

The charts should be laid over the curve so that the lowest ordinate of the curve is above the axis of the charts. This obviates any difficulty from sign of the ordinates.

The additions can be made very rapidly and accurately by marking off the positive ordinates in succession on one edge of a strip of paper and the negative ordinates on the opposite edge, and taking the difference of the lengths.

Charts for any other order can be prepared in exactly the same manner.

Where it is known that harmonics, which are an odd multiple of the order to be determined, are not present, or where high accuracy is not needed, the same charts may be used to determine the harmonic coefficients by the Fischer Hinnen method. In this case, only the central ordinates of each group are utilized and their sums (ordinates taken alternately plus and minus) are divided by the number of ordinates.

The method which has been described is designated as the three-ordinate rule, there being three ordinates per half period of the harmonic component. For low-order components, this number of ordinates may not fix the curve to be analyzed closely enough to determine the coefficients with accuracy. For this purpose a five-ordinate rule and a seven-ordinate rule have been devised.

For the five-ordinate rule it is assumed that the curve to be analyzed can be represented in each interval by an equation of the form

$$y = a_0 + a_1x + a_2x^2 + a_3x^3 + a_4x^4$$

It is found that the resultant ordinate spacings are $x_1 = 0.0881h$, and $x_2 = 0.3326h$. The three central ordinates are closely grouped and, as a result, the curve will be defined with

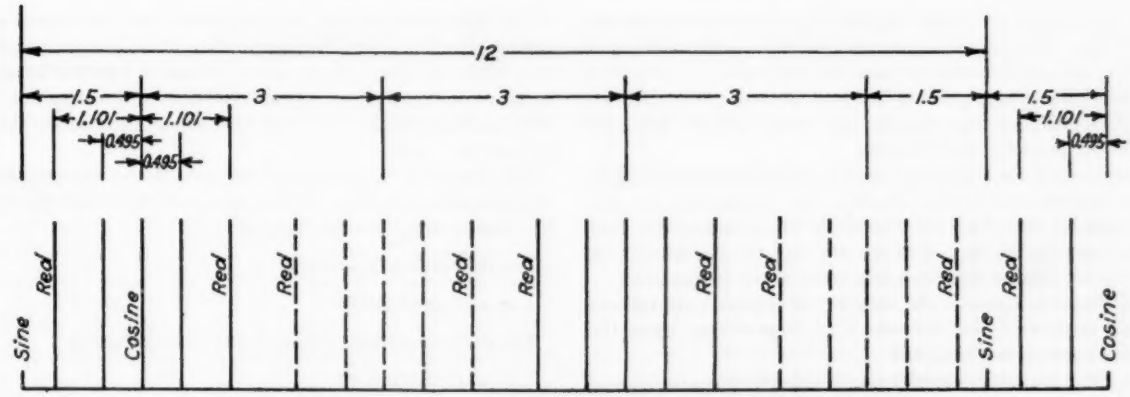

FIG. 3 HARMONIC-ANALYSIS CHART—SECOND ORDER (FIVE-ORDINATE RULE)
(a_2 or β_2 = [1/4π] [sum of the black ordinates plus one-half of the red ordinates]. The solid lines are taken as positive and the dashed lines are taken as negative.)

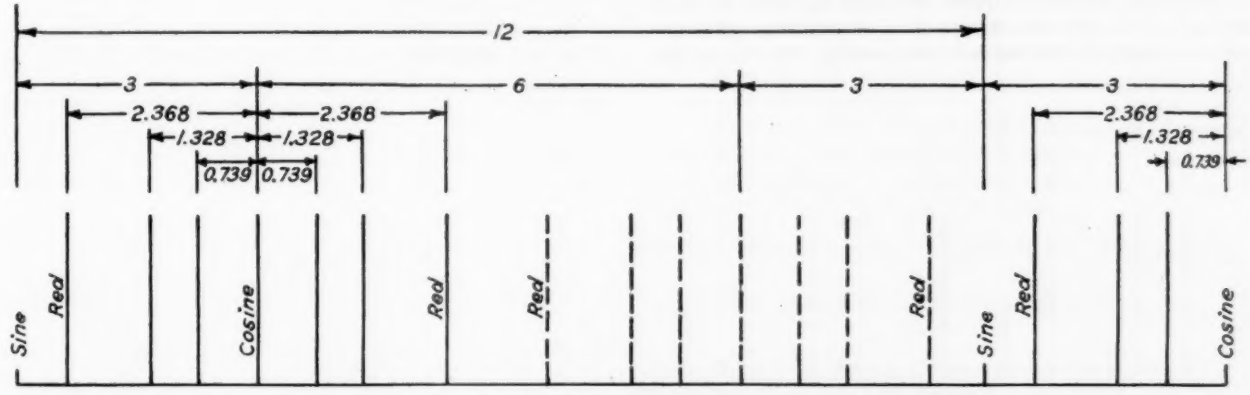

FIG. 4 HARMONIC-ANALYSIS CHART—FIRST ORDER (SEVEN-ORDINATE RULE)
(a_1 or β_1 = [1/2π] [sum of the black ordinates plus one-half of the red ordinates]. The solid lines are taken as positive and the dashed lines are taken as negative.)

but little greater accuracy than when the three-ordinate rule is used.

A five-ordinate rule of much higher accuracy can be obtained by taking the sum of the three central ordinates plus one half the sum of the two end ordinates. The conditions for this case for any order n lead to

$$\frac{1}{nh}\int_{-h/2}^{h/2}(a_0 + a_1x + a_2x^2 + a_3x^3 + a_4x^4)\cos\frac{\pi x}{h}\,dx$$

$$= M(4a_0 + 2a_2x_1^2 + a_2x_2^2 + 2a_4x_1^4 + a_4x_2^4)$$

from which by equating the coefficients of the a's

$$M = (4/\pi)(1/8n)$$

$$2x_1^2 + x_2^2 = (2h^2/\pi^2)[(\pi^2/2) - 4]$$

$$2x_1^4 + x_2^4 = (4h^4/\pi^4)[(\pi^4/16) - 3\pi^2 + 24]$$

solving

$$x_1 = 0.1652h$$

$$x_2 = 0.3673h$$

Fig. 3 shows a second-order chart spaced for the five-ordinate rule with half end ordinates. In making up an actual chart, the half ordinates should be ruled in red.

A seven-ordinate rule with full ordinates cannot be obtained as the equations for the ordinate spacing have imaginary roots. However, a seven-ordinate rule with half end ordinates can be obtained. The equations are

$$M = (4/\pi)(1/12n)$$

$$\frac{1}{nh}\int_{-h/2}^{h/2}(a_0 + a_1x + a_2x^2 \ldots\ldots a_4x^6)\cos\frac{\pi x}{h}\,dx$$

$$= M[6a_0 + a_2(2x_1^2 + 2x_2^2 + x_3^2) + a_4(2x_1^4 + 2x_2^4 + x_3^4) + a_6(2x_1^6 + 2x_2^6 + x_3^6)]$$

leading to

$$2x_1^2 + 2x_2^2 + x_3^2 = (6h^2/\pi^2)[(\pi^2/4) - 2]$$

$$2x_1^4 + 2x_2^4 + x_3^4 = (6h^4/\pi^4)[(\pi^4/16) - 3\pi^2 + 24]$$

$$2x_1^6 + 2x_2^6 + x_3^6 = \frac{6h^6}{\pi^6}\left[\frac{\pi^6}{64} - \frac{\pi^4 \times 6 \times 5}{16} + \frac{\pi^2 \times 6 \times 5 \times 4 \times 3}{4} - 6!\right]$$

solving

$$x_1 = 0.1232h$$
$$x_2 = 0.2214h$$
$$x_3 = 0.3946h$$

In Fig. 4 is shown the first-order chart using the seven-ordinate rule with half end ordinates. It will be seen that the distribution of the ordinates is such as to determine the curve very accurately.

It is evident that the foregoing rules by no means exhaust the possibilities. Rules might be devised having an even number of ordinates, use other multiples than one-half, rules of more than seven ordinates, etc., etc. It is believed, however, that the foregoing three-ordinate, five-ordinate, and seven-ordinate rules will cover all the practical requirements.

In practice, for the analysis of such curves as the turning-effort curve of internal-combustion engines, we customarily use the seven-ordinate rule for the first-order component, the five-ordinate rule for the second order, and the three-ordinate rule or the Fischer Hinnen rule for components of any higher order.

It is difficult to appraise the accuracy of approximate rules of harmonic analysis. This depends to a large extent upon the particular curve being analyzed.

The error in the foregoing rules may be expressed as a function of the higher components which are odd multiples of the order under consideration, but no clear idea of the accuracy of the rules would be given by such equations. In curves with high-order components of large amplitude (ripples) particular care must be taken, and any of the approximate methods of analysis may fail to give accurate results for the low-order components. It is noted that if the rules are applied to analyze a sine curve, the actual amplitude of which is unity, the three-ordinate rule gives an amplitude of 0.9925; the five-ordinate an amplitude of 1.00000723 and the seven-ordinate an amplitude of 1.0000231, which does not imply that in actual use the seven-ordinate rule is less accurate than the five-ordinate rule.

The author is indebted to Frederick Porter for assistance in the numerical solution of the equations given in this paper. More accurately the spacings are:

For the three-ordinate rule

$$x_1 = 0.266526638h$$

For the five-ordinate rule with half end-ordinates

$$x_1 = 0.165155076h$$
$$x_2 = 0.367257584h$$

For the seven-ordinate rule with half end-ordinates

$$x_1 = 0.123223004h$$
$$x_2 = 0.221410966h$$
$$x_3 = 0.394629380h$$

Thermal Stresses in Plates[1]

By JOHN L. MAULBETSCH,[2] CANTON, OHIO

The author presents solutions of the problem of thermal stresses in thin plates of uniform thickness with simply supported edges when the temperature varies only along the thickness of the plate. For the case of polygonal-shaped plates it is shown that the solution can be deduced from the problem of the torsion of prismatical bars, the cross section of which has the same shape as the plate. The exact solutions for cases of equilateral triangular and square plates are given. Although only the case of small deflections is considered, its limitations are treated in detail.

Introduction

IF A PLATE of uniform thickness has its two faces kept at different uniform temperatures, there will be a flow of heat from one face to the other, and for a homogeneous material, there will be a temperature distribution varying linearly over the thickness of the plate. If the plate is free of constraints, there will be, in general, no stresses resulting from such nonuniform heating. Stresses will be produced if displacements of the

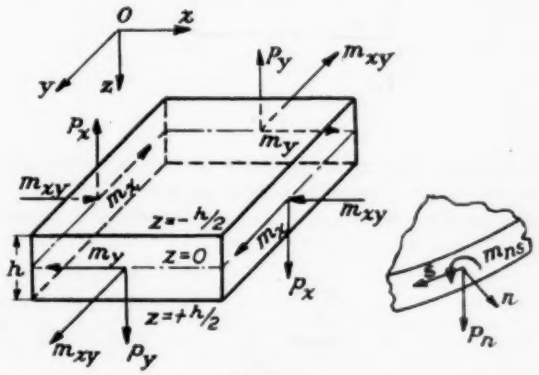

FIG. 1

plate are prevented, for instance, by some type of supports along the edges.[3] In this paper thin plates with simply supported edges are considered.

The application of the results is limited by the usual assumptions made in the theory of thin plates with small deflections. The assumptions are: (1) That the material is homogeneous, isotropic and follows Hooke's law, (2) that straight lines initially normal to the middle surface remain straight and normal to that surface after bending, and (3) that deflections are small compared to the thickness.

The following nomenclature will be used:

t_o = difference of temperature between the upper and lower faces of the plate. This temperature difference is positive if the temperature of the lower face is greater than the temperature of the upper face

x, y, z = coordinate axes. The middle plane of the initially flat plate is chosen as the x-y plane. The lower face of the plate is the plane $z = +h/2$, and the upper face $z = -h/2$

w = deflection of the plate. This deflection is positive when it occurs in the direction of the positive z-coordinate

α = coefficient of thermal expansion

E = modulus of elasticity

ν = Poisson's ratio

$D = Eh^3/12(1-\nu^2)$ = flexural rigidity of the plate

m_x, m_y = bending moments per unit length

m_{xy}, m_{ns} = twisting moment per unit length

p_x, p_y, p_n = shearing forces per unit length

The positive directions of moments and forces are shown in Fig. 1.

Thermal Stresses in Plates With Simply Supported Edges

Under nonuniform heating, a plate with free edges is bent to a spherical surface. This bending can be eliminated by applying uniformly distributed bending moments along the edges of the plate. When the plate is held flat, let it be fastened to simple supports along the edges, and then let the applied couples be removed. The removal of these couples will produce some bending in the plate, and the stresses due to this bending, together with the stresses produced initially by the uniformly distributed couples, will represent the thermal stresses which are produced in the plate due to nonuniform heating.

Thus, the problem of thermal stresses in plates with simply supported edges is divided into (1) the determination of stresses in a plate free from constraints produced by uniformly distributed couples, and (2) the determination of stresses in a simply supported plate submitted to couples uniformly distributed along the edges. The first problem can be solved readily, but the second requires, in the case of plates of polygonal shape, solution of a differential equation of the second order.[4] The same type of differential equation occurs also in the torsion problem of prismatical bars and in the one of the deflection of membranes. Solutions are known for these cases and can be used in the cases considered in this paper.

Thermal Stresses in an Equilateral Triangular Plate Simply Supported at the Edges. Let a be the height of the triangle and x and y be the coordinate axes as shown in Fig. 2. The deflection w due to nonuniform heating is found, as shown in Appendix 2, to be

$$w = -\frac{(1+\nu)}{2}\frac{\alpha t_o}{h}\left[\frac{(x^2+y^2)}{2} - \frac{(x^3-3xy^2)}{2a} - \frac{(2a^2)}{27}\right] \quad \ldots [1]$$

The bending and twisting moments are

Presented at the National Applied Mechanics Meeting of The American Society of Mechanical Engineers held at the University of Michigan, Ann Arbor, Mich., June 18–19, 1935.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until February 10, 1936, for publication at a later date.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[4] See Appendix 1.

$$\left.\begin{aligned} m_x &= -(1/24)\ \alpha t_o Eh^2\ (1 + 3x/a) \\ m_y &= -(1/24)\ \alpha t_o Eh^2\ (1 - 3x/a) \\ m_{xy} &= (1/24)\ \alpha t_o Eh^2\ (3y/a) \end{aligned}\right\} \quad \ldots\ldots\ldots [2]$$

In the case of plates of polygonal shape, as is shown in Appendix 1, the shearing forces p_x and p_y vanish, and the sum of the bending moments m_x and m_y is constant at every point of the plate and is equal to $-Et_o h^2/12$.

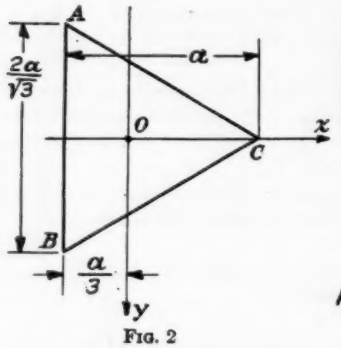

FIG. 2

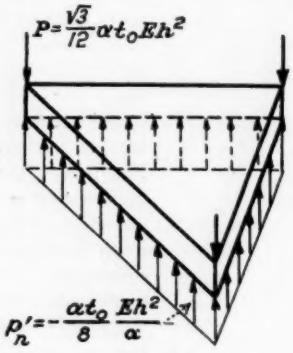

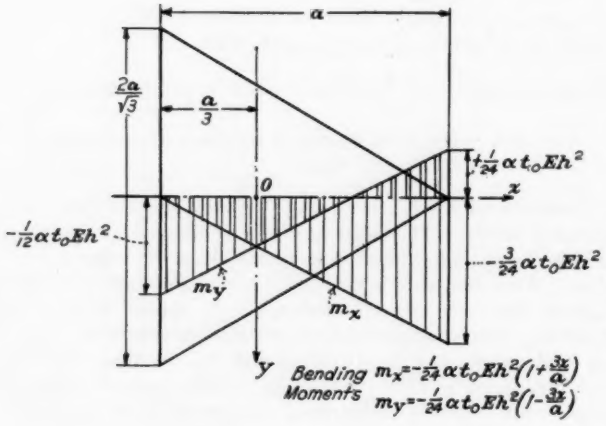

FIG. 3

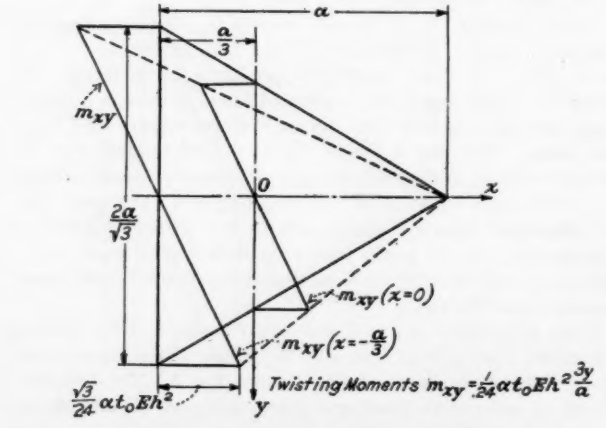

FIG. 4 DISTRIBUTION OF BENDING AND TWISTING MOMENTS IN EQUILATERAL TRIANGULAR PLATE

These expressions do not contain ν, that is, thermal stresses in such plates are independent of Poisson's ratio. The moments m_x, m_y, and m_{xy} depend only on the coefficient of linear expansion and on the modulus of elasticity E of the material, for a plate of definite dimensions a and h and for a certain temperature difference t_o.

Along the boundary of the equilateral triangular plate, there is a uniform distribution of reaction forces of intensity $(-\alpha t_o/8)(Eh^2/a)$ and at each corner there acts a concentrated reaction $(\sqrt{3}/12)\alpha t_o Eh^2$ as shown in Fig. 3. This system of boundary forces is in equilibrium.

The variations of m_x, m_y, and m_{xy} over the plate are shown in Fig. 4. The bending moments have the largest values at the corners. Therefore, since the stresses are proportional to the moments, the greatest tensile and compressive stresses are also at the corners. In the case of brittle materials such as glass, the failure of which can be predicted by means of the maximum-stress theory, cracks due to nonuniform heating would be expected to develop at these points. In the case of ductile materials such as steel, the maximum-shear theory applies, and it can be seen that the maximum shearing stress occurs also at the corners. Yielding of the material will therefore start at these points.

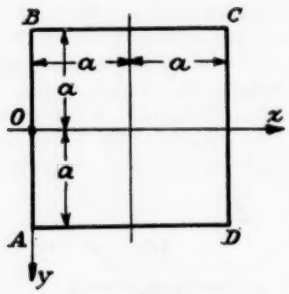

FIG. 5

Square Plate. Let $2a$ be the length of the sides of the square and let the system of coordinates be as shown in Fig. 5. The expressions for the deflection and moments, as derived in Appendix 2, are

$$w = \frac{16}{\pi^3} a^2 (1 + \nu) \frac{\alpha t_o}{h} \sum_{n = 1,3,5\ldots}^{\infty} \frac{1}{n^3} \left[1 - \frac{\cosh (n\pi y/2a)}{\cosh (n\pi/2)} \right] \times \sin \frac{n\pi x}{2a} \quad \ldots\ldots [3]$$

$$\left.\begin{aligned} m_x &= -(E/3\pi) h^3 \alpha t_o\ S_1 \\ m_y &= -(E/3\pi) h^3 \alpha t_o\ [(\pi/4) + S_1] \\ m_{xy} &= (E/3\pi) h^3 \alpha t_o\ S_2 \end{aligned}\right\} \quad \ldots\ldots [4]$$

In Equations [4]

$$S_1 = \sum_{n = 1,3,5\ldots}^{\infty} \frac{1}{n} \left[\frac{\cosh (n\pi y/2a)}{\cosh (n\pi/2)} - \frac{e^{n\pi y/2a}}{e^{n\pi/2}} \right] \cos \frac{n\pi x}{2a} + \frac{1}{4} \log \frac{\cosh [(\pi/2) - (\pi y/2a)] + \cos (\pi x/2a)}{\cosh [(\pi/2) - (\pi y/2a)] - \cos (\pi x/2a)}$$

$$S_2 = \sum_{1,3,5\ldots}^{\infty} \frac{1}{n} \left[\frac{\sinh (n\pi y/2a)}{\cosh (n\pi/2)} - \frac{e^{n\pi y/2a}}{e^{n\pi/2}} \right] \cos \frac{n\pi x}{2a} + \frac{1}{4} \log \frac{\cosh [(\pi/2) - (\pi y/2a)] + \cos (\pi x/2a)}{\cosh [(\pi/2) - (\pi y/2a)] - \cos (\pi x/2a)}$$

The distribution of m_x, m_y, and m_{xy} is shown in Figs. 6 and 7. It is seen that the maximum bending moments occur along the

edges of the plate and the largest twisting moments near the corners. The reactions of the supports along the edges of the plate are illustrated in Fig. 8. Due to symmetry the same conditions exist along all four edges of the square plate. Between points B and B_1 there will be a distribution of reaction forces of intensity

$$p'n = -\frac{E}{6}\alpha t_o \frac{h^2}{a}\left[\sum_{1,3,5\ldots}^{\infty}\left(\tanh\frac{n\pi}{2} - 1\right)\sin\frac{n\pi x}{2a} + \frac{1}{2\sin(\pi x/2a)}\right] \quad \ldots\ldots\ldots [5]$$

The distribution of forces near the corners is treated in Appendix 2. It is shown that over a distance c from the corners, their resultant is

$$P_{AB} = (m_{xy})_{\substack{x=c \\ y=a}} \quad \ldots\ldots\ldots [6]$$

and, relative to point B, their resultant moment is

$$M_{AB} = \frac{2}{3\pi^2} Eh^3\alpha t_o \sum_{1,3,5\ldots}^{\infty}\frac{1}{n^3}\tanh\frac{n\pi}{2}\sin\frac{n\pi c}{2a} \quad \ldots\ldots [7]$$

The distance c from the corner, along which the exact distribution of forces is unknown may be taken equal to the thickness of the plate, since it is usual to assume in the theory of thin

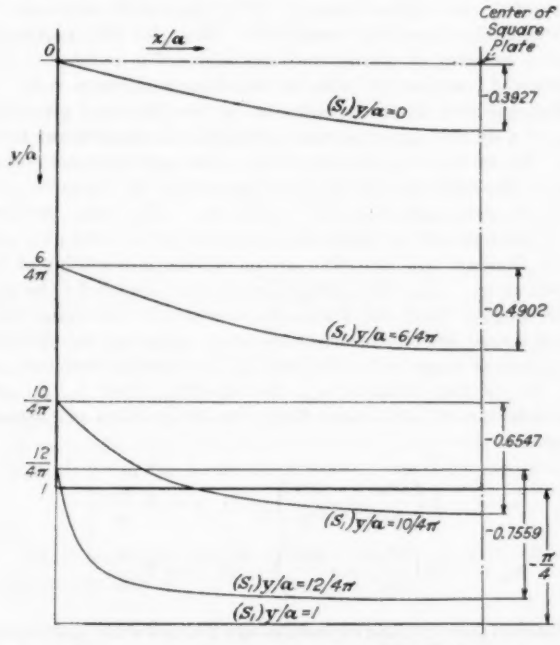

FIG. 6 DISTRIBUTION OF S_1 OVER ONE QUADRANGLE OF THE SQUARE PLATE

(Bending moments: $m_x = -[E/3\pi]h^3\alpha t_o S_1$ and $m_y = -[E/3\pi]\alpha t_o h^2[(\pi/4) + S_1]$.)

plates that the stress distribution is not given correctly by the mathematical theory for points situated at distances from the edges less than the thickness of the plate. If there is yielding of the material near the corners, then the distance c must be taken up to the point where yielding begins if this distance is larger than the thickness of the plate. The investigation of the danger of yielding of the material can be made only for specific dimensions, material, and temperatures.

CONCLUSIONS

The stresses σ_x, σ_y, and τ_{xy} vary linearly over the thickness of the plate and their maximum values occur at the upper and lower faces of the plate. They are determined by means of the known relations[5]

$$\sigma_x = \pm 6(m_x/h^2),\ \sigma_y = \pm 6(m_y/h^2),\ \tau_{xy} = \pm 6\,(m_{xy}/h^2)$$

In the cases of triangular and rectangular plate the moments

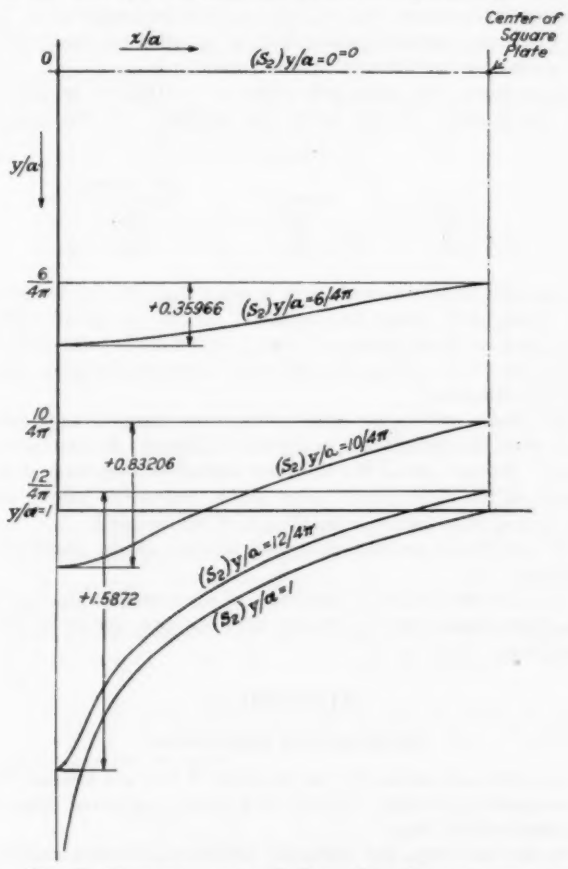

FIG. 7 DISTRIBUTION OF S_2 OVER ONE QUADRANGLE OF THE SQUARE PLATE

(Twisting moment $m_{xy} = [E/3\pi]h^3\alpha t_o S_2$.)

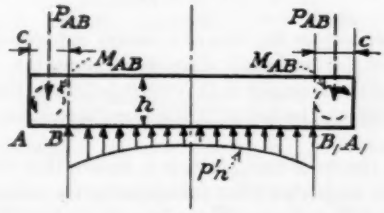

FIG. 8

are proportional to h^2, hence the thermal stresses will be independent of the thickness h. They are proportional to the coefficient of linear expansion α, the modulus of elasticity E and the difference of temperature t_o. However, the values of t_o are larger in thick plates than in thin plates for the same difference in gas temperatures,[6] so that the thicker the plate the greater the thermal stresses.

[5] "Die Elastische Platten," by A. Nadai, Julius Springer, Berlin, Germany, 1925.

[6] The difference of temperature t_o is not the difference of temperatures between the fluids or gases in contact with the faces of the

The results derived apply only to the case of deflections which are small compared to the thickness of the plate. In the case of the square plate, the maximum deflection occurs at the center of the plate, and from Equation [3]

$$w_{max}/h = (4/\pi^3)\,(2a/h)^2\,(1+\nu)\,\alpha t_o\,0.57107$$

It is seen that for a given material, the ratio w_{max}/h is proportional to $(2a/h)^2$ and to the difference of temperature t_o. Assuming, for instance, that w_{max}/h must not be greater than $^1/_2$, the maximum admissible value for t_o up to which the theory may be applied can be calculated in functions of $2a/h$.

Assuming a steel plate and taking $\alpha = 0.056/10^4$ in. per in. per deg F and $\nu = 0.3$, Table 1 is obtained. In the case of

TABLE 1

$2a/h$	t_o max, F	Max stress, lb per sq in.
50	375	31500
100	94	7900
200	23	1900

plates with small ratios of $2a/h$, smaller than 100 for instance, the theory will always be applicable because to obtain values of t_o such as those given in Table 1, it would be necessary to have very large temperature differences between the gases separated by the plate.[7]

For plates with larger ratios of $2a/h$ the theory is applicable only when the difference of temperature between the two faces is small. In such plates the thickness cannot be very large if the length of the plate is to be kept within reasonable values, and the drop of temperature in the plate itself will be small.

If concrete is considered instead of steel similar results are obtained.

It is seen then that the limitation of the theory to the case of small deflections does not greatly limit its applicability to practical cases.

Appendix 1

Mathematical Derivations

As explained previously the problem of thermal stresses due to nonuniform heating of a plate with simply supported edges is divided into two steps.

In the first step, the uniformly distributed couples, counteracting the thermal bending of the free plate produce at every point of the plate a bending moment[3]

$$M = -(1+\nu)\,D(\alpha t_o/h) \qquad [8]$$

The second step is the case of a simply supported plate submitted to couples uniformly distributed along the edges. The magnitude of these couples is $(1+\nu)\,D\,(\alpha t_o/h)$ so that when the second step follows the first step, the edges become free of bending moments.

From the theory of thin plates it is known that the deflection w of a simply supported plate submitted to the action of couples uniformly distributed along the edges must satisfy the differential equation[8]

$$\frac{\partial^4 w}{\partial x^4} + 2\,\frac{\partial^4 w}{\partial x^2 \partial y^2} + \frac{\partial^4 w}{\partial y^4} = 0 \qquad [9]$$

with the boundary condition $w = 0$

$$\frac{\partial^2 w}{\partial n^2} + \nu\,\frac{\partial^2 w}{\partial s^2} = -(1+\nu)\,\frac{\alpha t_o}{h}$$

where n indicates the direction of the outer normal to the boundary and s is the tangent to boundary of the plate, as shown in Fig. 1.

If the plate is of polygonal shape, the partial differential equation of the fourth order may be reduced to one of the second order.[8] It is shown that a polygonal boundary consists of straight lines along which $(\partial^2 w/\partial s^2) = 0$, since $w = 0$ at the boundary. Therefore, along a straight boundary, the second boundary conditions are

$$(\partial^2 w/\partial n^2) = -(1+\nu)\,\alpha t_o/h$$

but[9]

$$\frac{\partial^2 w}{\partial n^2} + \frac{\partial^2 w}{\partial s^2} = \frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 u}{\partial y^2}$$

and since $(\partial^2 w/\partial s^2) = 0$

$$\frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial y^2} = -(1+\nu)\alpha t_o/h \qquad [10]$$

This equation needs to be satisfied along the boundary of the plate only. However, if w satisfies this equation over the whole region with the boundary condition $w = 0$, it is seen that w will also satisfy the original Equation [9] of the fourth order and its corresponding boundary conditions. Thus, for this particular case of bending of plates, the calculation of w reduces to the solution of Equation [10] with the boundary condition $w = 0$.

Superposition of the second step on the first step gives the case of a simply supported plate submitted to nonuniform heating. In the first step the plate remains flat, and the total deflection is the deflection obtained by integration of Equation [10] with the prescribed boundary conditions. The same problem of thermal stresses in plates was treated by N. Yamaguti and R. G. Olsson,[10] who derived a partial differential equation of the fourth order. The first author also gave a solution for the case of rectangular plate, but it contains very slowly converging series which do not lend themselves to accurate numerical calculations. By means of known relations[5] between the bending moments m_x, m_y, the twisting moment m_{xy}, the shearing forces p_x, p_y, and the deflection w, one obtains finally for the problem of thermal stresses

$$\left.\begin{aligned} m_x &= -D\left(\frac{\partial^2 w}{\partial x^2} + \nu\,\frac{\partial^2 w}{\partial y^2}\right) - (1+\nu)\,D\,\frac{\alpha t_o}{h} \\ m_y &= -D\left(\frac{\partial^2 w}{\partial y^2} + \nu\,\frac{\partial^2 w}{\partial x^2}\right) - (1+\nu)\,D\,\frac{\alpha t_o}{h} \end{aligned}\right\} \qquad [11]$$

the second parts in these expressions are the uniformly distributed moments of the first step

$$m_{xy} = -D\,(1+\nu)\,\frac{\partial^2 w}{\partial x \partial y} \qquad [12]$$

---

plate, but only a fraction of it, due to the drop of temperature in the layers of fluids touching the faces. Assuming still air on both sides of a steel plate, one finds that t_o is 1/300 of the difference of temperatures between the gases if the plate is 1 in. thick, if the plate is 6 in. thick, then this ratio is 1/27.

[7] It is to be noted that the theory must be applied to cases where the maximum temperature of the plate is still low enough to have the material under conditions satisfying the assumptions of the theory of elasticity.

"Die Biegung der rechteckigen Platte veränderlichen Dicke," by R. G. Olsson, Dissertation, Berlin, 1932.

$$\left.\begin{aligned} p_x &= -D\frac{\partial}{\partial x}\left(\frac{\partial^2 w}{\partial x^2}+\frac{\partial^2 w}{\partial y^2}\right) \\ p_y &= -D\frac{\partial}{\partial y}\left(\frac{\partial^2 w}{\partial x^2}+\frac{\partial^2 w}{\partial y^2}\right) \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [13]$$

It is to be noted that for a polygonal plate one has because of Equations [13] and [10]

$$p_x = p_y = 0$$

that is, the shearing forces are zero.

Also adding m_x and m_y and making use of Equation [10]

$$m_x + m_y = -E\,\alpha t_0 h^2/12$$

The sum of the bending moments m_x and m_y is constant at every point of the plate and is independent of Poisson's ratio.

The reactions of the supports along the edges should represent the twisting moments. These moments can be replaced by a distribution of shearing forces

$$p_n' = -\partial m_{ns}/\partial s \ldots\ldots\ldots\ldots\ldots\ldots [14]$$

and by concentrated forces at the corners. If m_1 and m_2 are the twisting moments at a corner of the plate, the concentrated force P at this corner is

$$P = m_1 - m_2 \ldots\ldots\ldots\ldots\ldots\ldots [15]$$

The rules for the sign of the moments and forces in Equations [14] and [15] are: The twisting moment m_{ns} is positive when the vector m_{ns} representing the twisting moment in a right-handed system coincides with the outer normal to the boundary, and the forces p'_n and P are positive when their direction coincides with the positive z-axis.

Appendix 2

Equilateral-Triangular Plate

Referring to Fig. 2, the solution of Equation [10] in the case of an equilateral triangle, from the problem of torsion, is

$$w = -\frac{(1+\nu)}{2}\frac{\alpha t_0}{h}\left[\frac{(x^2+y^2)}{2} - \frac{(x^3-3xy^2)}{2a} - \frac{2a^2}{27}\right]$$

By means of Equations [11] and [12], the expressions for the moments, Equation [2], are derived. The boundary conditions, shown in Fig. 3, are determined by Equations [14] and [15].

Square Plate

Again using the solution of Equation [10] as obtained in the torsion problem

$$w = \frac{16}{\pi^3}(1+\nu)a^2\frac{\alpha t_0}{h}\sum_{n=1,3,5\ldots}^{\infty}\frac{1}{n^3}\left[1-\frac{\cosh(n\pi y/2a)}{\cosh(n\pi/2)}\right]\sin\frac{n\pi x}{2a}$$

and from Equations [11] and [12]

$$m_x = -\frac{E}{3\pi}h^2\alpha t_0\sum_{n=1,3,5\ldots}^{\infty}\frac{1}{n}\frac{\cosh(n\pi y/2a)}{\cosh(n\pi/2)}\sin\frac{n\pi x}{2a} \ldots [16]$$

$$m_y = +\frac{E}{3\pi}h^2\alpha t_0\sum_{n=1,3,5\ldots}^{\infty}\left[\frac{1}{n}\frac{\cosh(n\pi y/2a)}{\cosh(n\pi/2)}\sin\frac{n\pi x}{2a} - \frac{\pi}{4}\right] \ldots [17]$$

$$m_{xy} = \frac{E}{3\pi}h^2\alpha t_0\sum_{n=1,3,5\ldots}^{\infty}\frac{1}{n}\frac{\sinh(n\pi y/2a)}{\cosh(n\pi/2)}\cos\frac{n\pi x}{2a} \ldots\ldots [18]$$

As in the case of the triangular plate, these expressions are independent of Poisson's ratio.

N. Yamaguti[10] calculated the values of the moments by taking the first five terms of these series and obtained errors as large as 5 per cent in the numerical values. These series may be transformed so as to improve the accuracy of the computations. It is done as follows:

Bending Moments m_x and m_y. It is noted that with increasing values of n, the terms of the series m_x as given in Equation [16] differ less and less from the terms of[11]

$$\sum_{n=1,3,5\ldots}^{\infty}\frac{1}{n}\frac{e^{n\pi y/2a}}{e^{n\pi/2}}\sin\frac{n\pi x}{2a} = \frac{\tan^{-1}}{2}\frac{\sin(\pi x/2a)}{\sinh[(\pi y/2a)-(\pi/2)]} \ldots [19]$$

An accurate approximation of the sum of the series m_x can be found by taking the sum of the series given in Equation [19] and adding to it a correction due to the difference in value of the terms of the two series. This difference is[12]

$$\sum_{n=1,3,5\ldots}^{\infty}\frac{1}{n}\left[\frac{\cosh(n\pi y/2a)}{\cosh(n\pi/2)} - \frac{e^{n\pi y/2a}}{e^{n\pi/2}}\right]\sin\frac{n\pi x}{2a}$$

This new series is rapidly convergent and the first three terms are sufficient to give an accuracy of 0.01 per cent.

The expression for the bending moment m_x is then as given by Equations [4].

The values of the bending moment m_y follow from those of m_x since the sum of m_x and m_y is a constant at every point of the plate.

Twisting Moment m_{xy}. The series of m_{xy} as given in Equation [18] may be similarly transformed into a better converging series, if one makes use of[11]

$$\sum_{n=1,3,5\ldots}^{\infty}\frac{1}{n}\frac{e^{n\pi y/2a}}{e^{n\pi/2}}\cos\frac{n\pi x}{2a} = \frac{1}{4}\log\frac{\cosh[(\pi/2)-(\pi y/2a)]+\cos(\pi x/2a)}{\cosh[(\pi/2)-(\pi y/2a)]-\cos(\pi x/2a)}$$

One obtains then the expression given in Equations [4] for m_{xy}.

To find the boundary forces, consider the edge AD shown in Fig. 5 where $y = a$ and $0<x<a$. Due to symmetry the conditions along the other edges of the square plate will be identical.

From Equations [4], one obtains for the forces at the edge

$$p_n' = -\frac{E}{6}\alpha t_0\frac{h^2}{a}\left[\sum_{n=1,3,5\ldots}^{\infty}\left(\tanh\frac{n\pi}{2}-1\right)\sin\frac{n\pi x}{2a} + \frac{1}{2\sin(\pi x/2a)}\right]$$

[11] "Elementary Treatise on Fourier's Series, and Spherical, Cylindrical and Ellipsoidal Harmonics With Application to Problems in Mathematical Physics," by W. E. Byerly, Ginn & Company, Boston, Mass., 1893, p. 100.

[12] This procedure is justifiable since the two series are uniformly convergent for an interval $\delta \leq x \leq 2\pi - \delta$, where δ is a quantity satisfying the condition $0 < \delta < \pi$. See "Theorie und Anwendung der Unendlichen Reihen," by K. Knopp, Julius Springer, Berlin, Germany, 1930, p. 360.

The variation of $(p_n')_{y=a}$ as given by this equation is shown in Fig. 8. The series is uniformly convergent for an interval $\delta \leqq x \leqq 2\pi - \delta$ with $0 < \delta < \pi$. When δ is made very small, x approaches the value 0 or $2a$, and p_n' increases without limit.

The concentrated forces at the corners cannot be obtained from Equation [15], for when x approaches 0 or $2a$, the value of the

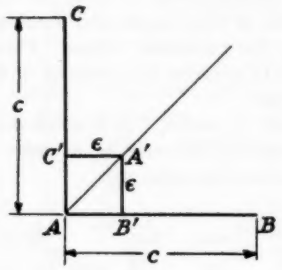

FIG. 9

twisting moment tends to approach infinity. The infinite forces given by the mathematical solution at the corners cannot exist in practical cases, but some indications of the conditions near these points can be derived from this solution.

Consider the element $AB'A'C'$ of side ϵ in Fig. 9 as being separated from the plate. If the stress conditions within the rest of the plate are not to be altered, the internal stresses existing along $B'A'$ and $A'C'$ prior to removal of the element must be considered as applied forces. The vertical forces resulting from the distribution of forces along $AB'A'C'C$ may be determined. When ϵ is made smaller and smaller this force will be the resultant of the forces acting along BA and AC. Because of symmetry, the resultant of the forces distributed along BA is equal to the resultant along AC so that the resulting force acting on BA may be determined. Hence

$$P_{AB} = (m_{xy})_{\substack{x=c \\ y=a}}$$

The moment M_{AB} of the resultant force P_{AB} relative to point B must be equal to the sum of the twisting moments m_{xy} distributed along AB, since the system of forces p_n' and P_{AB} must be equivalent to the system of twisting moments m_{xy}. Therefore

$$M_{AB} = \frac{2}{3\pi^2} Eh^3\alpha t_o \sum_{n=1,3,5\ldots}^{\infty} \frac{1}{n^2} \tanh \frac{n\pi}{2} \sin \frac{n\pi c}{2a}$$

ACKNOWLEDGMENTS

The Strength and Stiffness of Cylindrical Shells Under Concentrated Loading

By R. J. ROARK,[1] MADISON, WIS.

In certain structures and under certain conditions of use, cylindrical or nearly cylindrical shells are subjected to concentrated loading. This paper presents empirically derived formulas for the stresses and deflections produced by such loading, and describes the tests on which these formulas are based.

INTRODUCTION

IN CERTAIN structures and under certain conditions of use, cylindrical or nearly cylindrical shells are subjected to concentrated loading. Examples of this are found in standpipes or water tanks with internal spider bracing, in jacketed pressure containers and boilers, in airplane fuselages of the monocoque type, and in submarine hulls. Usually the magnitudes of the forces involved are more or less conjectural, and the degree of uncertainty as to form, area over which the load is distributed, and boundary conditions, is such as to make the development and application of a precise theoretical method for calculating stresses and deflections impracticable. It would seem more expedient to resort to empirical methods based on experiment.

In connection with tests to determine the bending stresses present in partly filled pipes of large diameter, the author made use of specimens and equipment at hand to investigate the effect of concentrated loading. From the data secured, empirical formulas have been developed which are believed to be of value in predicting the stress and deflection to be expected from the application of widely separated concentrated loads to a thin cylindrical shell whose length is great in comparison with its diameter. It is the purpose of this paper to describe these tests and to present the formulas based thereon.

Test Specimens

For investigating stresses and local deformations, two large steel cylinders were used. One of these was a specially constructed, longitudinally welded cylinder 0.129 in. thick, 23 in. diameter, and 10 ft long, with open ends. The other was a segment of seamless rolled pipe, 0.330 in. thick, 23.5 in. diameter, and 12 ft long. This second specimen was tested first with open ends and afterward with constrained ends. Constraint was secured by welding plates, $^1/_8$ in. thick and 3 ft square, against the end of the pipe and then cutting holes in these plates of nearly the same diameter as the pipe, leaving, in effect, wide flanges on the ends of the pipe sufficiently rigid to prevent appreciable deformation. Fig. 1 represents this test piece with flanges attached.

The first cylinder described was very nearly uniform in thickness; the second, though regular in outline, varied considerably in thickness, measurements ranging from 0.318 in. to 0.331 in. It was therefore necessary to cut holes and make local measurements at the point of loading to ascertain the thickness there, and the results for stress at points remote from the load are in some measure vitiated by uncertainty as to the exact thickness of metal at those points.

For further study of deformations, two long seamless brass tubes were used. One of these was 12 ft long, 2.5 in. diameter, and 0.029 in. thick; the other was 6 ft long, 3 in. diameter, and 0.065 in. thick. It is believed that because of the great length of these tubes in comparison with their diameters, end effects were eliminated, and conditions secured comparable to those in a cylinder of infinite length.

Method of Testing

Steel Cylinders. In order to eliminate the effect of variation in the supporting reactions and in order to secure symmetry it was desired to employ a loading that comprised two equal and opposite concentrated forces, acting at points diametrically opposite, and so applied as to produce no change in the forces

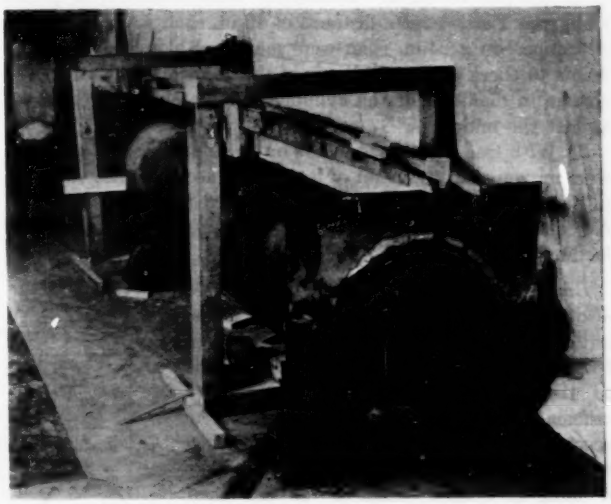

Fig. 1 Steel Cylinder With Flanges Used to Determine Effect of End Constraint

that supported the specimen. This was accomplished by means of the system of levers and deadweights shown in Fig. 2. The specimen was supported at the ends by light rods. The lever system, constructed of light planking, was balanced by means of counterweights W_1 and W_2 so that when separately supported at C it hung free in balance. A deadweight W, hung on the knife edge at D, tended to spread the levers, producing equal and opposite forces at A and B which were transmitted through round-ended pins to the inner surface of the cylinder. The apparatus was carefully calibrated in a testing machine of small capacity, and the load-multiplication factor was found to agree very closely with that calculated from the dimensions of the lever arms, showing that there was very little friction and that distortion and binding had little effect. The deadweight W was so chosen as to make each of the applied loads 120 lb for the thin cylinder and 620 lb for the thick cylinder, these loads

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until October 30, 1935, for publication at a later date.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

being judged the greatest that could be used without danger of overstressing.

Strains were measured by means of Huggenberger extensometers, and a gage length of $^1/_2$ in. was used except at points remote from the load, where a gage length of 1 in. was used. For purposes of reference, the top element of the cylinder was taken as the Y-axis and the circumference at mid-length as the X-axis. In accordance with this, longitudinal stresses are

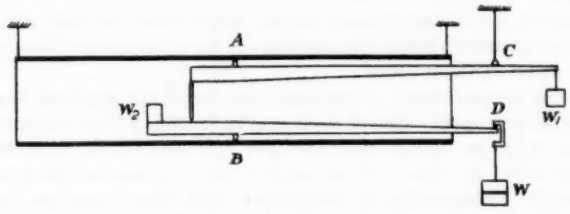

FIG. 2 METHOD OF LOADING USED IN TESTING STEEL CYLINDERS FOR STRESS AND DEFLECTION

herein denoted by the subscript y and circumferential stresses by the subscript x.

Tests and strain measurements were made as follows:

1 With load at $x = 0$, $y = 0$, x and y strains were measured at points along the Y-axis from the load to the end of the cylinder, and at points along the X-axis each way from the point of loading until bending vanished. Deflections were measured at points along the Y-axis over a distance of 10 in. each way, and center deflections on a 24-in. span were measured along adjacent elements to check the x coordinate of the point of inflection. The change in diameter of the cylinder was measured at each end and at the middle.

2 With load at various points on the Y-axis, x and y strains were measured at the point of loading, to ascertain the variation in maximum stress as the load approached the end of the pipe. No deflection measurements were taken for this off-center loading in the case of the steel pipes.

Brass Cylinders. The brass tubes were also subjected to equal and opposite loads, but on account of the small diameter of these specimens it was necessary to apply the loads to the outer surface. Fig. 3 represents schematically the method employed. The specimen was supported at the ends by counterweighted cords running over pulleys, so that it hung in neutral balance. It was then brought down until it contacted the round-pointed pin A, after which it was loaded by a dead load W placed on the yoke or frame Y, the pressure being transmitted to the specimen by the pin B, diametrically above A. This produced an equal and opposite reaction at A. Deflections at the point of loading were measured by the separately supported Ames dial C, the increment in the dial reading giving twice the actual deflection. Deflections at points away from the load were measured by two Ames dials mounted on a movable frame, one below and one above the specimen.

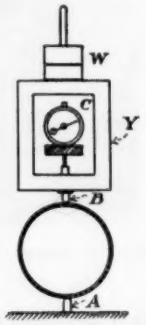

FIG. 3 METHOD OF LOADING USED IN TESTING BRASS TUBES FOR DEFLECTION

These specimens were used to study: (1) The deflection produced at various points along the loaded element when the load was applied at a point remote from the ends, and (2) the deflection produced at the load when the load was applied at various points, from the extreme end of the tube back to the point at which the deflection became practically the same as for loading at mid-length.

TEST RESULTS AND FORMULAS

STRESSES

The strain measurements, made over lengths of at least $^1/_2$ in., provided means of ascertaining only the average stresses over corresponding distances. Because of the rapid variation of stress near the load, it was necessary in some cases to estimate, from these average values, the probable value of the stress at definite points. This required certain assumptions as to the law of stress variation. After the assumptions are made, the method used for adjusting the average stresses, and the empirical formulas adopted, can best be considered jointly for each of the questions of stress intensity and distribution studied. These will now be enumerated in order.

(1) Variation of circumferential stress along the loaded circumference, or

$$s_x = f(x) \text{ at } y = 0, \text{ load at } x = 0, y = 0$$

(2) Variation of longitudinal stress along the loaded circumference, or

$$s_y = f(x) \text{ at } y = 0, \text{ load at } x = 0, y = 0$$

(3) Variation of circumferential stress along the loaded element, or

$$s_x = f(y) \text{ at } x = 0, \text{ load at } x = 0, y = 0$$

(4) Variation of longitudinal stress along loaded element, or

$$s_y = f(y) \text{ at } x = 0, \text{ load at } x = 0, y = 0$$

(5) Variation of circumferential and longitudinal stress at point of loading as load approaches end of cylinder, or

$$s_x \text{ max and } s_y \text{ max} = f(y) \text{ with load at } x = 0, y = y$$

(6) Effect of end constraint on stresses.

These six questions are now discussed in turn.

(1) $s_x = f(x)$ *at* $y = 0$. It appeared that the results obtained by the application of the theory of elasticity to the case of rectangular flat strips might be adapted to this case, since the tests showed that only a comparatively narrow strip along the loaded element of the cylinder was appreciably stressed. Nadai[2] and Timoshenko[3] discuss the problem of the flat strip, and Nadai gives formulas for finding the transverse stress s_x produced in a strip of infinite length by a concentrated load applied at mid-width which reduces to

$$M_x = [(1 + \theta)/4\pi]P \log (2a/\pi x) \quad [1]$$

$$\max M_x = [(1 + \theta)/4\pi]P \log(2a/\pi b) + (P/4\pi) \quad [2]$$

where M_x = transverse bending moment per linear inch, in-lb; θ = Poisson's ratio (here taken as 0.27 for steel); P = concentrated load, lb; a = width of strip, in.; x = distance from load, measured crosswise of the strip, and supposed to be very small, in.; b = radius of the circular area over which it is assumed that the nominally concentrated load is distributed, in.

Equation [1] was divided through by the section modulus of the unit strip, $^1/_6\ t^2$ (where t = thickness of the strip, in.) and written as

$$s_x = [KP \log(CR/x)]/t^2 \quad [3]$$

where R = radius of the cylinder, in., and K and C are constants to be determined empirically. It was found that both circum-

[2] "Über die Spannungsverteilung in einer durch eine Einzelkraft belasteten rechteckigen Platte," by A. Nadai, *Der Bauingenieur*, January 15, 1921, p. 11.

[3] "Über die Biegung der allseitig unterstutzen rechteckigen Platte unter wirking einer Einzellast," by S. Timoshenko, *Der Bauingenieur*, January 31, 1922, p. 51.

ferential and longitudinal strains practically vanished at $x = 2.5$ in., indicating for C a value of about 0.215. By setting Equation [3] equal to the measured stress, values of K for different values of x were determined, and the average of these was found to be 0.42. The values thus found for K and C inserted in Equation [3] give, as the adopted empirical formula for $s_x = f(x)$ at $y = 0$

$$s_x = [P/t^2][0.42 \log (0.215\, R/x)] \quad [4]$$

To obtain s_x at the load, the term $(1 + \theta)/4\pi$ in Equation [2] was replaced by 0.07 and the term $2a/\pi b$ by $0.215R/b$, to correspond with the empirically determined values used in Equation [4]. The resulting formula for maximum circumferential stress is

$$\max s_x = [P/t^2][0.42 \log (0.215R/b) + (6/4\pi)] \quad [5]$$

In Fig. 4 is plotted a graph obtained from Equations [4] and [5], evaluated for the load used in testing the thin cylinder and for the dimensions of the thin cylinder. The plotted points

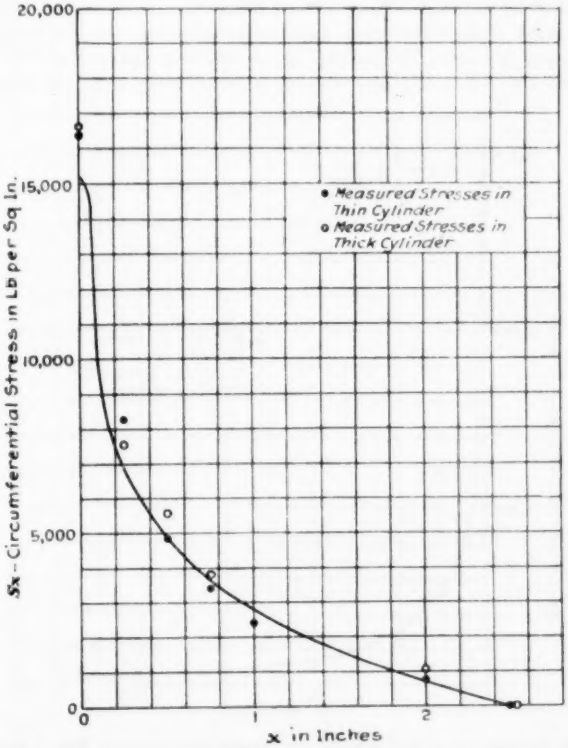

FIG. 4 CIRCUMFERENTIAL STRESS IN CYLINDRICAL SHELL RESULTING FROM CONCENTRATED LOAD. STRESS PLOTTED AS FUNCTION OF x, DISTANCE FROM LOAD MEASURED CIRCUMFERENTIALLY

indicate the measured stresses, the solid circles representing results secured with the thin cylinder, and the open circles results secured with the thick cylinder, these latter being the measured stresses multiplied by the factor $P't^2/Pt'^2$, where P and P' are the loads, and t and t' the thicknesses, for the thin and thick cylinders, respectively. For $x = 0$ the plotted point does not represent the average stress as measured over a gage length of $^1/_2$ in. centered on $x = 0$, $y = 0$; it represents the *estimated* stress at the point $x = 0$, $y = 0$, and was obtained from the average stress as follows: Equation [4] was plotted to a large scale for values of x up to 0.25 in. From this graph, it was found that the ratio of maximum stress (at $x = 0$) to the average stress (between $x = 0$ and $x = 0.25$) was 1.5. The measured stress over the $^1/_2$-in. gage length was therefore simply multiplied by 1.5 to give the value plotted in Fig. 4.

(2) $s_y = f(x)$ *at* $y = 0$. According to the analysis for flat strips previously referred to the values of s_x and s_y are equal at

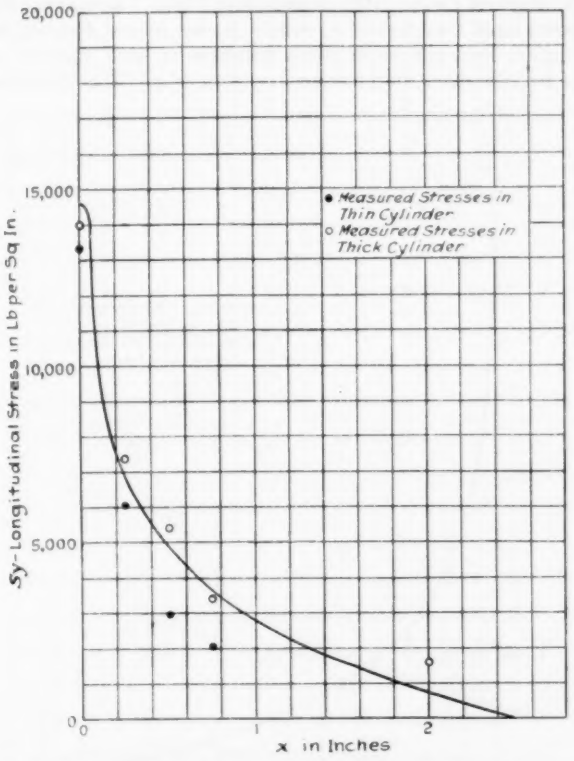

FIG. 5 LONGITUDINAL STRESS IN CYLINDRICAL SHELL RESULTING FROM CONCENTRATED LOAD. STRESS PLOTTED AS FUNCTION OF x, DISTANCE FROM LOAD MEASURED CIRCUMFERENTIALLY

any point except the point of loading, hence Equation [4] gives the longitudinal as well as the circumferential stress. For the point of loading, the formula for bending in the flat strip is

$$\max M_y = [(1 + \theta)/4\pi]P \log(2a/\pi b) + (\theta P/4\pi) \quad [6]$$

Making the same modifications as were made for the case of max M_x, we have

$$\max s_y = [P/t^2][0.42 \log(0.215R/b) + (6\theta/4\pi)] \quad [7]$$

When s_y was calculated by Equations [6] and [7] and plotted, the ratio of max s_y to the mean s_y over a gage length of $^1/_2$ in. was found to be 1.47. The curve of Fig. 5 is a graph of Equation [4] and Equation [7] and the plotted points represent experimentally determined values of s_y, the results obtained with the thin cylinder being indicated as before by solid circles and those obtained with the thick cylinder by open circles. The values at $x = 0$ were obtained by multiplying the mean stresses measured over a $^1/_2$-in. gage length there by the factor 1.47.

(3) $s_x = f(y)$ *at* $x = 0$. The analysis of the flat strip does not yield a formula that can be adapted for this case, and so, as in the cases subsequently discussed, an attempt was made to fit a purely empirical equation to the experimental results. It was considered necessary that the equation agree with Equation [4] at $y = b$ (that is, at the edge of the loaded area) and that it should represent with reasonable fidelity the stresses adjacent to the load; for points remote from the load the stresses are so small as to be of practically no consequence.

The equation adopted was

$$s_x = [P/t^2][0.42 \log(\beta R/y)] \quad [8]$$

where $\beta = 0.215 + 0.5\,[(y - b)/R]^{1/2}$

The graph of Equation [8] is plotted in Fig. 6. Because of the known rapid variation of s_x with x, it was judged desirable to estimate, from the mean stress measured at each value of y, the *probable* stress at the point $x = 0$, $y = y$. This was done

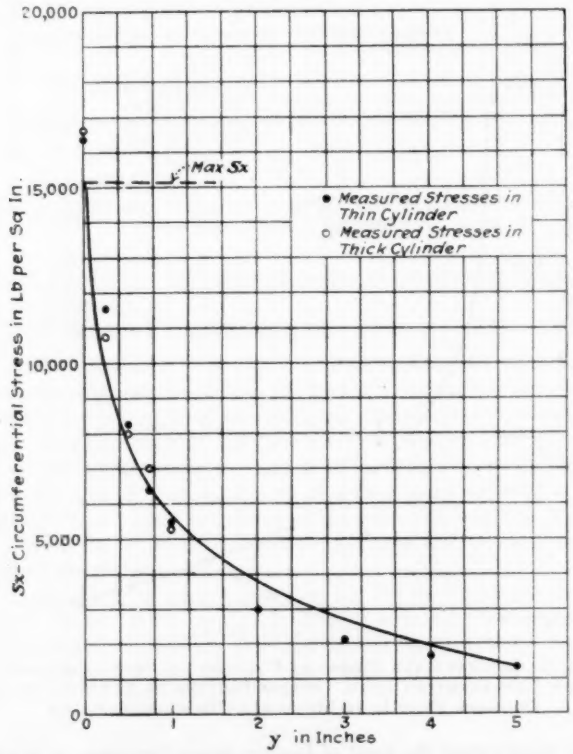

FIG. 6 CIRCUMFERENTIAL STRESS IN CYLINDRICAL SHELL RESULTING FROM CONCENTRATED LOAD. STRESS PLOTTED AS FUNCTION OF y, DISTANCE FROM LOAD MEASURED LONGITUDINALLY

by plotting the mean stresses s_x over $^1/_{\bar{4}}$-in. gage lines centered at $x = 0$, $^1/_4$, $^1/_2$, and $^3/_4$ in. The curve of estimated actual stress was then drawn in so as to be consistent with these mean values. This procedure was carried out for several different values of y and the ratio of s_x at $x = 0$ to mean s_x at $x = 0$, at any given place along the cylinder, was determined by interpolation from the several values thus obtained. The correction factors secured in this way ranged from 1.5 (at $y = 0$) down, approaching unity as y increased. The values of s_x thus arrived at are of course approximate, but it is believed that they represent the true stresses much better than do the mean stresses as measured.

(4) $s_y = f(y)$ *at* $x = 0$. The equation

$$s_y = [1 - 1.1(y/R)^{1/4}]s_x \quad [9]$$

was found to fit the test results fairly well. Fig. 7 shows a graph of this equation, and the plotted points represent the mean measured stresses, the same legend being followed as before. Because of the essentially straight-line character of the curve over short distances, the mean stresses are taken to represent the actual stresses with sufficient accuracy.

(5) s_x *max and* s_y *max* $= f(y')$ *with load at* $x = 0$, $y = y'$. Tests to determine the variation in maximum stresses as the load approached the end of the cylinder were made on the thin cylinder only. The measured mean stresses, corrected in each case by the proper factor (1.5 for s_x and 1.47 for s_y) are plotted on Fig. 8, and the equations adopted are graphed. These curves have the equations

$$\max s_x = \max s_{x0}[0.7\,R/(y' + b)]^{1/4} \quad [10]$$

$$\max s_y = \max s_{y0}(y'/0.2R)^{1/2} \quad [11]$$

where y' denotes the distance from the end of the cylinder to the load and max s_{x0} and max s_{y0} denote the maximum stresses produced by a load remote from the end of the cylinder, as given by Equations [5] and [7].

Equations [10] and [11] apply only for values of y' less than those which make max s_x = max s_{x0} and max s_y = max s_{y0} that is, Equation [10] applies only when $y' + b < 0.7R$ and Equation [11] applies only when $y' < 0.2R$.

(6) *Effect of End Constraint on Stresses.* The stresses at and near the load were found to be unaffected by end constraint except when the load was applied very near the ends. This would be expected from the results indicated in Fig. 8, which show that end effect vanishes within a short distance. Tests on the thick cylinder with constrained ends indicated that the maximum stresses produced by loading up to within a distance of 0.2 R from the end could be assumed approximately equal to those

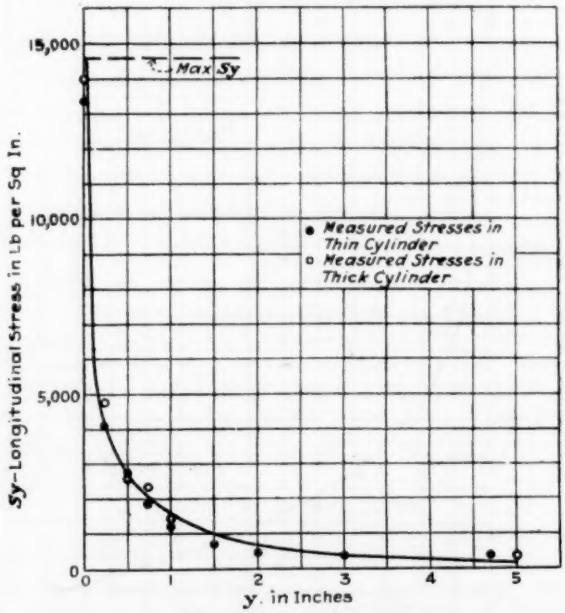

FIG. 7 LONGITUDINAL STRESS IN CYLINDRICAL SHELL RESULTING FROM CONCENTRATED LOAD. STRESS PLOTTED AS FUNCTION OF y, DISTANCE FROM LOAD MEASURED LONGITUDINALLY

produced by loading at or near mid-length, and that from that point to the end the stresses at the point of loading may be assumed to diminish linearly to zero.

DEFLECTIONS

The only laws of deflection for which formulas were sought were:

(*a*) The deflection d at any point (0, y) along the loaded element, with load remote from end of cylinder, and

(*b*) The deflection D at the point of loading, with the load applied at any point (0, y).

As has been explained, the steel cylinders were used to study the deflection adjacent to the point of loading, while the brass tubes were used to study the deflection at various distances

from the load, under conditions comparable to those in a cylinder of infinite length, and to study the influence of the position of the load on the maximum deflection.

(a) $d = f(y)$, *Load Remote From End of Cylinder.* It was thought that a strip along the loaded element of the cylinder might be regarded as a beam on an elastic foundation, the support being provided by the series of elastic hoops comprising successive segments of the shell. It was assumed that the deflection at the point of loading would be proportional to P and to the square of the radius, and inversely proportional to E and the cube of the thickness, that is, that $D = C(PR^2/Et^3)$, where C is an empirical constant. Comparison with test results gave 0.135 as an average value of C, and so the formula

$$D = 0.135PR^2/Et^3 \quad [12]$$

was adopted, as giving the deflection at the point of loading when the load is remote from the end of the cylinder.

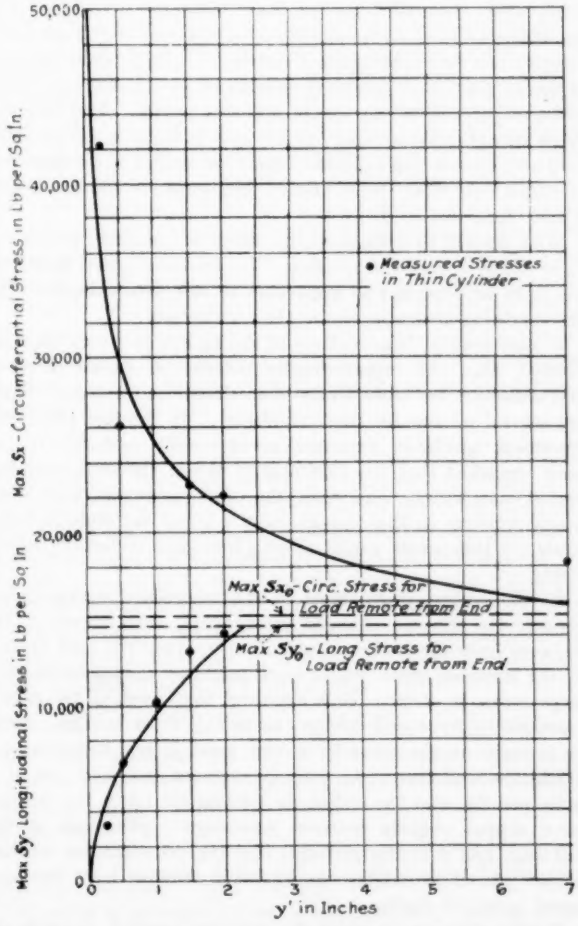

FIG. 8 MAXIMUM STRESSES IN CYLINDRICAL SHELL DUE TO CONCENTRATED LOAD. STRESSES PLOTTED AS FUNCTION OF y', DISTANCE OF LOAD FROM END OF CYLINDER

The deflection at any point of a beam on an elastic foundation may be expressed by the equation $d = De^{-\beta y}(\cos \beta y + \sin \beta y)$ where D = deflection at the load, d = deflection at a distance y therefrom, and β is equal to $(K/4EI)^{1/4}$, where K = elastic resistance of the foundation per linear inch of beam per unit of deflection. Since, in the case of the cylinder, K is measured by the stiffness of a unit ring or segment, it is proportional to Et^3/R^3. Substituting this for K in the expression for β, and noting that the width of the hypothetical strip that constitutes the beam may reasonably be assumed to be proportional to R and that therefore I is proportional to Rt^3, it is found that β is proportional to $1/R$. It was found, with the brass tubes, that the deflection practically vanished at $y = 8R$, and this condition gives $0.3125/R$ for the value of β. In the case of the elastic beam, the deflection is of course a periodic function and

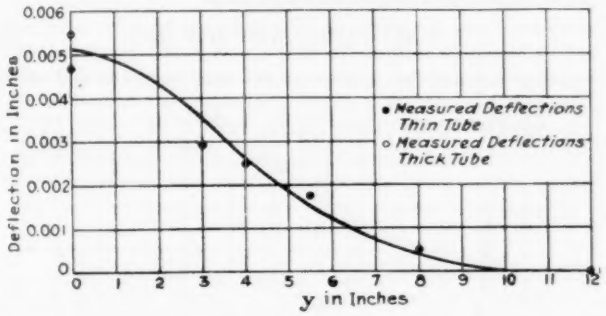

FIG. 9 DEFLECTION OF BRASS TUBE PRODUCED BY CONCENTRATED LOAD. DEFLECTION PLOTTED AS FUNCTION OF y, DISTANCE FROM LOAD MEASURED LONGITUDINALLY

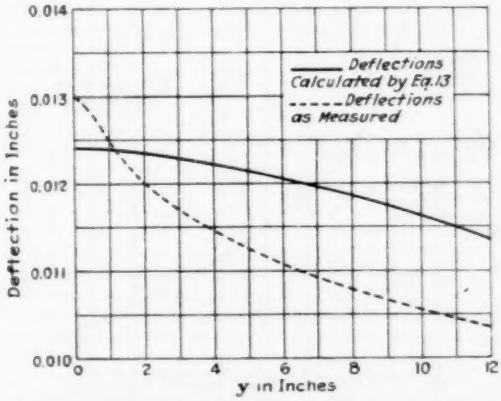

FIG. 10 DEFLECTION OF STEEL CYLINDER PRODUCED BY CONCENTRATED LOAD. DEFLECTION PLOTTED AS FUNCTION OF y, DISTANCE FROM LOAD MEASURED LONGITUDINALLY

negative deflections are obtained; this may very well be the case also with the cylinder, but such deflections, if present, are negligibly small, and in the specimens tested could not be detected with the apparatus used. It is necessary therefore only to consider the deflections between the point of loading and points distant $8R$ to either side thereof, and the formula

$$d = (0.135\ PR^2/Et^3)(e^{-\beta y})(\cos \beta y + \sin \beta y) \quad [13]$$

where $\beta = 0.3125/R$ was adopted as being in reasonable accord with experimental results. The curve of Fig. 9 represents Equation [13] plotted for the thin brass tube and the measured deflections for that specimen. The deflection at load as determined for the thick tube is also plotted, the actual measured deflection having been multiplied by the ratio of the quantities PR^2/Et^3 for the two specimens to make it comparable with the deflection of the thin tube.

In Fig. 10 are shown the graph of Equation [13], calculated for the thin steel cylinder and the actual elastic curve as determined by careful measurement made near the load. It is clear that Equation [13] does not represent closely the *form* of the deflection curve near the load, and that the analogy of the beam on an elastic support could not be expected to yield a satis-

factory formula for stresses. The sharp curvature under the load indicated by the experimentally determined curve is consistent with the high stresses found at that point.

(*b*) $D = f(y)$, *Load at* $(0, y)$. The variation of deflection at load with distance from the end of the cylinder was found to be as shown in Fig. 11, where the plotted points represent experimental results secured with the thin brass tube. The equation of the curve found to best fit the points is

$$[0.48 - 0.22(y'/R)^{0.35}][PR^2/Et^2] \quad [14]$$

where y' denotes the distance of the load from the end of the cylinder. When y' becomes equal to 4.4 R, the deflection is practically equal to that produced by a load indefinitely remote from the end.

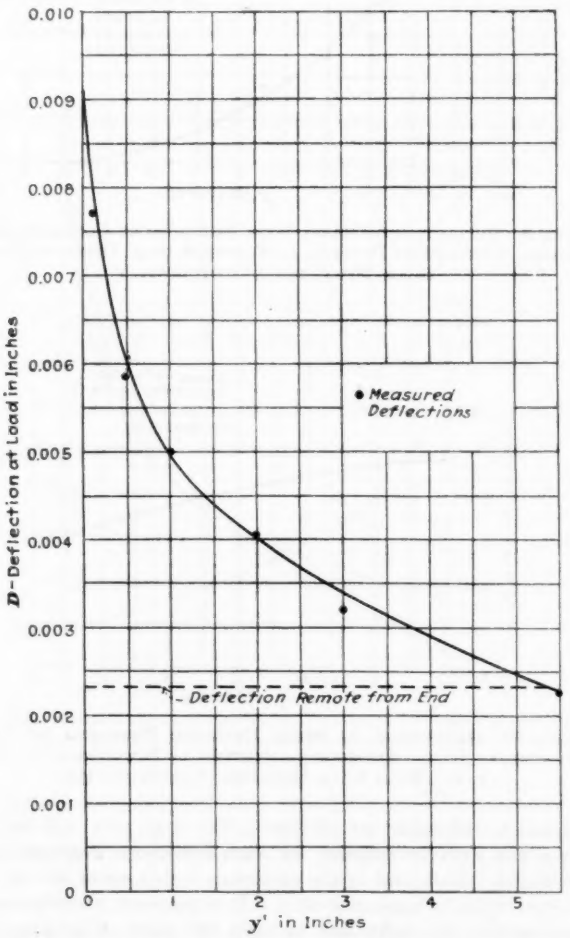

FIG. 11 DEFLECTION UNDER 5-LB CONCENTRATED LOAD OF A BRASS TUBE 2.5 IN. DIAM AND 0.029 IN. THICK. DEFLECTION PLOTTED AS FUNCTION OF y', DISTANCE FROM END OF TUBE TO THE LOAD

CHANGES IN DIAMETER

In addition to the measurements of deflection on which Equations [12], [13], and [14] are based, the changes in the vertical and horizontal diameters of the thick steel cylinder were determined at the loaded section and at the ends. Under loads each equal to 698 lb, the vertical diameter increased 0.0229 in. at the loaded section and 0.0039 in. at the ends, while the horizontal diameter decreased 0.0126 in. at the loaded section and 0.0036 in. at the ends.

It may be of interest to ascertain the length of a segment of the cylinder which, under the same loads uniformly distributed along opposite elements, would suffer the same change in vertical diameter as occurred in the cylinder at the loaded section. Using the ring formula: $\Delta D = 0.149\ PR^3/EI$, where ΔD denotes change in diameter, it is easy to show that the length of this segment is 6.9 times the radius. A similar computation for the brass tubes gives a length 7.3 times the radius. It appears, therefore, that the change in diameter produced in a long cylinder at the point of loading can be calculated on the assumption that the loads are uniformly distributed along opposite elements of a ring having a length equal to seven times the radius.

CONCLUSION

The results of the tests indicate that both the stiffness and strength of a thin cylinder under concentrated loading are greater than probably would be supposed. As is the case with flat plates, the stresses become negligibly small at a comparatively short distance from the load. Because of the fact that the higher stresses are so sharply localized, end effects are small except when the load is applied very near the ends, and it appears probable that other boundary conditions would also have little effect on stresses at any except adjacent points. The formulas given should therefore apply to any case in which a concentrated load acts upon a thin cylindrical plate, no matter how supported, provided only that the boundary and supports are sufficiently remote from the load.

With respect to deflections, the effect of boundary conditions is, as might be expected, greater. The formulas given, therefore, can only be regarded as applicable to complete cylinders that are very long in comparison to their diameters.

It may appear, from a study of the figures on which they are plotted, that the experimentally determined values of stress and deflection are more erratic than should be the case. There are several reasons for this irregularity. In the first place, the specimens available were not geometrically perfect. It has been remarked that the thickness of one of the steel cylinders varied considerably, and while the other specimens were more nearly uniform in this respect, even a small variation in these relatively thin shells would affect stress and deflection appreciably.

In the second place, most of the quantities measured, especially the stresses, changed very rapidly with respect to the distance from the load, and so failure to apply the load exactly at the intended point would have produced disproportionately large errors in stress. It is apparent that most of the points representing measured stresses, as in Fig. 6 for example, could be brought on the curve by a very small lateral displacement. While the load was never entirely removed during a test, it is quite possible that the end of the loading pin (A in Fig. 2) may have slipped slightly between successive applications of the full load, and it is also probable that the extensometer was not always placed at exactly the intended distance from the supposed point of loading.

Finally, the way in which the load was applied, through the placing by hand of a deadweight on a yielding support, made it very difficult to avoid some dynamic effect. Every effort was made to ease the load on so as to reduce this effect to a minimum, but the operation was a fatiguing one and it is possible that there was occasional overloading, too slight to be revealed by recovery or vibration and yet sufficient to introduce an appreciable error. It should, however, be remarked that every experimental value, whether representing a stress or a deflection, is the mean of several observations, the load being applied and removed until at least two successive readings were obtained that agreed as closely as the instrument could be read.

Recent Research Work in Lubrication

By GEORGE B. KARELITZ,[1] NEW YORK, N. Y.

I—GENERAL

THE increase in speed of machinery and the larger loads imposed on rubbing surfaces bring the matter of lubrication and the mechanism of bearings forcibly to the attention of mechanical engineers. Much has been done to disseminate and popularize the recent findings on the theory of lubrication. In this respect the review and bibliography given herein will be helpful as will reference to the work done under the auspices of the A.S.M.E. (1).[2]

II—HYDRODYNAMICAL THEORY AND DESIGN APPLICATIONS

In regard to hydrodynamical theory, Needs (2, 3) has shown the effect of a finite bearing length and the resulting end leakage upon the pressure distribution, carrying capacity, and friction of the oil film. In this work Needs employed the electric analogy of Kingsbury to study the conditions in a 120-deg bearing. The data obtained give a firmer basis for the application of the theory to the design of power bearings. Further tests by Baudry and Tichvinsky (4) on the performance of actual large-size bearings have been reported and the results compared with the theoretical values expected. An interesting review of standard practice in bearing design in the light of hydrodynamic theory has been presented by Howarth (5, 6). This review was based on statistical design data collected from the leading machinery manufacturers. Troublesome vibration which sometimes occurs in bearings due to the instability of the oil film has been discussed by Newkirk (7). In this work, means to prevent and cure the vibration were presented.

III—OILINESS

The question of oiliness, its physical meaning and relation to the lubricating quality of lubricants has received much attention both here and abroad. The mechanism of the extreme-pressure lubricants and the effect of sludging or oxidation on the lubricating qualities of the oil has been investigated and discussed by various authorities (8, 9, 10, 11). Among the several methods advocated for measuring the adhesive property of the lubricant or the thickness of the adhered layer a centrifugal device has been described by Sperry (12).

IV—INTERNAL-COMBUSTION ENGINE LUBRICATION

Particular attention has been paid to the necessary physical properties of lubricants for, and the behavior of such in internal-combustion engines both for automobile and aviation purposes (13, 14, 15).

V—VISCOSITY MEASUREMENT

Standardization of viscosities for industrial lubricating oils has been considered and charts for the practical classification of mineral lubricants have been published (6, 16). The advisability of the universal adoption of absolute-viscosity units instead of the commercial units now in common use, has been discussed and advocated. In this connection, further work has been done on instruments for measuring the absolute viscosity directly, both for laboratory and industrial uses (17, 18).

Design Data

It is important that the data contained in technical papers be made readily available to designing engineers. In order to satisfy these needs of industry, this section of the Journal will include a concise presentation of data and information drawn chiefly from papers previously published by the Applied Mechanics Division of The American Society of Mechanical Engineers.

The data are prepared by a subcommittee of the Applied Mechanics Division on strength of materials (R. E. Peterson, chairman), under the guidance of S. Timoshenko.

Torsional Stresses in Shafts Having Grooves or Fillets

By L. S. JACOBSEN,[1] STANFORD UNIVERSITY, CALIF.

THE general problem of torsional stresses in shafts having grooves or fillets was first solved by Michell (1) in 1900. A little later Föppl (2) outlined a graphical method whereby solutions might be obtained in specific cases, and in 1907 Willers (3) actually determined the magnitudes of such stresses in two typical sections by a graphical method of his own. About fifteen years later, Liljeblad (4) found an analytical expression for the stress concentration near a fillet in a shaft and applied it to practical sections. Shortly after, the author of this article described an electrical analogy (5) of torsion by means of which experimental determinations of stresses might be readily made for any axial outline of a shaft of circular cross section. Finally, in 1929, Sonntag (6) published an investigation, using an approximate method, of the three most typical forms of axial changes used in practice, as shown in Fig. 1.

By means of the hydrodynamic analogy it can be shown that the torsional stress at the bottom of the semicircular groove, Fig. 1*a*, approaches a value of twice the maximum stress in the straight part of the shaft as the radius of the groove is diminished. Sonntag's results for this case apply to a groove of any size and are

$$\tau_{max} = \frac{16M}{\pi d^3}\left(\frac{2D}{D + 2r}\right)$$

The more general section, shown in Fig. 1*b*, has also been studied by Sonntag, and for this groove his results are

$$\tau_{max} = \frac{16M}{\pi d^3}\left[\frac{(D - d + 2r)(d + 2r)^2 + 4r^2(D - d - 2r)}{2rD(d + 4r)}\right]$$

The section shown in Fig. 1*c* is perhaps the one most commonly used in practice, inasmuch as very few shafts are of one diameter only. Willers considered this case graphically for the ratio of $D/d = 1.33$. He found that the maximum stress occurs at a point slightly to the right of the point of tangency of the fillet with the outline of the smaller shaft. The studies made by the author (5) using the electrical analogy, confirm this fact and are, moreover, in good agreement with Willers' results. Five ratios

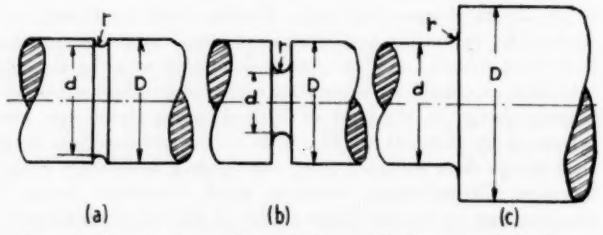

FIG. 1 NOTATION FOR SHAFTS HAVING GROOVES OR FILLETS

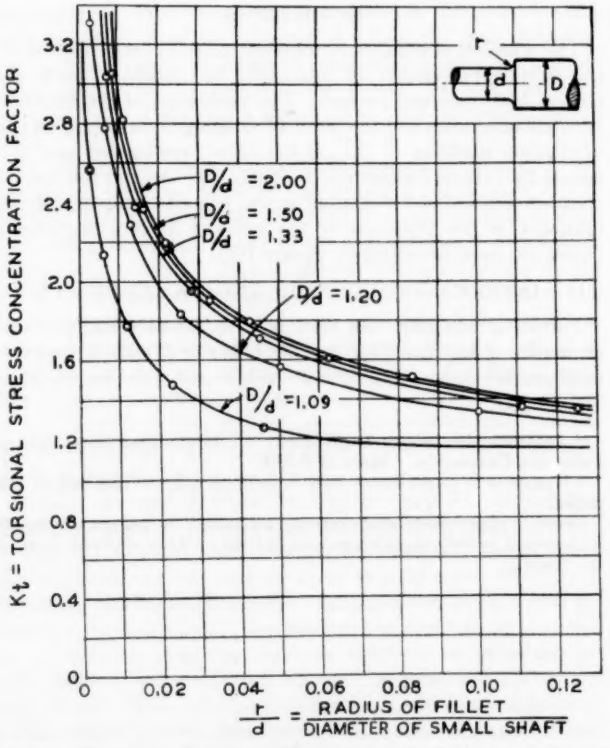

FIG. 2 TORSIONAL-STRENGTH-CONCENTRATION FACTORS IN SHAFTS WITH FILLETS

[1] Professor, Department of Mechanical Engineering, Stanford University, Calif.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

of D/d were investigated, namely: 1.09, 1.20, 1.33, 1.50, and 2.00. Values of the stress-concentration factor K_t, i.e., the ratio between the peak stress in the fillet to the nominal computed torsional stress $\tau = \frac{16M}{\pi d^3}$ in the smaller shaft, as found by these tests are given in Fig. 2, for various values of the ratio D/d and r/d. For values of D/d not shown on the curves interpolation may be used with sufficient accuracy for most practical purposes.

Sonntag's approximate analytical formula for the case shown in Fig. 1*c* is

$$\tau_{max} = \frac{16M}{\pi d^3 D}\left[\frac{3}{2}\frac{(d+2r)(d+4r)}{(d+6r)} + \frac{(D-d-2r)(d+12r)}{12r}\right]$$

Results computed by this formula are in fairly good agreement with those obtained experimentally (5) for values of D/d near unity; however, for larger values of D/d there is considerable difference and for such cases the curves of Fig. 2 should be used.

If shafts of complicated axial outlines are to be studied for torsional stresses, the electrical analogy will give answers without the expenditure of much mental effort. All that is necessary for carrying out the analogy is a two-dimensional, or nearly two-dimensional, conductor, e.g., a plate. However, in order that the analogy may be established, the conductivity of the plate must be proportional to the cube of the distance from one edge. In the practical case, this is effected by making the thickness of the plate proportional to the cube of the distance from the edge; in other words, the cross section of the plate resembles that of a hollow-ground razor blade.

The plate is then cut to have the same boundary as the outline of the axial section of the shaft, the thin edge of the plate coinciding with the center line of the shaft, and the thickness of the plate at the boundary being proportional to the cube of the distance of the boundary from the thin edge.

Assuming that the ends of the plate are maintained at a constant electric potential, so that the current near the boundary of the plate follows the boundary, the potential gradient anywhere in the plate may be measured experimentally by a Wheatstone bridge and a galvanometer. The torsional stress at a point in the shaft is then proportional to the measured potential gradient in the plate at the corresponding point multiplied by the distance of the point from the thin edge of the plate. It is usually a matter of a few minutes of experimentation to find the point at which the maximum stress occurs, i.e., maximum gradient times distance from the thin edge.

In order that the accuracy of the analogy may be satisfactory, the thickness of the plate must be kept as small as possible, so as to approximate a two-dimensional current flow. But in order that the manufacture of the plate may not be too expensive, due to the accuracy needed, the thickness must be appreciable. These two demands are contradictory, and a compromise must be sought. In 1926 the author used an analytic bath of shallow proportions in which the depth increased as the cube of the distance. A 10 per cent copper-sulphate solution is satisfactory. Work of this type has been carried out in Germany recently (7).

Anecdotal History of the Science of Sound

ANECDOTAL HISTORY OF THE SCIENCE OF SOUND. By Dayton Clarence Miller, D.Sc., L.L.D. Professor of Physics, Case School of Applied Science, Cleveland. The Macmillan Company, New York, N. Y., 1935. Cloth, 5¾ × 8½ in., 114 pp., 15 plates, $2.50.

REVIEWED BY A. L. KIMBALL[1]

NO ONE interested either in the theory or the application of sound should fail to possess this little volume written by the most distinguished exponent of this field we have in the country today. Doctor Miller with his fine physical perception, together with his long experience, and wide contacts, is eminently fitted for this task.

Although, as the name implies, much of the book is given to anecdotes, these are chosen in a way which gives an illuminating picture of the development of the science of acoustics in both its experimental and theoretical aspects, with many side lights on the parallel development of musical instruments and sound-measuring devices.

An attractive feature of the book is a number of plates showing portraits of many of the pioneers and illustrations of apparatus made by them.

Many facts of interest appear which are not generally known, some even to specialists, I venture to say. It appears, for example, that Galileo's researches give "the first enunciation of the principles of sound which are really scientific," and his own words, quoted in this connection on the vibration of strings and cords, show how far ahead of his time was this great pioneer of the inductive method of scientific research.

Not the least interesting of many personal side lights are those regarding more recent investigators, such as Tyndall, König, Rayleigh, Webster, Sabine, and Bell, with all of whom, except Tyndall, Dr. Miller was personally acquainted.

This book is written with an appreciation of pioneer work of a more analytical character as well as of experimental, which will be pleasing to those who incline toward the theoretical.

A bibliography of all works referred to is given at the end.

Aerodynamic Theory

AERODYNAMIC THEORY. Dr. William Frederick Durand, editor-in-chief. Vol. 2. Division E. Julius Springer, Berlin, 1935. Cloth, 6 × 9 in., xv plus 367 pp., 113 figs., and 4 plates. Special price only until the publication of the last volume, rm. 20.

REVIEWED BY J. C. HUNSAKER[2]

TO present a useful review of this, the second volume of the series of six, it seems necessary to consider its place in the whole work. Dr. Durand, under his precept as general editor has undertaken to organize and coordinate the work of the world's most eminent authorities into a comprehensive and permanent record of the present state of aerodynamic theory. That such a record is in effect a record of twenty-five years' progress is due to the fact that modern aerodynamics has been developed within these few years. Consequently, the contributors drafted by Dr. Durand are themselves men whose own work constitutes a large part of the body of this theory.

The six volumes, of which four have appeared in rapid succession, will contain a stock taking of general fluid mechanics; the mechanics of perfect fluids, of viscous and of compressible fluids, the application of theory and experimental technique to airfoils, bodies, propellers, etc., the dynamics of the airplane and airship, performance of aircraft, the hydrodynamics of sea planes and the aerodynamics of cooling. From this plan it can be seen that volume one, reviewed in the June, 1935, issue of this JOURNAL, is an introduction and a foundation for the entire structure. It set forth the mathematical and analytical methods which are to be later applied, as aerodynamics, to the design of aircraft.

Volume two, now before us, is evidently the first floor of this figurative structure. Here Professor Th. von Kármán of Pasadena and Professor J. M. Burgers of Delft, in happy collaboration, present a comprehensive and masterly treatment of the mechanics of nonviscous imcompressible fluids and in particular the aerodynamics of wings. This treatment is rigorous and elegant, and it is also clear, because the authors have taken pains to make it so. The editor states that the whole is the joint work of the two authors but that von Kármán primarily contributed the chapter on the theory of wings of infinite span and the chapter on the wake, while the other five chapters are by Burgers. The reader should be grateful to whichever of these able scientists proposed the wholesome innovation of commencing each chapter with a precise yet nonmathematical statement of the physical problem to be considered, a discussion of the methods of attack which might be employed in the solution, and finally a forecast of just what will be done, with reasons for the course to be taken. In consequence, each chapter has unity and purpose and a definite relation both to what precedes and to what follows.

Chapter 1 gives a general description of the nature of the flow of air around a wing and explains the process by which lift is created, develops the conceptions of circulation and induced drag, bound and trailing vortices, and establishes the approximate equivalence of an airfoil and a system of vortices.

Chapter 2 deals with the idealized case of two-dimensional flow around an airfoil of infinite span in an ideal fluid. This is the classical Lanchester-Prandtl wing theory. The general wing theory is postulated as the problem of calculating the velocity and pressure field around a wing of given cross section. The development proceeds from a first approximation with a vortex filament replacing the wing, then to a second approximation using a vortex sheet, and finally to the theory of the thin airfoil. The various methods of conformal transformation are next used to compute, from potential flow theory, the flow paterns of the well known families of thick "mathematical" airfoils (Joukowski, von Kármán, Trefftz, von Mises).

Chapters 3 and 4 treat the more nearly practical problem of flow about an airfoil of finite span. This is the most important section of the volume and is entirely new (to this reviewer) in that the starting point is the investigation of the influence the surface forces, on the airfoil, have on the motion of a fluid. The present treatment is logical and powerful. Chapter 3 begins with the Euler hydrodynamical equations of motion, completed by generalized force terms. By successive approximations, these

[1] Engineering General Department, General Electric Company, Schenectady, N. Y. Mem. A.S.M.E.

[2] Professor of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Mass. Mem. A.S.M.E.

equations of motion are solved and the principal theorems regarding induced drag, wake, downwash, lift, vorticity, etc. are established as a consequence. This chapter is essentially a mathematical tool for application in chapter 4 to a series of important problems.

Chapter 4 is in three parts: Part *A* is devoted to the computation of the distribution of lift over the span and the corresponding induced drag and the effect of ailerons, sweep back, taper, twist, and yaw. Part *B* deals with the distribution of lift and drag over multiplanes. Part *C* establishes a thoretical basis for estimating the effect on airfoils of boundaries parallel to the direction of general flow, such as the ground, wind-tunnel walls, etc.

Chapter 5 deals with nonuniform and curvilinear motion and, due to the relatively undeveloped nature of this field, the discussion is more brief. Perhaps when flapping wings become of other than academic or ornithological interest this material may form a basis for further extension of the theory.

Chapters 6 and 7 discuss the development of the vortex system downstream of the airfoil and the theory of the wake. The latter is suggestive of the need for future progress as the whole phenomenon of resistance is involved. At a certain inclination to the direction of motion the flow of real fluids separates from the back of an airfoil giving rise to a turbulent wake, high drag, and reduced lift. In this short chapter von Kármán confines himself to the results obtained from the Helmholtz theory of the discontinuous potential, the von Kármán "vortex street" and Oseen's "vortex field." These assume an ideal fluid. The turbulence of real fluids will be a subject for a later volume.

There is a good index and for each chapter there is an adequate bibliography. It should be realized that the entire wing theory is "applied mathematics," but the presentation here is so clearly done that, with the aid of volume 1 of the series, a diligent reader requires no more than an engineer's equipment of mathematics.

The Hardness of Metals and Its Measurement

THE HARDNESS OF METALS AND ITS MEASUREMENT. By Hugh O'Neill, D.Sc., M.Met. Senior Lecturer in Metallurgy in the Victoria University of Manchester. Chapman & Hall, Ltd., London, 1934. Cloth, 6 × 9½ in., 292 pp., 119 figs., 123 tables, 25s.

REVIEWED BY J. R. TOWNSEND[3]

THIS book is an exhaustive study of the property of hardness of metals. Aside from the distinction of being the first and only book on this important subject it is a model of clear and balanced exposition of a well-known but not fully understood property of metals. This book should be of interest not only to testing engineers but to metallurgists and scientists as well. It is another volume added to the fast-growing library on physical metallurgy or the science and use of metals.

Dr. O'Neill has boldly faced the problem of hardness in his introductory essay by bringing to bear all of the existing physical, mechanical, and physical-chemical theory on the problem. He shows the present practices of hardness measurement are widespread regardless of the fact that they may not be on a good foundation of fundamental theory. On the other hand consideration of the available fundamental theory does not permit one to formulate a hardness test that is wholly satisfactory in the sense that the hardness of all materials may be referred to a fundamental concept in terms of length, mass, and time. The conclusion is drawn that for all practical purposes the hardness of metals may be expressed in terms of "mass hardness." This term takes into consideration the fact of the heterogeneity of metals; that metals as we have to deal with them are a conglomerate of crystals of different hardness, plasticity, orientation, and size. The mass hardness then of a metal at a given temperature is its reaction to local indentation and this reaction should be expressed in terms which recognize viscosity and elasticity in metals and which allow for the fact that the intensity or degree of indentation may affect the specific reaction.

In spite of the fact that there is not available means of making such a test for the hardness of metals the practice of hardness testing with a variety of machines has progressed to the point that practice has far outstripped theory. In fact there has been excellent standardization of hardness testing in the field of specifications. The fact that these methods are in general use and widely understood is no reason why we should be satisfied with the present state of our knowledge. Dr. O'Neill's book is very provocative of thought in this regard and stimulating in presenting the broad panorama of facts that must be taken into consideration in the solution of the problem.

Aside from the basic statement of the problem the book contains an exhaustive review of the various hardness tests that have been devised in Europe and America. Many comparisons are drawn between the hardness values determined by the various hardness-testing machines for commonly used metals. While more emphasis is placed on European practice this is hardly a defect to thoughtful readers familiar with American practices. The book does not cover adequately the subject of the hardness test as related to specification use or to calibration and methods of manipulation of specific hardness testers. This is a very important subject in the technology of metals. While data are given showing the relationship of hardness to per cent reduction, heat treatment, and correlations between tensile strength, fatigue endurance, and hardness there is little if anything on the subject of minimum thickness of metal for reliable hardness measurement, or the minimum width, or how curved or irregular surfaces should be treated. These are most important problems in the engineering of metals. However, in view of the complete review of fundamental knowledge that is given, the absence of such data does not impair the usefulness of the book in giving a thorough understanding of the background of knowledge on the subject.

Dr. O'Neill quite properly accents the work done by Meyer and his analysis of the Brinell test or ball-indentation test. Meyer's test consists in measuring the load to produce unit deformation of the metal. The difficulty of measuring the diameter of an indentation in a metal by a ball because of the rim of metal that is thrown up and the irregular shape of the indentation due to irregular recovery of the metal and its directional reaction caused by cold work is clearly brought out in the book. The solution of this problem is not adequately explored, however. Since the deformation of a metal by a ball combines such factors as elasticity, plasticity, elastic recovery, and the directional effect of this recovery in cold-rolled metals the solution is obviously in the direction of measuring the deformation in terms of penetration of the spherical indentor with the load on. The author quite properly states that depth measurements after the load is removed are more unreliable than diameter measurements, due to shallowing of the indentation. Furthermore, it is possible to measure better the indentation of a ball penetrator with the load on than the diameter of an irregular indentation since accurate means of mechanically measuring depth are available while width measurements would require a microscope and visual observation. Meyer's constants may be accurately determined by the load required to produce unit deformation in terms of depth of indentation. Such measurements have been reported by the reviewer in the Proceedings of the American Society for Testing Materials.

[3] General Development Laboratory, Bell Telephone Laboratories, Inc., New York City.

In conclusion therefore it may be said that Dr. O'Neill has produced a valuable summary of hardness testing of metals which should be found in the library of every engineer, metallurgist, and scientist interested in the important subject of hardness. The Proceedings of the American Society for Testing Materials cover exhaustive studies of hardness as affecting specifications and use and the work of Dr. O'Neill is a fitting companion to this work to present the broad picture of hardness.

Resistance of Materials

RESISTANCE OF MATERIALS. By Fred. B. Seely, Professor of Theoretical and Applied Mechanics, University of Illinois. Second edition. John Wiley & Sons, New York. Chapman & Hall, Ltd., London, 1935. Cloth, 6 × 9 in., 436 pp., 383 figs., $3.75.

REVIEWED BY T. MCLEAN JASPER[4]

THE proper use of materials is one of the most important tasks which confront the engineer of today, and Professor Seely in his new edition of "Resistance of Materials" has succeeded in presenting, in a concise and simple manner, many of the more recent methods of applying materials to structural design.

The method employed of clarifying involved principles by practical illustrative problems should prove most helpful to the student and practicing engineer.

One feature of the book is the profuse collection of illustrative diagrams which helps the engineer to grasp fully the problems with which he is confronted.

The language of the book is simple and direct which allows no misinterpretation of the information available within its covers.

Teachers and design engineers will do well to study this book for its treatment of current engineering problems.

Metallic Arc Welding

METALLIC ARC WELDING. By H. Harris, Ph.D., D.I.C., A.R.C.S. Longmans, Green & Company, New York, N. Y. Edward Arnold & Co., London, 1935. Cloth, 5¾ × 9 in., viii plus 199 pp., 99 illustrations, $6.

REVIEWED BY CHAS. H. JENNINGS[5]

DR. HARRIS' book on metallic arc welding is a comprehensive summary of the present knowledge on the metallurgy of arc welding and should be of great assistance to engineers in connection with the production of metallic arc welds of the quality required by present-day practice.

The major portion of the book is devoted to the analysis of welds made on low-carbon structural steels of the types used for general pressure vessels, machinery, and constructional work. Excellent discussions are given on the effect of welding on the base metal, crystallization in multiple-layer welds, peening, residual stresses and stress relief, and the physical properties of welds. Coated and bare electrodes are discussed from the standpoint of effect of coating composition on the soundness of the weld deposit and the chemical changes resulting from the transfer of metal through the arc.

The influence of oxygen and nitrogen in steel and weld metal is thoroughly discussed in accordance with present-day theories. Typical test data are given to illustrate the age-hardening phenomena attributed to these elements. Metallurgical problems encountered while welding (1) alloy structural steels, (2) austenitic stainless, (3) manganese steels, (4) nickel, and (5) monel metal are also considered.

The book is ably written and illustrated and its value is greatly enhanced by the inclusion of the large number of references used in compiling the data given.

Noise

NOISE. A COMPREHENSIVE SURVEY FROM EVERY POINT OF VIEW. By N. W. McLachlan, D.Sc. (Engineering) London, M.I.E.E. Oxford University Press, New York, 1935. Cloth, 4¾ × 7¼ in., 148 pp., 62 figs., $2.25.

REVIEWED BY A. L. KIMBALL[6]

THIS little book is among the best the writer has seen on this subject, in that it combines to an unusual degree a clear grasp of fundamentals and practical experience. To anyone who wishes to acquire an overall picture of the subject in a reasonable number of pages, including its technical physiological and psychological aspects, this book is recommended.

The first chapter on general considerations presents the difficult subjects of the relation between noise-meter readings, loudness sensation, and masking effects unusually clearly, although the author prefers to use the term "reference tone level," abbreviated "reftone level," rather than "loudness level," because the decibel scale is not such as to truly measure loudness.

The second and third chapters cover measurement of noise and frequency analysis.

The fourth chapter takes up noise in buildings in an interesting way with illustrations. The specific method used is the most direct and practical one which the writer has thus far seen, and he intends to make use of it in his own work.

The next three chapters cover briefly, traffic noise, train noise, and noise of airplanes, ships, propellers, and motor vehicles. An outline of what it has been possible to accomplish thus far in these fields is given with a few illustrations.

Chapters 8 and 9 go into the important subjects of vibration of machinery and noise from electrical apparatus, with a simple illustration of how to use elastic suspensions in preventing noise transmission. A brief résumé of the sources of noise in generators and in motors, and the cause of thermionic-valve noise also appears.

The final chapter goes into the physiological and psychological effects of noise.

It is, of course, impossible to treat such a broad subject in as much detail as would be required by a specialist in one particular field, but the author has succeeded in doing a very good piece of work considering the small size of the book.

Geometry

ANALYTICAL GEOMETRY OF THREE DIMENSIONS. By D. M. Y. Sommerville, M.A., D.Sc., Professor of Pure and Applied Mathematics, Victoria University College, Wellington, N. Z. The Cambridge University Press, Cambridge, Eng., and The Macmillan Company, New York, 1934. Cloth, 6 × 9 in., 416 pages, 49 figs., $4.75.

REVIEWED BY J. ORMONDROYD[7]

THE style in which this text on analytical geometry is written makes it difficult to understand unless studied under the guidance of an instructor. It can be recommended to engineers only as a reference work which is slightly more elementary, compact and modern than Salmon's classical treatise on the same subject.

Siphon Spillways

SIPHON SPILLWAYS. By A. H. Naylor, M.Sc., Assoc. M.Inst.C.E., M.Inst.W.E. Longmans, Green & Company, New York. Edward Arnold & Co., London, 1935. Cloth, 5¼ × 8½ in., 80 pp., 40 figs., 7 plates, $3.40.

REVIEWED BY M. P. O'BRIEN[8]

ALTHOUGH many papers have already been published on the design of siphon spillways, this small volume will prove useful because it presents in some detail the basic considerations underlying the design of an important installation. Following a review of the principal types of siphons and a discussion of the head necessary to cause priming, application is made to the Laggan Siphons of the North British Aluminum Company. The computations are given in detail and the computed discharge is compared with that shown by model tests. Useful data on the formation of intake vortices and the necessary size of air vents are included.

It is regrettable that the author did not expand his theoretical treatment of siphons, especially that portion dealing with the head necessary to prime and the mapping of streamlines. The latter problem appears to be one which is especially suitable for solution by the electric analogy but the method outlined by the author is probably sufficiently accurate. It is an example of the value of the mathematical approach in the solution of practical problems.

The author proposes as the measure of siphon efficiency the ratio of the actual discharge to that which would occur if a perfect vacuum existed at the highest point of the throat. This concept was originally advanced by J. C. Stevens but was abandoned by him in favor of a coefficient based upon the discharge area. The author's proposal does not give a direct comparison of different siphons because low-head siphons will show low efficiencies no matter how small their friction losses may be. The coefficient based on discharge area gives a direct indication of these losses and is believed to be preferable.

The many practical observations regarding siphon design and behavior are an important feature of this work. In general, the treatment is clear and concise and it is recommended for reference by engineers concerned with the design of this type of hydraulic structure.

Science and Social Needs

SCIENCE AND SOCIAL NEEDS. By Julian Huxley. Harper and Brothers, New York and London, 1935. Cloth, 5½ × 8½ in., 287 pp., illustrated, $2.75.

REVIEWED BY JOHN M. LESSELLS[9]

THE basis for "Science and Social Needs" was furnished by a "tour of British Science" which the author made and refers specifically to conditions of science in Great Britain. Some of the material was broadcast by the British Broadcasting Corporation but considerable amplification and additions have been made to the material to form the contents of this volume.

The first chapter is an introduction by Sir William Bragg, entitled "Science—Friend or Enemy." In this Sir William prepares the way for the author's presentation by taking us on an imaginary journey through the Royal Institution. The experiments of Rumford on heat are mentioned. These are well known but it is illuminating to learn that Rumford was interested in applying knowledge to relieve the common lot. Davy's work on the miner's lamp, the electrical experiments of Faraday, Tyndall's work on bacteriology, Rayleigh's on acoustics, and Dewar's on the liquefaction of gases are all cited as scientific discoveries which have later blossomed into useful industries. A warning note is struck, however, when he reminds his readers that while science has been shown by these and other examples to have been beneficial to the human race there are other cases such as the use of science in war where it is applied for mutual injury.

Four chapters take the form of a dialogue between the author and Professors Levy, Blackett, and Sir T. Barlow, while the remainder discuss the state of science in certain industries as the author found it during his tour.

While the book describes conditions as they exist in Great Britain, and for this reason is of more interest to British readers, it nevertheless possesses a certain attraction for American readers as indicating the relative status of research in the two countries, judged by expenditures per capita. Nevertheless, the reader gains the impression that while such material may be impressive when heard over the radio it is tedious to follow. The basic questions as to the proper control of scientific research and whether science is responsible for our present economic ills are left unanswered.

If the purpose of the book is to make the man in the street au fait with the present-day achievements and future possibilities of applied science then it has a worth-while objective. In this respect, although the book is sketchy and not at all conclusive, it paints a picture in simple language which may be absorbed by the non-technical reader.

Higher Mathematics for Engineers and Physicists

HIGHER MATHEMATICS FOR ENGINEERS AND PHYSICISTS. By Ivan S. Sokolnikoff, Assistant Professor of Mathematics, University of Wisconsin; and Elizabeth S. Sokolnikoff, formerly Instructor in Mathematics, University of Wisconsin. McGraw-Hill Book Company, New York, 1934. Cloth, 6 × 9 in., 482 pp., $4.

REVIEWED BY GEORGE B. KARELITZ[10]

IN the preface to this work the authors state: "Intimate contact with students in engineering and other applied sciences has convinced the authors that most of the students emerging from the usual course in calculus are not sufficiently mature mathematically to undertake independent reading of the more advanced works on mathematics." This deficiency also interferes with the reading of the more advanced works in engineering and the volume may be well recommended as a means for overcoming, in large measure, these shortcomings.

Chapter 1 deals with elliptic integrals. Chapter 2 gives the approximate solution of algebraic equations followed by chapter 3 on determinants and matrices. Chapter 4 deals with infinite series and tests for convergence, expansion in the power series, and gives a demonstration of its application to approximate formulas. Chapter 5 discusses partial derivatives and differentiation with illustrative problems in geometry and physics, together with a discussion of maxima and minima of functions of two or more variables. Chapter 6 discusses Fourier series, chapter 7 multiple integrals with suitable geometrical illustrations and problems. Chapter 8 is on line integrals and Green's theorem, while chapter 9 deals with improper intergrals. Chapter 10 on ordinary differential equations is well developed, both in its elementary form of presentation and in the manner in which the authors

[8] Associate Professor of Mechanical Engineering, College of Engineering, University of California, Berkeley, Calif. Assoc-Mem. A.S.M.E.

[9] Consulting Mechanical Engineer, Swarthmore, Pa. Mem. A.S.M.E.

[10] Associate Professor, Department of Mechanical Engineering, Columbia University, New York. Mem. A.S.M.E.

develop the significance of the methods. Applications by illustrations and problems are given in the various fields of physics. Partial-differential equations in chapter 11 are treated in the same manner. Chapter 12 gives a brief discussion of vector analysis with several pertinent examples of the application to physics. Chapter 13 discusses probability and contains a number of problems illustrating the practical application. Chapter 14 is devoted to curve fitting and empirical formulas, interpolation and, numerical integration. Chapter 15 discusses the elements of conformal representation.

The book presents an assembly of separate additional chapters of algebra and calculus which should be incorporated as the working tools of the engineer and physicist. The contents are rather disjointed and unsystematic but the reader obtains the impression that they are the results of careful study of the actual needs of the student andt hat the material has been chosen on the basis of the mentioned "intimate contact." It is to be regretted that the authors did not find it possible to include in the book paragraphs treating with approximate solutions of differential equations as a counterpart of the chapter on approximate solutions of algebraic equations. The book would probably be of more value to students had the authors included a larger number of physical applications, such as additional examples of setting up differential equations, or practical applications of Green's theorem. The authors may also be reproached for excessive sketchiness in parts, as for instance in the last chapter where a few paragraphs on complex numbers would be very useful to the reader.

Apart from these criticisms the volume covers a vast amount of material which has been chosen on the basis of experience collected at the University of Wisconsin where "engineering mathematics" has been taught for a number of years. The book is now introduced as a text in a corresponding course in mathematics at Columbia University and has been found to be very useful. It will also be adequate for any engineer who would wish to improve his mathematical equipment.

Thermodynamics

THE THERMODYNAMICS OF ELECTRICAL PHENOMENA IN METALS. By P. W. Bridgman. The Macmillan Company, New York, 1934. Cloth, 5¾ × 8½ in., 200 pp., 33 figs., $3.75.

REVIEWED BY JOHN A. GOFF[11]

IN THIS rather compact volume, Professor Bridgman has collected the substance of a number of papers which he has written during the last ten years on the interrelations of a thermodynamic character between various electrical properties of metals. The volume is written primarily for the physicist and discusses phenomena with which the engineer is perhaps unfamiliar. Nevertheless, there appear at various places applications of the laws of thermodynamics which cannot help but clarify their meaning and emphasize their limitations even to the engineer. Notable among these applications is the demonstration on page 30 that a fluid in motion must convect with it in addition to its intrinsic energy a quantity of energy equal to the product of pressure times volume. This demonstration is based on the broad proposition that it is impossible to add energy to any region of space without effecting some real physical and permanent changes within the region.

In chapter 1, Professor Bridgman examines the fundamental notions and experiments involved in the notion of the electrical field. He discusses a number of idealized experiments intended to show the nature of the fundamental ideas and to distinguish quantities having direct physical meaning from mathematical constructions devised to cover regions incapable of direct physical exploration but which satisfy thermodynamics and join on smoothly with directly measurable quantities. Into the list of already accepted constructional quantities he introduces the ideas of "driving emf" and "working emf" and shows that in complicated cases, such as a metal carrying currents derived from a thermal-electromotive force, the two are not at all equal. Of particular interest is the author's steadfast recognition of the reality of the Poynting vector which he invokes to show that no information whatever can be obtained from energy considerations as to the distribution of potential jumps making up the observed Volta difference of potential between two metals; and that energy of position in the electrostatic field cannot properly be assigned to electricity as it moves about.

In chapter 2, Professor Bridgman discusses thermoelectric phenomena and shows that no rigorous application of the Second Law of Thermodynamics comprehending the irreversible effects of Joulean heat and thermal conduction has yet been made which imposes any useful restriction on the magnitudes of the various quantities involved. He attempts to show, however, that the analysis of Kelvin which ignores these irreversible effects is all right by applying the Second Law to a thermocouple so proportioned as to make the irreversible effects a maximum. The author also attacks the conventional account of the action at an interface between two metals when there is a Peltier heat, or the action in the body of a metal with a temperature gradient where Thomson heat is absorbed, and offers an account in which, at the interface, there is no "driving emf" but there is "working emf" equal to the Peltier heat, while in the body of the metal where there is a temperature gradient there is a "driving emf" distributed according to the temperature. On the basis of this account, he deduces an expression for the quantity of energy convected by the current which is essentially different from that deduced from the conventional account.

In chapter 3, the Volta effect is subjected to a searching examination which shows from thermodynamic reasoning the reality of what Tonks and Langmuir have called "surface heat of charging" and suggests that the way toward experimental verification lies in the direction of improved vacuum technique to yield satisfactory reproducible values of the Volta difference of potential for comparison with the Peltier heat. In chapter 4, the subject is thermoionic emission and the laws of thermodynamics are applied to the electron gas surrounding every metal to draw important deductions regarding the surface heat of charging.

There follow in succeeding chapters similar discussions of the effect of surface charge on vapor pressure and electron emission, thermoelectric phenomena in crystals, transverse phenomena including the Hall effect, and connections with the electron theory of metals and photoelectric phenomena. To those equipped to read these later chapters, Professor Bridgman's philosophy must contribute an added interest by bringing into focus with his vigorous and penetrating mind many things which have heretofore evaded such attention.

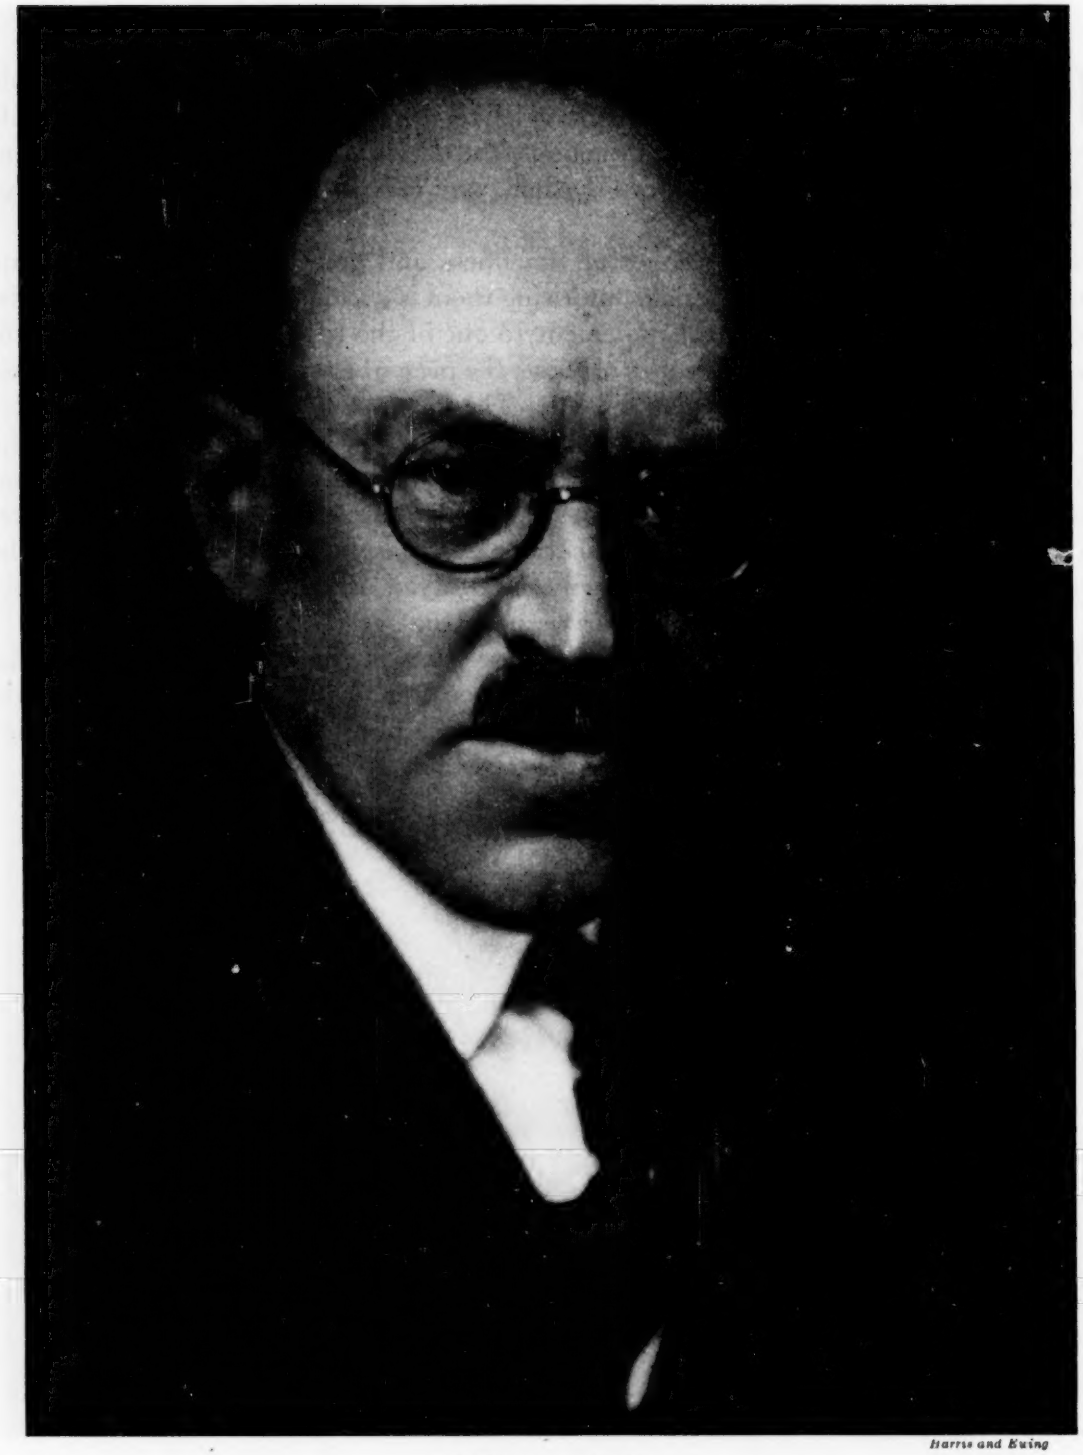
Copyrighted, 1935, by THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS



Foreword

THE Transactions of The American Society of Mechanical Engineers include selected technical papers and reports delivered at meetings of the Society, its Professional Divisions, and its Local Sections, the *Journal of Applied Mechanics* (contributions of the Applied Mechanics Division), and certain Records of the Society of permanent value.

In order to secure the advantages of timeliness and greater usefulness in issuing these Society Records, the material comprising them is divided into a number of parts, each one of which is mailed as a supplement to one of the regular monthly sections of the Transactions. For 1935, the first of these, the present issue, contains the personnel of the Council and committees for the year. The second, to be issued sometime later in the year, will contain the memorial notices of deceased members. Following the plan adopted in 1934, it is expected that the reports of Council and the Society's committees will appear as a supplement to the November issue. The presidential address and the indexes to miscellaneous publications, *Mechanical Engineering*, and to the Transactions themselves, must, necessarily, be delayed until 1936, and will probably be mailed as a supplement to the January issue of that year.

In binding the 1935 Transactions, all of these parts of the Society Records will be assembled at the back of the volume as has been customary for several years. To aid in locating references in the bound volumes, the page numbers of the sections containing the Society Records are preceded by the letter RI.

THE COMMITTEE ON PUBLICATIONS

Harris and Ewing

RALPH E. FLANDERS

PRESIDENT OF THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS
1934–1935

Ralph E. Flanders

RALPH E. FLANDERS, president of The American Society of Mechanical Engineers for the term 1934–1935, is president of the Jones & Lamson Machine Company and of the Bryant Chucking Grinder Company, both of Springfield, Vt. He was born at Barnet, Vt., on September 28, 1880, and was educated at the Central Falls (R. I.) High School. His early experience in machine design and construction was received at Brown & Sharpe Manufacturing Company, Taft-Pierce Manufacturing Company, International Paper Box Machine Company, and General Electric Company. After four years as associate editor of *Machinery* and two years as sales engineer with the Fellows Gear Shaper Company, he joined the Jones & Lamson Machine Company in 1912 as manager of the Fay Lathe Department. In 1914 he was made general manager and in 1933 president of the company.

Mr. Flanders is regarded as a national authority on machine design and construction, especially on the engineering problems of screw threads and thread grinding. His 1924 A.S.M.E. paper on "The Design, Manufacture, and Production Control of a Standard Machine" brought a successful solution to the problem of building machinery economically at widely varying rates of demand.

Mr. Flanders has devoted a large amount of time and effort to the welfare of his profession, serving on many committees of The American Society of Mechanical Engineers. Since 1921 he has been a member and since 1930 chairman of the Sectional Committee on Standardization and Unification of Screw Threads. He represented the A.S.M.E. on the National Screw Thread Commission from 1919 to 1924. He has been a member since 1926 and chairman since 1930 of the Special Research Committee on Strength of Gear Teeth. He served on the Publications Committee from 1918 to 1924 and acted as chairman in 1925 through 1928. He was a manager of the Society from 1926 to 1929 and vice-president in 1930 and 1931.

He was a delegate of the A.S.M.E. to the American Engineering Council in 1924–1925. Since 1932 he has been active in the Public Works program of the Council, and was a member of its Committee on Government Reorganization. As chairman of its Committee on the Relation of Consumption, Production, and Distribution he has been in a position of strong leadership.

Serving as president of the National Machine Tool Builders Association in 1924, Mr. Flanders presented a presidential address that dealt with current economic problems. In this address he pointed out the importance of the transition from the economy of need to the economy of plenty, a contribution of great importance to economic thinking of the times. His address before The American Society of Mechanical Engineers in December, 1930, on "Engineering, Economics, and Social Well-Being" marks his entry into a course of economic study, discussion, and writing that has brought him to the forefront of leadership in his field and led to his selection as a member of the American Engineering Council's Committee on the Relation of Consumption, Production, and Distribution, already mentioned. He is also a director of the Social Science Research Council.

Upon the passage of the National Industrial Recovery Act in 1933 and the organization of the National Recovery Administration, Mr. Flanders was called into service as a member of the Industrial Advisory Board. He is also a member of the Business Advisory and Planning Council appointed by Secretary of Commerce, Daniel C.

Roper. At the conference of the industrial leaders engaged in the administration of various codes for industries held in Washington the first week in March, 1934, his grasp of the basic industrial and economic problems at the present time enabled him to step into a position of leadership in the discussion, which had a profound effect on the deliberations of that important occasion.

Mr. Flanders has written on a wide range of subjects. In his early career his papers and books on gears and gear machinery were highly regarded. Later his discussions of industrial and economic problems have appeared in a wide range of magazines and and his book, "Taming Our Machines," published in 1931, was very well received.

Mr. Flanders was granted the degree of Mechanical Engineer by Stevens Institute of Technology in June, 1932, and the degree of Master of Arts by Dartmouth College the same year. In June, 1934, he was honored with the degree of Doctor of Science, by Middlebury College, and Doctor of Engineering by Brooklyn Polytechnic Institute. He is lecturer at the Tuck School of Business Administration at Dartmouth College and has spoken before many groups of economists, engineers, and industrialists on subjects dealing with economics, engineering, and related problems.

The American Society of Mechanical Engineers

THE members of the Council and of its standing and special committees given on the following pages are those in office on February 1, 1935, serving for the official year 1934–1935. The terms of office of members of other committees are not fixed by the official calendar.

TREASURER

ERIK OBERG

SECRETARY

C. E. DAVIES

Executive Committee of Council

RALPH E. FLANDERS, *Chairman* — ALFRED IDDLES
WILLIAM L. BATT — HARRY R. WESTCOTT
JAMES A. HALL

Advisory Members: Chairmen of the Finance Committee, the Local Sections Committee, and the Professional Divisions Committee

Chairmen of Standing Committees

Representatives on Council but without vote

Finance, WALTER RAUTENSTRAUCH
Meetings and Program, R. I. REES
Publications, S. W. DUDLEY
Membership, H. A. LARDNER
Professional Divisions, W. A. SHOUDY
Local Sections, W. L. DUDLEY
Constitution and By-Laws, H. H. SNELLING
Awards, W. L. BATT
Relations With Colleges, W. L. ABBOTT
Education and Training for Industries, G. A. SEYLER
Library, E. P. WORDEN
Research, G. M. EATON
Standardization, C. W. SPICER
Power Test Codes, F. R. LOW
Safety, W. M. GRAFF
Professional Conduct, C. G. SPENCER

ASSISTANT SECRETARIES

ERNEST HARTFORD — C. B. LEPAGE

EDITOR

G. A. STETSON

Standing Committees

FINANCE

WALTER RAUTENSTRAUCH, *Chairman and Representative on Council* (1936)

W. T. CONLON (1935) — T. R. WEYMOUTH (1938)
W. D. ENNIS (1937) — K. M. IRWIN (1939)
Council Representatives { E. C. HUTCHINSON (1935); J. H. HERRON (1936)

MEETINGS AND PROGRAM

R. I. REES, *Chairman and Representative on Council* (1935)
E. C. HUTCHINSON (1936) — CLARKE FREEMAN (1938)
H. N. DAVIS (1937) — R. F. GAGG (1939)
Junior Adviser: To be appointed

PUBLICATIONS

S. W. DUDLEY, *Chairman and Representative on Council* (1936)
W. F. RYAN, *Vice-Chairman* (1937) — M. H. ROBERTS (1938)
S. F. VOORHEES (1935) — G. F. BATEMAN (1939)
O. B. SCHIER, 2ND, *Junior Adviser* (1935)

Advisory Members: A. J. DICKIE, E. B. NORRIS, E. L. OHLE
(Personnel of Special Committee, p. 8)

MEMBERSHIP

H. A. LARDNER, *Chairman and Representative on Council* (1935)
R. H. MCLAIN (1936) — L. R. FORD (1938)
C. L. DAVIDSON (1937) — F. C. SPENCER (1939)

Advisory Member: O. E. GOLDSCHMIDT (1935)

PROFESSIONAL DIVISIONS

W. A. SHOUDY, *Chairman and Representative on Council* (1935)
K. H. CONDIT (1936) — CROSBY FIELD (1938)
G. B. PEGRAM (1937) — L. K. SILLCOX (1939)

(Personnel of Professional Divisions' Executive Committees, p. 9)

LOCAL SECTIONS

W. L. DUDLEY, *Chairman and Representative on Council* (1935)
To be appointed (1936) — W. R. WOOLRICH (1938)
R. E. W. HARRISON (1937) — D. B. PRENTICE (1939)

Junior Advisers

JENSEN CLAUSEN — S. E. OREN
F. X. KROGMANN — J. M. TUCKER

(Personnel of Local Sections' Executive Committees, p. 12)

CONSTITUTION AND BY-LAWS

H. H. SNELLING, *Chairman and Representative on Council* (1935)
RICHARD KUTZLEB, JR. (1936) — W. H. KAVANAUGH (1938)
H. B. LEWIS (1937) — R. D. BRIZZOLARA (1939)

Junior Adviser: G. N. COLE (1935)

AWARDS

The members of this Committee serve as members also of the Special Council Committee on Honors

W. L. BATT, *Chairman and Representative on Council* (1935)
HERMAN DIEDERICHS (1936) — L. P. ALFORD (1938)
R. C. H. HECK (1937) — HARTE COOKE (1939)
Junior Adviser: C. B. ARNOLD (1935)

RELATIONS WITH COLLEGES

W. L. ABBOTT, *Chairman and Representative on Council* (1935)
E. W. BURBANK (1936) — W. A. HANLEY (1938)
R. V. WRIGHT (1937) — F. V. LARKIN (1939)
Junior Advisers { R. F. WARNER, JR. (1935); G. D. WILKINSON, JR. (1935)

(Student Branches and Officers, p. 18)

EDUCATION AND TRAINING FOR THE INDUSTRIES

G. A. SEYLER, *Chairman and Representative on Council* (1935)
C. J. FREUND (1936) — J. A. RANDALL (1938)
JOHN YOUNGER (1937) — P. E. BLISS (1939)

LIBRARY

E. P. WORDEN, *Chairman and Representative on Council* (1935)
G. F. FELKER (1936) — J. S. KERINS (1938)
L. K. SILLCOX (1937) — The Secretary, C. E. DAVIES, *Ex-Officio*

RESEARCH

Organized in 1909 to supervise all research activities of the Society, to cooperate with similar committees of kindred societies, to encourage research, and to disseminate knowledge of researches conducted in the United States and in other countries

G. M. EATON, *Chairman and Representative on Council* (1935)
D. B. BULLARD (1936) — H. A. JOHNSON (1938)
C. R. RICHARDS (1937) — N. E. FUNK (1939)

(*Personnel of Special Committees, p. 20*)

STANDARDIZATION

Organized in April, 1911, to supervise all standardization activities of the Society and to advise concerning the Society's participation in the activities of the American Standards Association

C. W. SPICER, *Chairman and Representative on Council* (1935)
ALFRED IDDLES (1936) — WALTER SAMANS (1938)
L. A. CORNELIUS (1937) — O. A. LEUTWILER (1939)

(*Personnel of Special Committees, p. 22*)

POWER TEST CODES

Organized December, 1918, to revise and extend the Power Test Codes of the Society. These codes had been formulated by various technical committees appointed to develop particular codes. This work began in 1886

F. R. LOW, *Chairman and Representative on Council* (1935)
R. H. FERNALD, *Acting Chairman*

Term expires 1935

ATLANTA

Organized: 1913
Territory: Radius of sixty miles from Atlanta, Ga.
Place of Meeting: Atlanta Athletic Club
Number of Members: 70

EXECUTIVE COMMITTEE

E. W. KLEIN, *Chairman*
W. C. WROE, *Vice-Chairman*
R. M. MATSON, *Secretary-Treasurer*
GEORGE BRAUNGART, JR.
J. W. PARKER, JR.
P. R. YOPP

BALTIMORE

Organized: 1916
Territory: Radius of thirty miles from Baltimore, Md.
Place of Meeting: Engineers' Club of Baltimore
Luncheon meeting every Wednesday at 12:00 noon at Engineers' Club
Number of Members: 158

EXECUTIVE COMMITTEE

J. C. STROTT, *Chairman*
F. W. KOUWENHOVEN, *Secretary-Treasurer*
J. R. BAKER
O. C. CROMWELL
A. W. TAYLOR
K. A. HAWLEY
N. B. HIGGINS
J. E. HOWARD
A. L. PENNIMAN, JR.

BIRMINGHAM

Organized: 1915
Territory: Radius of sixty miles from Birmingham, Ala.
Place of Meeting: Auditorium of the Alabama Power Company Building
Number of Members: 51

EXECUTIVE COMMITTEE

J. A. SIRNIT, *Chairman*
J. W. ESHELMAN, *Vice-Chairman*
R. A. POLGLAZE, *Secretary-Treasurer*
J. M. GILFILLAN
J. W. ORCUTT

BOSTON

Organized: 1909
Territory: Radius of thirty miles from Boston, Mass.
Place of Meeting: Rooms of the Engineering Societies of Boston
Local Organization: Engineering Societies of Boston
Number of Members: 501

EXECUTIVE COMMITTEE

A. W. BENOIT, *Chairman*
J. T. CROGHAN, *Vice-Chairman*
G. C. EATON, *Secretary-Treasurer*
E. L. ROOT
W. E. FARNHAM
W. F. RYAN

BRIDGEPORT

Organized: 1917, as a Branch of Connecticut Section; reorganized as a Section, 1923
Territory: Fairfield County, Conn.
Place of Meeting: University Club
Number of Members: 107

EXECUTIVE COMMITTEE

H. E. WELLS, *Chairman*
H. P. HARRIS, *Vice-Chairman*
W. H. SNIFFEN, *Secretary*
C. N. HOAGLAND, *Treasurer*
T. H. BEARD
JULIUS BRENZINGER

BUFFALO

Organized: 1915
Territory: Radius of thirty miles from Buffalo, N. Y.
Place of Meeting: Hotel Statler
Local Organization: Engineering Society of Buffalo
Number of Members: 162

EXECUTIVE COMMITTEE

J. L. YATES, *Chairman*
PAUL DUBOSCLARD, *Acting Vice-Chairman*
W. A. MILLER, *Secretary*
C. E. HARRINGTON, *Treasurer*
C. GALE KIPLINGER
J. ARTHUR FISH
H. D. MUNSON

CENTRAL PENNSYLVANIA

Organized: 1921
Territory: Radius of approximately sixty miles from State College, Pa.
Place of Meeting: Pennsylvania State College, State College, Pa.
Number of Members: 51

EXECUTIVE COMMITTEE

F. E. BURPEE, *Chairman*
C. E. BULLINGER, *Secretary-Treasurer*
G. F. ELLIOTT
H. A. EVERETT
S. K. HOFFMAN
C. H. KENT

CHARLOTTE

Organized: As a Branch, 1923; as a Section, 1927
Territory: Radius of sixty miles from Charlotte, N. C.
Number of Members: 23

EXECUTIVE COMMITTEE

W. S. LEE, JR., *Chairman*
H. M. MCKELVIE, *Vice-Chairman*
V. E. FULLER, *Secretary-Treasurer*
J. H. SADLER
ASA HOSMER, *Ex-Officio*

CHATTANOOGA

Organized: 1922
Territory: Radius of sixty miles from Chattanooga, Tenn.
Number of Members: 14

EXECUTIVE COMMITTEE

NEWELL SANDERS, *Chairman*
H. H. BAILEY, *Vice-Chairman*
F. WARD REILLY, *Secretary-Treasurer*
T. C. ERVIN
M. P. WALL

CHICAGO

Organized: 1913
Territory: Radius of fifty miles from Chicago, Ill.
Headquarters: Mid-West A.S.M.E. Office, 205 West Wacker Drive, Chicago, Ill.
Local Organization: Western Society of Engineers
Number of Members: 639

EXECUTIVE COMMITTEE

R. D. BRIZZOLARI, *Chairman*
A. E. GRUNERT, *Vice-Chairman*
F. B. ORR, *Secretary*
HUGO DIEMER, *Treasurer*
C. C. AUSTIN
C. B. COLE
L. D. GAYTON
W. W. WINTERROWD

CINCINNATI

Organized: 1912
Territory: Radius of thirty miles from Cincinnati, Ohio
Place of Meeting: Engineers' Club Rooms, Ninth & Race Sts.
Local Organization: Engineers' Club of Cincinnati
Number of Members: 199

EXECUTIVE COMMITTEE

J. T. FAIG, *Chairman*
G. A. SEYLER, *Vice-Chairman*
C. A. JOERGER, *Secretary-Treasurer*

W. W. TANGEMAN
H. C. UIHLEIN

CLEVELAND

Organized: 1918
Territory: Counties of Lorain, Cuyahoga Lake, Geauga, and Ashtabula in Ohio
Place of Meeting: Statler Hotel
Local Organization: Cleveland Engineering Society
Number of Members: 238

EXECUTIVE COMMITTEE

L. E. JERMY, *Chairman*
A. J. STOCK, *Vice-Chairman*
H. M. HAMMOND, *Secretary*
FERDINAND JEHL, *Treasurer*
E. H. WHITLOCK
DAVID GAEHR
H. A. MACKENZIE
MCREA PARKER
G. L. TUVE

COLORADO

Organized: 1919
Territory: Entire State of Colorado
Place of Meeting: Parisienne Rotisserie Inn, Denver, Colo.
Local Organization: Colorado Engineering Council (Colorado Society of Engineers)
Number of Members: 84

EXECUTIVE COMMITTEE

F. A. LOCKWOOD, *Chairman*
G. A. RICHTER, *Secretary-Treasurer*
L. D. CRAIN
F. H. PROUTY
ARTHUR HALLIWELL
J. A. HUNTER
D. J. NEVILL

COLUMBUS

Organized: 1920
Territory: Counties of Union, Delaware, Licking, Madison, Franklin, Fayette, Pickaway, and Ross in Ohio
Place of Meeting: Batelle Memorial Institute and Ohio State University
Local Organization: Engineers' Club of Columbus
Number of Members: 79

EXECUTIVE COMMITTEE

F. W. MARQUIS, *Chairman*
H. S. DICKERSON, *Vice-Chairman*
E. M. SAMPSON, *Secretary-Treasurer*
S. R. BEITLER
T. H. KERR

DAYTON

Organized: 1926
Territory: Counties of Drake, Miami, Champaign, Preble, Montgomery, Greene, and northern part of Butler and Warren in Ohio
Place of Meeting: Engineers' Club of Dayton
Local Organization: Engineers' Club of Dayton
Number of Members: 73

EXECUTIVE COMMITTEE

J. Q. SALISBURY, *Chairman*
R. W. MARTIN, *Vice-Chairman*
W. E. BLANK, *Secretary*
B. E. TATE, *Treasurer*

E. R. BREAKER

INDIANAPOLIS

Organized: 1916
Territory: Radius of eighty miles from Indianapolis, within Indiana
Place of Meeting: Place varies
Local Organization: Indiana Engineering Society
Number of Members: 115

EXECUTIVE COMMITTEE

D. B. PRENTICE, *Chairman*
J. H. MAGUIRE, *Vice-Chairman*
J. C. SIEGESMUND, *Secretary-Treasurer*
F. C. HOCKEMA
HOMER RUPARD

INLAND EMPIRE

Organized: 1921
Territory: East of Columbia River in State of Washington, and Counties of Okanogan and Benton, and portion of Northern Idaho
Place of Meeting: Davenport Hotel, Spokane
Luncheon Meetings every Wednesday at 12:00 noon, Davenport Hotel, Spokane
Local Organization: Associated Engineers of Spokane
Number of Members: 21

EXECUTIVE COMMITTEE

D. R. GRAY, *Chairman*
U. B. HOUGH, *Vice-Chairman*
C. I. CARPENTER, *Secretary-Treasurer*
H. F. GAUSE
H. J. MACCAMY
L. J. POSPISIL

KANSAS CITY

Organized: 1921
Territory: Radius of sixty miles from Kansas City, Mo.
Place of Meeting: Hotel President
Local Organization: Engineers' Club of Kansas City
Number of Members: 89

EXECUTIVE COMMITTEE

E. L. MCDONALD, *Chairman*
E. D. HAY, *Vice-Chairman*
H. A. SMITH, *Secretary*
P. A. WHITE, *Treasurer*
H. A. ATWATER
W. G. CRAMER
E. L. HENDRICKSON
F. J. [illegible]BAUR
A. C. KIRKWOOD
J. A. WALTER

KNOXVILLE

Organized: 1923
Territory: All the counties east of the west boundaries of the following, Morgan, Roane, Loudon, McMinn, Scott, and Polk, Tenn., and Bell County, Ky.
Place of Meeting: Andrew Johnson Hotel
Number of Members: 39

EXECUTIVE COMMITTEE

E. W. PALMER, *Chairman*
J. P. FERRIS, *Vice-Chairman*
E. L. CARPENTER, *Secretary-Treasurer*
WALTER CARSON, JR.
WENDELL KENNEDY
W. F. SEARLE, JR.

LOS ANGELES

Organized: 1915
Territory: South of southern boundaries of following counties, Monterey, Kings, Tulares, and Inyo, Calif.
Place of Meeting: Place varies
Local Organization: Technical Societies of Los Angeles
Number of Members: 318

EXECUTIVE COMMITTEE

D. P. VAIL, *Chairman*
J. R. HOFFMAN, *Vice-Chairman*
S. M. DUNN, *Secretary-Treasurer*
E. C. BARKSTROM
D. E. DICKEY
L. G. METCALF
W. ROY SHETTEL

LOUISVILLE

Organized: 1922
Territory: Radius of thirty miles from Louisville, Ky.
Place of Meeting: Engineers' and Architects Club of Louisville
Local Organization: Engineers' and Architects Club
Number of Members: 34

EXECUTIVE COMMITTEE

J. F. HURST, *Chairman*
L. S. VANCE, *Vice-Chairman*
H. H. FENWICK, *Secretary-Treasurer*
B. M. BRIGMAN
J. H. ROMANN

MEMPHIS

Organized: 1923
Territory: Radius of sixty miles from Memphis, Tenn.
Number of Members: 28

EXECUTIVE COMMITTEE

L. H. HUNGATE, JR., *Chairman*
R. V. DOWNS, *Vice-Chairman*
J. J. RYAN, *Secretary-Treasurer*
T. H. ALLEN
M. W. RICE
W. H. ROBERTS
J. S. ROBINSON

MERIDEN

Organized: 1917, as a Branch of Connecticut Section; reorganized as a Section, 1923
Territory: Meriden, Middletown, Southington, Portland, Plantsville, and Wallingford, Conn.
Place of Meeting: State Trade School Auditorium
Number of Members: 25

EXECUTIVE COMMITTEE

C. A. NEWTON, *Chairman*
R. W. STETSON, *Secretary-Treasurer*
H. C. CASHEN
J. A. HUTCHINSON
L. B. MARCY
E. A. ROBINSON

METROPOLITAN

Organized: 1910
Territory: Metropolitan District, New York and New Jersey
Place of Meeting: Engineering Societies Building, New York, N. Y.
Number of Members: 3459

Executive Committee

J. N. Landis, *Chairman*
R. B. Purdy, *Secretary*
W. H. Armacost, *Treasurer*
W. W. Clinedinst
E. S. Crosby
W. C. Glass
John Hoffhine
T. E. Keating
W. L. Tann
G. B. Pegram, *Ex-Officio*

MID-CONTINENT

Organized: 1919
Territory: Entire States of Oklahoma and Arkansas, and a part of Louisiana. In Texas north of the southern boundaries of the counties of Gaines, Dawson, Bordon, Scurry, Fisher, Jones, and Shackelford
Place of Meeting: 213 Midco Building, Tulsa, Okla.
Number of Members: 148

Executive Committee

Hollis P. Porter, *Chairman*
J. M. McGregor, *Vice-Chairman*
J. F. Eaton, *Secretary*
H. W. Manley, *Treasurer*
F. S. Kelly, Jr.
V. L. Maleev
R. G. Paddock

MILWAUKEE

Organized: 1904
Territory: Radius of fifty miles from Milwaukee, Wis.
Place of Meeting: Milwaukee Athletic Club
Local Organization: Engineers' Society of Milwaukee
Number of Members: 196

Executive Committee

W. D. Bliss, *Chairman*
A. H. Luedicke, *Secretary-Treasurer*
C. A. Cahill
Hans Dahlstrand
F. H. Dorner
Arthur Simon

MINNESOTA

Organized: Minneapolis, 1913; St. Paul, 1913; merged the two Sections, 1934
Territory: Entire State of Minnesota
Place of Meeting: Minnesota Union
Local Organization: Minneapolis Engineers' Club, Minnesota Federation of Architectural and Engineering Societies
Number of Members: 92

Executive Committee

G. F. Endicott, *Chairman*
Melvin Ovestrud, *Vice-Chairman*
L. A. Cobb, *Secretary-Treasurer*
P. J. Frawley
R. E. Gibbs
C. A. Herrick
H. O. Washburn

NEBRASKA

Organized: 1922
Territory: State of Nebraska, and Council Bluffs, Iowa
Place of Meeting: Lincoln and Omaha
Local Organization: Engineers' Club of Lincoln and Omaha
Number of Members: 32

Executive Committee

W. L. DeBaufre, *Chairman*
R. B. Boals, *Vice-Chairman*
A. A. Luebs, *Secretary-Treasurer*
A. E. Bunting
C. F. Moulton
R. H. Park
R. J. Prohaska

NEW BRITAIN

Organized: 1921, as a Branch of Connecticut Section; reorganized as a Section, 1923
Territory: New Britain, Plainville, Forestville, Bristol, Kensington, and Berlin, Conn.
Place of Meeting: Auditorium of the State Trade School
Number of Members: 35

Executive Committee

R. A. Grise, *Chairman*
P. W. Bauer, *Vice-Chairman*
C. W. Lund, *Secretary-Treasurer*
R. H. Barlow
B. S. Lewis
H. L. Spaunburg
C. C. Stevens
W. Clements Zinck

NEW HAVEN

Organized: 1912; reorganized, 1923
Territory: Portions of New Haven and Middlesex Counties, Conn.
Place of Meeting: Mason Laboratory, Yale University
Number of Members: 88

Executive Committee

C. W. Taylor, *Chairman*
H. R. Polleys, *Secretary-Treasurer*
A. L. Breckenridge
M. J. Radecki
P. H. English
G. E. Hulse
J. C. Menzies

NEW ORLEANS

Organized: 1916
Territory: All of Louisiana except the northern part allotted to Mid-Continent Section
Place of Meeting: Room 422, St. Charles Hotel
Local Organization: Louisiana Engineering Society
Number of Members: 83

Executive Committee

R. F. Muller, *Chairman*
C. A. Bender, Jr., *Secretary-Treasurer*
D. W. Stewart
J. S. Netherwood
A. D. Stancliff

NORTH TEXAS

Organized: 1922
Territory: Radius of one hundred and twenty-five miles from Dallas, in Texas
Place of Meeting: University Club, Dallas, Texas
Local Organization: Technical Club of Dallas
Number of Members: 50

Executive Committee

E. W. Burbank, *Chairman*
R. R. Crowdus, *Secretary-Treasurer*
R. W. Howe
P. M. Cordell
W. B. Gregory

NORWICH

Organized: 1930
Territory: Counties of Tolland, Windham, and New London in Connecticut, and Westerly District in Rhode Island
Place of Meeting: Arcanum Club, 150 Main St., Norwich
Number of Members: 30

Executive Committee

Lovelock Holm, *Chairman*
W. E. Beaney, *Secretary-Treasurer*
C. E. Barber
W. L. Edel
F. S. English
C. W. Phelps
L. E. Whiton

ONTARIO

Organized: 1917
Territory: Province of Ontario, Canada
Place of Meeting: Mining Building, University of Toronto
Number of Members: 86

Executive Committee

O. W. Ellis, *Chairman*
F. G. East, *Secretary-Treasurer*
E. A. Allcut
W. S. Ball
C. H. McL. Burns
P. G. Welford
F. H. Eland
S. L. Fear
W. G. McIntosh
W. A. Osbourne
W. A. Richards

OREGON

Organized: 1919
Territory: State of Oregon and that territory in Washington within a radius of thirty miles from Portland, Ore.

Place of Meeting: University Club, Portland, Ore.
Local Organization: Oregon Society of Engineers
Number of Members: 52

EXECUTIVE COMMITTEE

W. H. MARTIN, *Chairman*
J. E. DYER, *Secretary-Treasurer*
S. M. LISTER
G. F. MCDOUGALL
A. A. OSIPOVICH

PENINSULA

Organized: 1923
Territory: West of the east boundaries of the following counties: Emmet, Charlevoix, Antrim, Kalkaska, Missaukee, Clare, Isabella, Gratiot, Clinton, Eaton, Calhoun, and Branch, Mich.
Place of Meeting: Grand Rapids, Mich.
Local Organization: Engineers' Club of Grand Rapids
Number of Members: 50

EXECUTIVE COMMITTEE

LEROY L. BENEDICT, *Chairman*
B. A. PARKS, *Vice-Chairman*
F. H. MEYER, *Secretary-Treasurer*
S. H. DOWNS
C. H. GRINNELL
E. E. NORMAN

PHILADELPHIA

Organized: 1912
Territory: Counties of Bucks, Montgomery, Chester, Philadelphia, Delaware, Pa., and the State of Delaware
Place of Meeting: Philadelphia Engineers' Club
Local Organization: Philadelphia Engineers' Club
Number of Members: 771

EXECUTIVE COMMITTEE

G. E. CROFOOT, *Chairman*
W. F. OBERHUBER, *Vice-Chairman*
J. P. HARBESON, *Secretary-Treasurer*
E. R. GLENN
C. C. JONES
COLEMAN SELLERS, 3RD

PITTSBURGH

Organized: 1920
Territory: Counties bounded by and including Beaver, Butler, Venango, Forest, Jefferson, Indiana, Somerset, Fayette, Greene, and Washington, Pa.
Place of Meeting: Engineers' Society of Western Pennsylvania, William Penn Hotel
Local Organization: Engineers' Society of Western Pennsylvania
Number of Members: 365

EXECUTIVE COMMITTEE

L. E. HANKISON, *Chairman*
K. F. TRESCHOW, *Secretary-Treasurer*
R. B. AMBROSE
LOUIS ELLMAN
W. N. FLANAGAN
R. J. S. PIGOTT

PLAINFIELD

Organized: 1921
Territory: Plainfield and territory included between Elizabeth, Bound Brook, Metuchen, and Watchung, N. J.
Place of Meeting: Elks Club, Elizabeth, Park Hotel, Plainfield
Local Organization: Plainfield Engineers Club, Singer Engineering Society
Number of Members: 217

EXECUTIVE COMMITTEE

F. C. SPENCER, *Chairman*
RICHARD KAIER, *Vice-Chairman*
D. V. WATERS, *Secretary*
J. P. FABER, *Treasurer*
W. B. UPDEGRAFF

PROVIDENCE

Organized: 1920
Territory: Radius of thirty miles from Providence, R. I.
Place of Meeting: Providence Engineering Society Building, 195 Angell St., Providence, R. I.
Local Organization: Providence Engineering Society
Number of Members: 134

EXECUTIVE COMMITTEE

A. C. CHICK, *Chairman*
Z. R. BLISS, *Vice-Chairman*
A. WILLIAM MEYER, *Secretary-Treasurer*
F. A. CHIFFELLE
C. F. MILLER
S. A. VAULE

RALEIGH

Organized: As a Branch, 1923; as a Section, 1927
Territory: Radius of sixty miles from Raleigh, N. C.
Place of Meeting: N. C. State College, Raleigh, N. C.
Local Organization: N. C. Engineering Council, Raleigh Engineers Club
Number of Members: 31

EXECUTIVE COMMITTEE

R. P. KOLB, *Chairman*
R. S. WILBUR, *Vice-Chairman*
J. M. FOSTER, *Acting Secretary-Treasurer*
R. D. ANTHONY
B. B. GUY

ROCHESTER

Organized: 1919
Territory: Radius of thirty miles from Rochester, N. Y.
Place of Meeting: Rochester Engineering Society Rooms, Sagamore Hotel
Local Organization: Rochester Engineering Society, Sagamore Hotel
Number of Members: 99

EXECUTIVE COMMITTEE

A. E. SCHELL, *Chairman*
W. D. SEELEY, *Vice-Chairman*
I. G. MCCHESNEY, *Secretary-Treasurer*
O. V. SPRAGUE
J. F. ANCONA
K. C. CASTLE, JR.
C. C. ROSS

ROCK RIVER VALLEY

Organized: 1926
Territory: Radius of thirty miles from Rockford, Ill.
Local Organization: Rockford Engineering Society
Number of Members: 43

EXECUTIVE COMMITTEE

F. P. GRUTZNER, *Chairman*
M. B. MACNEILLE, *Vice-Chairman*
HERMAN HUGLE, *Secretary-Treasurer*
A. C. MATTISON
ROBERT VON ROTZ

ST. JOSEPH VALLEY

Organized: 1929
Territory: Counties of La Porte, Starke, Pulaski, St. Joseph, Marshall, Fulton, Elkhart, and Kosciusko in Indiana, and Cass and Berrien Counties in Michigan
Place of Meeting: Morningside Hotel, South Bend, Ind.
Local Organization: St. Joseph Valley Engineers' Club
Number of Members: 35

EXECUTIVE COMMITTEE

C. R. ADAMS, *Chairman*
C. C. WILCOX, *Vice-Chairman*
K. W. KNORR, *Secretary-Treasurer*

ST. LOUIS

Organized: 1909
Territory: Radius of thirty miles from St. Louis, Mo.
Place of Meeting: Place varies
Local Organization: Engineers' Club of St. Louis
Number of Members: 213

EXECUTIVE COMMITTEE

R. M. BOYLES, *Chairman*
G. L. SHANKS, *Vice-Chairman*
E. H. SAGER, *Secretary-Treasurer*
E. W. DAVIS
J. R. JACKSON
F. W. RABE

SAN FRANCISCO

Organized: 1910
Territory: All territory north of the northern boundaries of the counties of San Luis Obispo, Kern, and San Bernardino
Place of Meeting: Engineers' Club, 206 Sansome St.
Luncheon Meetings every Thursday at 12:15 Noon at the Engineers' Club
Local Organization: San Francisco Engineers' Club
Number of Members: 337

EXECUTIVE COMMITTEE

H. B. LANGILLE, *Chairman*
F. W. COLLINS, *Vice-Chairman*
R. L. GRUTZMACHER, *Secretary-Treasurer*
S. R. DOWS
W. M. MOODY
M. P. O'BRIEN
H. J. SMITH
LAWRENCE WASHINGTON

SAVANNAH

Organized: 1923
Territory: Radius of 125 miles from Savannah in Georgia
Place of Meeting: Savannah Hotel
Local Organization: Engineers' Council of Savannah Chamber of Commerce
Number of Members: 15

EXECUTIVE COMMITTEE

A. P. KEISKER, *Chairman*
BRUCE SAMS, *Vice-Chairman*
T. R. JONES, *Secretary*
FRANK EXLEY, *Treasurer*
W. H. ARTLEY
D. E. KEHOE
A. M. ORMOND

SCHENECTADY

Organized: As a Branch, 1919; as a Section, 1927
Territory: Radius of thirty miles from Schenectady, N. Y.
Place of Meeting: Edison Club Hall
Number of Members: 173

EXECUTIVE COMMITTEE

W. E. JOHNSON, *Chairman*
J. E. ANDERSON, *Secretary*
B. O. BUCKLAND, *Treasurer*
A. I. LIPETZ
A. J. NERAD
E. L. ROBINSON

SUSQUEHANNA

Organized: 1927
Territory: Counties of Cumberland, Dauphine, Lebanon, Adams, York, and Lancaster
Place of Meeting: Engineering Society of York
Local Organization: Engineering Society of York
Number of Members: 67

EXECUTIVE COMMITTEE

WILLIAM NOYES, *Chairman*
JACOB FISCH, *Vice-Chairman*
H. B. MARTIN, *Secretary-Treasurer*
WALTER KNAPP
R. M. SPENGLER

SYRACUSE

Organized: 1920
Territory: Radius of thirty miles from Syracuse, N. Y.
Place of Meeting: Ball Room of the Onondaga Hotel
Local Organization: The Technology Club of Syracuse
Number of Members: 115

EXECUTIVE COMMITTEE

H. B. CRAIG, *Chairman*
S. T. HART, *Vice-Chairman*
E. K. RHODES, *Secretary-Treasurer*
K. H. CASKEY
D. W. DIEFENDORF
A. G. FORSSELL
E. W. ZIMMERMAN

TOLEDO

Organized: 1920
Territory: Radius of thirty miles from Toledo, Ohio
Place of Meeting: University Club, Toledo, Ohio
Local Organization: Affiliated Technical Societies of Toledo
Number of Members: 58

EXECUTIVE COMMITTEE

E. P. RAYMOND, *Chairman*
HENRY KERR, *Vice-Chairman*
C. W. KIRSCH, *Secretary-Treasurer*
R. M. BATCH
D. M. PALMER, *Ex-Officio*
D. L. FELTHAM
J. R. MOSER
C. B. SCHAFER
I. F. ZAROBSKY

TRI-CITIES

Organized: 1920
Territory: Radius of thirty miles from Moline, Ill.
Place of Meeting: Rock Island, Ill., Moline, Ill., and Davenport, Iowa
Luncheon Meeting every Wednesday, Davenport Hotel, 12:00 Noon
Number of Members: 62

EXECUTIVE COMMITTEE

R. M. BARNES, *Chairman*
G. T. SCHOEMAKER, *Vice-Chairman*
C. A. CARLSON, *Secretary-Treasurer*
J. M. HARTMAN
W. P. HUNT
J. H. PLOEHN

UTAH

Organized: 1923
Territory: State of Utah
Place of Meeting: University Club, Salt Lake City
Local Organization: Utah Society of Engineers
Number of Members: 26

EXECUTIVE COMMITTEE

E. W. PACE, *Chairman*
W. J. COPE, *Vice-Chairman*
M. B. HOGAN, *Secretary-Treasurer*
JULIUS BILLETER
H. D. LANDES
F. W. MCENTIRE

UTICA

Organized: 1920
Territory: Radius of thirty miles from Utica, N. Y.
Local Organization: Mohawk Valley Technical Club
Number of Members: 26

EXECUTIVE COMMITTEE

E. G. MUNSON, *Chairman*
REX WITHERBEE, *Secretary-Treasurer*
W. J. CLEMENT

VIRGINIA

Organized: 1919
Territory: State of Virginia
Place of Meeting: Richmond, Norfolk, Charlottesville, Roanoke, University, Petersburg
Number of Members: 126

EXECUTIVE COMMITTEE

A. F. MACCONOCHIE, *Chairman*
F. T. MORSE, *Secretary*
H. C. HESSE, *Treasurer*
F. F. GROSECLOSE
J. B. WOODWARD
A. F. KEANE
E. F. KRONER
E. W. MILLER
E. J. F. WILSON

WASHINGTON, D. C.

Organized: 1919
Territory: District of Columbia
Place of Meeting: Auditorium, Potomac Electric Power Co., 10th & E Sts., Washington, D. C.
Number of Members: 162

EXECUTIVE COMMITTEE

H. N. EATON, *Chairman*
M. E. WESCHLER, *Vice-Chairman*
J. F. FOX, *Secretary-Treasurer*
M. X. WILBERDING
J. G. ADAIR
TAWSON PRICE
A. J. SCHWARTZ

WATERBURY

Organized: 1917, as a Branch of Connecticut Section; reorganized as a Section, 1923
Territory: Litchfield County and a portion of New Haven County
Place of Meeting: Waterbury Club
Number of Members: 72

EXECUTIVE COMMITTEE

M. J. DEMPSEY, *Chairman*
A. L. DAVIS, *Vice-Chairman*
R. L. PALATINE, *Secretary-Treasurer*
S. G. BEAN
E. J. DALY
J. H. ROBERTS

WEST VIRGINIA

Organized: 1925
Territory: State of West Virginia
Place of Meeting: Charleston, W. Va.
Number of Members: 61

EXECUTIVE COMMITTEE

E. L. HUDSON, *Chairman*
J. F. MALLOY, *Secretary-Treasurer*
E. R. HABICHT
ANDREW HILL

WESTERN MASSACHUSETTS

Organized: 1922
Territory: Includes counties of Berkshire, Franklin, Hampden, and Hampshire
Place of Meeting: Highland Hotel, Springfield, Mass.
Local Organization: Engineering Society of Western Massachusetts
Number of Members: 95

EXECUTIVE COMMITTEE

P. W. BIDWELL, *Chairman*
R. L. BOSWORTH, *Vice-Chairman*
L. G. CARLTON, *Secretary-Treasurer*
C. E. MAYNARD
E. LOVELL SMITH
G. R. WHOLEAN

WESTERN WASHINGTON

Organized: 1919
Territory: State of Washington west of the Columbia River with the exception of the territory included in the thirty-mile radius of Portland, Ore.
Place of Meeting: Engineers' Club, Arctic Bldg., Seattle, Wash.
Local Organization: Seattle Engineers' Club
Number of Members: 77

EXECUTIVE COMMITTEE

F. B. LEE, *Chairman*
R. E. JOHNSON, *Vice-Chairman*
R. L. DYER, *Secretary-Treasurer*
G. S. WILSON
C. P. MANN
W. A. MCKENZIE
R. E. WALTER

WORCESTER

Organized: 1915
Territory: Radius of thirty miles from Worcester, Mass.
Place of Meeting: Rooms of the Worcester Engineering Society
Local Organization: Worcester Engineering Society
Number of Members: 138

EXECUTIVE COMMITTEE

H. C. KENDALL, *Chairman*
S. N. MCCASLIN, *Secretary-Treasurer*
H. W. H. BETH
A. W. BLACKBURN
E. H. CARROLL
ROBERT ERICKSON
V. C. KING
T. L. F. LARSSON
K. C. MONROE
F. W. ROYS

YOUNGSTOWN

Organized: 1928
Territory: Counties of Trumbull, Mahoning, and Columbiana in Ohio, and Mercer and Lawrence in Pennsylvania
Place of Meeting: Central Y. M. C. A., Youngstown, Ohio
Number of Members: 67

EXECUTIVE COMMITTEE

E. M. RICHARDS, *Chairman*
S. M. ADAMS, *Secretary-Treasurer*
GORDON ARMSTRONG
E. E. KENDALL
R. M. SMITH
CORNEL KMENTT
M. H. MAWHINNEY
H. OVESEN
F. R. SCHAEFER

Student Branches

(Personnel of Standing Committee on Relations With Colleges, page 5. Communicate with Student Branch through Honorary Chairman)

Name and Location	Year Authorized	Chairman	Secretary	Honorary Chairman
Akron, Univ. of, Akron, Ohio	1924	WILLIAM LEAVENWORTH	PAUL WAGNER	F. S. GRIFFIN
Alabama Polytechnic Inst., Auburn, Ala.	1920	F. R. BALL, JR.	D. O. NICHOLS, JR.	C. R. HIXON
Alabama, Univ. of, University, Ala.[1]	1931	L. E. MORRISON	HERMAN SCHWABE	J. M. GALLALEE
Arkansas, Univ. of, Fayetteville, Ark.	1910	J. W. CARTINHOUR	R. H. BLOOD	R. G. PADDOCK
Armour Inst. of Technology, Chicago, Ill.	1909	J. H. DEBOO	F. J. MEYER	DANIEL ROESCH
Brooklyn, Polytechnic Inst. of, Brooklyn, N. Y.	1909	DONALD MCCORMICK	J. R. BLIZARD	GERADO IMMEDIATO
Brown Univ., Providence, R. I.	1923	R. S. SHAW	R. F. HOPKINS	J. A. HALL
Bucknell Univ., Lewisburg, Pa.	1916	J. D. MORRIS	G. F. ZIMMERMAN	G. M. KUNKEL
California Inst. of Technology, Pasadena, Calif.	1914	ALLEN RAY	ROBERT HALLANGER	HOWARD CLAPP
California, Univ. of, Berkeley, Calif.	1912	CHARLES HARBAND	W. L. RODMAN[2]	N. F. WARD
Carnegie Inst. of Technology, Pittsburgh, Pa.	1913	W. H. STAFFORD	WALTER APPLEGATE	S. B. ELY
Case School of Applied Science, Cleveland, Ohio	1913	R. A. TABORSKY	R. M. SKIDMORE	E. S. AULT
Catholic Univ of America, Washington, D. C.	1922	C. J. DVORAK	R. J. GREEN	M. E. WESCHLER
Cincinnati, Univ. of, Cincinnati, Ohio[3]	1909	GEORGE GENTRY	A. P. MCARTHUR	C. A. JOERGER
Clarkson College of Technology, Potsdam, N. Y.	1930	S. O. CARPENTER	E. I. BRICKER	J. H. DAVIS
Clemson Agricultural College, Clemson College, S. C.	1921	H. A. PLOWDEN	J. B. COX, JR.	B. E FERNOW
Colorado Agricultural College, Fort Collins, Colo.	1914	CARL RITTER	JOHN SUDDUTH	JOSEPH PINSKY
Colorado, Univ. of, Boulder, Colo.	1914	W. T. LUCKING	W. B. SWAN	G. S. DOBBINS
Columbia Univ., New York, N. Y.	1909	WILLIAM GEOGHEGAN	M. A. SHRIRO	J. R. HICKS
Cooper Union, New York, N. Y.	1920	N. M. STEFANO	M. YESOWITZ	H. F. ROEMMELE
Cornell Univ., Ithaca, N. Y.	1908	H. A. MASON	J. S. LESLIE	F. O. ELLENWOOD
Delaware, Univ. of, Newark, Del.	1929	EUGENE MADEY	D. W. SELBY	W. FRANCIS LINDELL
Detroit, Univ. of, Detroit, Mich.	1930	W. B. OAKLEY	KARL SANTTI	H. E. MAYROSE
Drexel Inst., Philadelphia, Pa.	1920	J. W. REID	A. E. JURAM[4]	DAWSON DOWELL
Florida, Univ. of, Gainesville, Fla.	1926	FRED HOWE	E. W. MCKNIGHT	B. R. VAN LEER
George Washington Univ., Washington, D. C.	1924	E. J. THOMAS	C. H. SWANSON	B. C. CRUICKSHANKS
Georgia School of Technology, Atlanta, Ga.	1915	M. G. KEISER	L. J. DRUM	N. C. EBAUGH
Idaho, Univ. of, Moscow, Idaho	1925			H. E. GAUSS
Illinois, Univ. of, Urbana, Ill.	1909	W. A. JOHNSON	C. W. BRISSENDEN	C. H. CASBERG
Iowa State College, Ames, Iowa	1919	D. E. PFITZENMAIER	W. J. SCHLAGEL	N. P. BAILEY
Iowa, State Univ. of, Iowa City, Iowa	1913	WILLIAM BUSBY	D. E. NELSON	R. M. BARNES
Johns Hopkins Univ., Baltimore, Md.	1917	T. H. MARSHALL	J. R. CURTIS, JR.	A. G. CHRISTIE
Kansas State Agricultural College, Manhattan, Kan.	1914	T. G. BECKWITH	R. E. TORKELSON	A. J. MACK

Special Research Committees

(*Personnel of Standing Committees, p. 6*)

LUBRICATION

Appointed October, 1915, to investigate the fundamental problems of lubrication, to formulate results of investigations previously made, and to keep in touch with contemporary research in this field

(The Committee is now being reorganized. In December, 1934, the Standing Committee on Research appointed a special committee to formulate a statement of the lubrication problem in its broad, present-day aspects and to recommend a program of research under the auspices of the A.S.M.E. The personnel of this special committee is as follows: N. E. FUNK, *Chairman*, D. B. BULLARD, M. D. HERSEY, G. B. KARELITZ, A. L. KINGSBURY, and W. F. PARISH.)

FLUID METERS

Appointed 1916, to develop the theory of fluid meters of all kinds and to report on the best methods for their installation and use

(Reorganized July, 1929)

R. J. S. PIGOTT, *Chairman*
J. R. CARLTON, *Secretary*
H. S. BEAN
S. R. BEITLER
R. K. BLANCHARD
G. D. CONLEE
W. W. FRYMOYER
LOUIS GESS
T. H. KERR
W. S. PARDOE
E. S. SMITH, JR.
R. E. SPRENKLE
E. C. M. STAHL
T. R. WEYMOUTH

THERMAL PROPERTIES OF STEAM

Appointed in December, 1921, to direct research on the thermal properties of water-vapor and steam from 0 C to the upper limits of temperature and pressure

(Reorganized April, 1929)

W. L. ABBOTT, *Vice-Chairman*
G. L. BOURNE
H. N. DAVIS
H. C. DICKINSON
ALEX DOW
A. M. GREENE, JR.
R. C. H. HECK
D. S. JACOBUS
J. H. KEENAN
F. G. KEYES
L. S. MARKS
G. A. ORROK
R. J. S. PIGOTT
H. V. RASMUSSEN
E. L. ROBINSON

STRENGTH OF GEAR TEETH

Appointed in December, 1921. Is investigating factors affecting the strength and life of gear teeth

R. E. FLANDERS, *Chairman*
C. H. LOGUE, *Secretary*
C. G. BARTH
EARLE BUCKINGHAM
A. M. GREENE, JR.
C. W. HAM
F. E. MCMULLEN
E. W. MILLER
ERNEST WILDHABER

CUTTING OF METALS

Appointed in September, 1923. Is studying the problems of metal cutting, including tool materials, tool design, lubrication, cooling, and speeds and feeds

COLEMAN SELLERS, 3RD, *Chairman*
L. N. GULICK, *Secretary*
A. L. DELEEUW
KING HATHAWAY
L. P. ALFORD
C. J. OXFORD
R. D. PROSSER

ELEVATOR SAFETIES

Appointed June, 1924, as a subcommittee of the Sectional Committee on Safety Code for Elevators, to study the function and operation of elevator safeties and buffers and their associated mechanisms and to develop methods of test for the approval of elevator safety devices

M. H. CHRISTOPHERSON, *Chairman*
O. P. CUMMINGS, *Vice-Chairman*
J. A. DICKINSON, *Secretary*
BASSETT JONES
D. L. LINDQUIST
M. G. LLOYD
J. J. MATSON
M. B. MCLAUTHLIN
W. S. PAINE
S. F. VOORHEES
S. W. JONES

MECHANICAL SPRINGS

Appointed December, 1923, to determine the status of the mechanical-spring art, to promote and conduct necessary and adequate research, and to develop the art to the point of standardization

J. R. TOWNSEND, *Chairman*
C. T. EDGERTON, *Secretary*
C. E. BARBA
W. G. BROMBACHER
R. W. COOK
W. T. DONKIN
RUPEN EKSERGIAN
G. E. HANSEN
BENJAMIN LIEBOVITZ
DAVID LOFTS
(R. D. BRIZZOLARA, *Alternate*)
A. N. LUKENS
D. J. MCADAM, JR.
R. E. PETERSON
J. B. REYNOLDS
J. W. ROCKEFELLER, JR.
B. W. ST. CLAIR
M. F. SAYRE
KEITH WILLIAMS
J. KAYE WOOD
F. P. ZIMMERLI
O. B. ZIMMERMAN

EFFECT OF TEMPERATURE ON THE PROPERTIES OF METALS

Appointed December, 1924, as a joint research committee of the A.S.T.M. and the A.S.M.E. to encourage the investigation and accumulation of data on the properties of metals used in the mechanic arts at extremely high and low temperatures

H. J. FRENCH, *Chairman*
N. L. MOCHEL, *Secretary*
A. D. BAILEY
R. A. BULL
E. S. DIXON
H. W. GILLETT
LOUIS JORDAN
H. J. KERR
C. L. KINNEY, JR.
H. W. MAACK
C. E. MACQUIGG
J. A. MATHEWS
P. E. MCKINNEY
E. L. ROBINSON
A. E. WHITE

BOILER FEEDWATER STUDIES

Appointed March, 1925, as a Joint Research Committee of the American Boiler Manufacturers Association, American Railway Engineering Association, American Water Works Association, Edison Electric Institute, the American Society for Testing Materials, and the A.S.M.E., to study methods of analysis and treatment of boiler feedwater for stationary and railroad practice

W. L. ABBOTT
S. B. APPLEBAUM
A. D. BAILEY
A. G. CHRISTIE
H. C. DINGER
D. K. FRENCH
R. E. HALL
J. A. HOLMES
C. F. HIRSHFELD
C. R. KNOWLES
A. L. PENNIMAN, JR.
E. B. POWELL
T. E. PURCELL
C. W. RICE
F. N. SPELLER
KURT TOENSFELDT
A. E. WHITE
J. D. YODER

CONDENSER TUBES

Appointed May, 1925, to investigate and report on the causes of failure of tubes used in steam condensers and similar heat interchange apparatus

A. E. WHITE, *Chairman*
BERT HOUGHTON, *Vice-Chairman*
P. A. BANCEL
R. H. BARBER
D. K. CRAMPTON
H. M. CUSHING
H. F. EDDY
V. M. FROST
W. L. GREEN, JR.
C. F. HARWOOD
C. F. HIRSHFELD
H. W. LEITCH
E. F. MILLER
W. B. PRICE
H. A. STAPLES
W. R. WEBSTER
ROBERT WORTHINGTON
REPRESENTATIVE OF BUREAU OF ENGINEERING, U. S. NAVY DEPARTMENT

WORM GEARS

Appointed May, 1927, to investigate certain problems in connection with the action of worm gear drives and to recommend improvements in their design, manufacture, and use

EARLE BUCKINGHAM, *Chairman*
G. H. ACKER
L. R. BUCKENDALE
W. H. HIMES
D. L. LINDQUIST
A. A. ROSS
B. F. WATERMAN
REPRESENTATIVE OF BUREAU OF ENGINEERING, U. S. NAVY DEPARTMENT

BOILER FURNACE REFRACTORIES

Appointed June, 1925, to determine the principal factors governing the failure of refractories in various types of installations, to subject these factors to detailed experimental analysis, to undertake the formulation of suitability tests and, if necessary, to attempt to develop a suitable refractory to meet the needs of severe service

W. A. Carter, *Chairman*
S. H. Barnum
G. A. Bole
M. C. Booze
W. H. Fulweiler
C. B. Grady
R. A. Heindl
C. F. Hirshfeld
O. P. Hood
R. K. Hursh
N. E. Lewis
J. S. McDowell
(F. A. Harvey, *Alternate*)
S. J. McDowell
Percy Nicholls
S. M. Phelps
E. B. Powell
R. A. Sherman
R. B. Sosman
L. J. Trostel
G. B. Wilkes

VELOCITY MEASUREMENT OF FLUID FLOW

Appointed November, 1927, to sponsor the development of an absolute method for determining the velocity of the flow of fluids by means of the location of nodal points in wave systems

W. F. Durand, *Chairman*
T. R. Weymouth

MEASURES OF MANAGEMENT

Appointed March, 1928, to attempt the reconciliation of certain economic laws affecting production, to develop formulas for management, and to collect and report information on management research

W. E. Freeland, *Chairman*
F. E. Raymond, *Secretary*
J. H. Barber
T. H. Brown
R. C. Davis
G. E. Hagemann

ABSORPTION OF RADIANT HEAT IN BOILER FURNACES

Appointed April, 1928, to make a study of the absorption of radiant heat in boiler furnaces with the purpose of developing recommendations on improved furnace design

W. J. Wohlenberg, *Chairman*
E. G. Bailey
R. M. Gates
C. W. Gordon
E. L. Lindseth
G. A. Orrok
R. J. S. Pigott
John Van Brunt

STRENGTH OF VESSELS UNDER EXTERNAL PRESSURE

Appointed June, 1929, to develop reliable design data on the strength of cylindrical and spherical surfaces under external pressure, particularly with reference to jacketed vessels

W. D. Halsey, *Chairman*
A. J. Ely
F. V. Hartman
T. McL. Jasper
A. W. Limont, Jr.
Carl Rigdon
H. E. Saunders
E. E. Shanor
J. H. Taylor
(F. S. G. Williams, *Alternate*)
D. B. Wesstrom
D. F. Windenburg

WIRE ROPE

Authorized in October, 1928, to study the factors affecting the life of wire rope so that it may be better understood and more effectively used

W. H. Fulweiler, *Chairman*
W. M. Bager
H. LeR. Brink
D. L. Lindquist
G. W. Martin
C. A. McCune
A. H. McDougall
B. V. E. Nordberg, Jr.
W. S. Paine
W. J. Ryan
George Simpson
L. E. Young

HEAVY DUTY ANTI-FRICTION BEARINGS

Appointed March, 1929, to investigate the possibilities and limitations of anti-friction bearings when applied to roll necks of rolling mills

W. Trinks, *Chairman*
H. E. Brunner
W. R. Clark
G. C. Farkell
H. H. Talbot
S. M. Weckstein
H. A. Winne

REMOVAL OF ASH AS MOLTEN SLAG FROM POWDERED-COAL FURNACES

Appointed March, 1929, to investigate the adding of fluxes as a means of increasing the fluidity of slag in boiler furnaces and thus permit its removal at operating furnace temperatures

K. M. Irwin, *Chairman*
Andrew Carnegie
T. G. Coghlan
H. M. Cushing
C. F. Hirshfeld
Percy Nicholls
E. B. Powell
P. B. Rice

AUTOMATIC OIL PIPE LINE PUMPING STATIONS

Authorized March, 1930, to develop methods of automatic control for oil pipe line pumping stations

W. G. Heltzel, *Chairman*
J. N. Hunter, *Vice-Chairman*
T. D. Williamson, *Secretary*
W. S. Baugh
W. C. Dreyer
W. H. Elliot
J. B. Ford
L. T. Gibbs
F. A. Graham
C. F. Guinn
A. N. Horne
J. K. McGoldrick
J. M. McGregor
J. B. McMahon
R. L. Middleton
O. L. Olsen
William Parkerson
W. R. Reed
F. A. Stivers
W. H. Stueve
Fred Thilenius
J. B. Thomas
F. E. Warterfield
Oscar Wolf

PRIME MOVERS FOR ROTARY DRILLING OF OIL WELLS

Appointed June, 1930, to investigate existing types of prime movers used for rotary drilling of oil wells as to their relative efficiencies, costs of operation, and general satisfaction

D. L. Trax, *Chairman*
Raymond Carr
W. H. Carson
R. R. Hawkins
H. W. Manley

CRITICAL PRESSURE STEAM BOILERS

Appointed June, 1931, to study the characteristics of high-pressure forced-circulation steam-generating units

A. A. Potter, *Chairman*
A. D. Bailey
E. G. Bailey
A. G. Christie
F. S. Clark
A. M. Houser
H. J. Kerr
G. A. Orrok
H. L. Solberg
P. W. Thompson

SAMPLING PULVERIZED FUEL IN A MOVING GAS STREAM

Appointed November, 1932, to investigate the present methods of sampling pulverized fuel and to evolve a generally satisfactory method that may be adopted as a standard

K. M. Irwin, *Chairman*
F. M. Gibson, *Secretary*
John Blizard
Ollison Craig
M. D. Engle
C. S. Gladden
A. E. Grunert
R. M. Hardgrove
J. C. Hardigg
H. J. Klotz
Henry Kreisinger
J. W. McKenzie
W. S. Morrison
G. B. Randall
R. C. Roe
E. H. Tenney

COTTON SEED PROCESSING

Appointed December, 1932, to study the mechanical problems involved in storing, conditioning, and cooking cotton seed meats

W. R. Woolrich, *Chairman*
Homer Barnes
E. L. Carpenter
W. D. Edwards
C. E. Garner
B. J. Sams

**Sole sponsorship. Sectional Committee organized November, 1926*

A.S.M.E. Members (Total personnel, 38)

†G. E. Hagemann, *Secretary*
M. F. Behar
C. N. Bigelow
Wallace Clark
H. G. Crockett
E. F. DuBrul
T. E. French
†D. B. Porter

TRANSMISSION CHAINS AND SPROCKETS

**Joint sponsorship with the Society of Automotive Engineers and the American Gear Manufacturers Association. Sectional Committee organized December, 1926*

A.S.M.E. Members (Total personnel, 16)

†F. V. Hetzel, *Chairman*
†G. M. Bartlett, *Secretary*
W. J. Belcher
Joseph Joy
†L. V. Ludy
†E. B. Nichols
F. L. Morse
G. A. Young
O. B. Zimmerman

WIRE AND SHEET METAL GAGES

**Joint sponsorship with the Society of Automotive Engineers. Sectional Committee organized November, 1927*

A.S.M.E. Members (Total personnel, 28)

J. F. Howe
†E. E. Rose

PIPE THREADS

**Joint sponsorship with the American Gas Association. Sectional Committee reorganized December, 1927. In August, 1908, the A.G.A. and the A.S.M.E. appointed a Joint Committee on this subject which was reorganized as a Sectional Committee under the procedure of the A.S.A. in the spring of 1919*

A.S.M.E. Members (Total personnel, 43)

B. H. Blood
A. F Breitenstein
E. J. Bryant
L. A. Cornelius
E. S. Cornell, Jr.
J. J. Crotty
J. J. Harman
†A. M. Houser
F. B. Howell
A. H. Jarecki
J. O. Johnson
W. R. Kremer
A. S. Miller
P. V. Miller
F. H. Morehead
W. C. Morris
S. F. Newman
E. S. Sanderson
L. N. Shannon
W. D. Sizer
J. H. Williams

ELECTRIC MOTOR FRAME DIMENSIONS

**Joint sponsorship with the National Electrical Manufacturers Association. Sectional Committee organized November, 1927*

A.S.M.E. Members (Total personnel, 31)

†W. F. Dixon, *Chairman*
C. A. Adams
S. A. Einstein
E. W. Ely
F. S. English
W. F. Jones
A. L. McHugh
P. G. Rhoads
†A. G. Trumbull
†E. H. Waring

WROUGHT IRON AND WROUGHT STEEL PIPE AND TUBING

**Joint sponsorship with the American Society for Testing Materials. Sectional Committee organized April, 1928*

A.S.M.E. Members (Total personnel, 39)

H. H. Morgan, *Chairman*
Sabin Crocker, *Secretary*
J. B. Aston
†A. M. Houser
†D. S. Jacobus
(F. S. Clark, *Alternate*)
W. R. Kremer
H. C. E. Meyer
F. H. Morehead
C. W. Mowry
†H. B. Oatley
A. L. Penniman, Jr.
(A. B. Morgan, *Alternate*)
F. N. Speller
J. R. Tanner
A. E. White
H. LeR. Whitney
G. H. Woodroffe

SPEEDS OF MACHINERY

**Sole sponsorship. Sectional Committee organized May, 1928*

A.S.M.E. Members (Total personnel, 29)

†C. M. Bigelow
R. C. Deale
Paul Diserens
F. S. English
A. E. Hall
D. C. Jackson
W. F. Jones
H. C. E. Meyer
John Reid
P. G. Rhoads
F. C. Spencer
O. B. Zimmerman

SCREW THREADS FOR HOSE COUPLINGS

**Sole sponsorship. Sectional Committee organized August, 1928*

A.S.M.E. Members (Total personnel, 24)

A. L. Brown, *Secretary*
†A. F. Breitenstein
W. L. Curtiss
†W. E. Dunham
J. J. Harman
(F. C. Ernst, *Alternate*)
A. M. Houser
H. C. E. Meyer
J. H. Williams

PLUMBING EQUIPMENT

**Joint sponsorship with the American Society of Sanitary Engineering. Sectional Committee organized August, 1928*

A.S.M.E. Members (Total personnel, 30)

†L. A. Cornelius
J. J. Crotty
O. E. Goldschmidt
G. W. Martin
(A. H. Morgan, *Alternate*)
†W. R. Webster

ROLLED THREADS FOR SCREW SHELLS OF ELECTRIC SOCKETS AND LAMP BASES

**Joint sponsorship with the National Electrical Manufacturers Association. Sectional Committee organized March, 1929*

A.S.M.E. Members (Total personnel, 18)

†E. J. Bryant
†Earle Buckingham
†E. S. Sanderson

STOCK SIZES, SHAPES, AND LENGTHS FOR HOT AND COLD FINISHED IRON AND STEEL BARS

**Sole sponsorship. Sectional Committee organized April, 1929*

A.S.M.E. Members (Total personnel, 24)

J. B. Aston
F. H. Dechant
†L. W. Williams
G. H. Woodroffe
O. B. Zimmerman

STANDARDIZATION AND UNIFICATION OF SCREW THREADS

**Joint sponsorship with the Society of Automotive Engineers. Sectional Committee originally organized in June, 1921. Reorganized in February, 1928*

A.S.M.E. Members (Total personnel, 37)

†R. E. Flanders, *Chairman*
†F. O. Wells, *Vice-Chairman*
Earle Buckingham, *Secretary*
H. E. Bilger
E. J. Bryant
G. S. Case
T. G. Crawford
†A. M. Houser (R. E. Perry, *Alternate*)
H. C. E. Meyer
†P. V. Miller
O. B. Zimmerman

PRESSURE AND VACUUM GAGES

**Sole sponsorship. Sectional Committee organized July, 1930*

A.S.M.E. Members (Total personnel, 45)

M. D. Engle, *Chairman* (A. B. Morgan, *Alternate*)
†A. W. Lenderoth, *Secretary*
E. J. Bryant
†J. P. Cavanaugh
Paul Diserens
W. F. Jones
R. J. Kehl
†J. C. McCune
A. H. Morgan
†S. A. Moss
H. B. Reynolds
C. Z. Rosencrans
W. C. Schoenfeldt

ALLOWANCES AND TOLERANCES FOR CYLINDRICAL PARTS AND LIMIT GAGES

**Sole sponsorship. Sectional Committee originally organized in June, 1920. Reorganized in September, 1930*

A.S.M.E. Members (Total personnel, 44)

F. E. Banfield (E. E. Blake, *Alternate*)
F. S. Blackall, Jr.
H. E. Brunner (William Jetter, *Alternate*)
E. J. Bryant
†Earle Buckingham
†F. H. Colvin
R. E. W. Harrison

P. V. Miller
W. C. Mueller
†E. C. Peck
W. C. Schoenfeldt
F. W. Stein
C. C. Stevens
O. B. Zimmerman

FOUNDRY EQUIPMENT AND SUPPLIES

**Joint sponsorship with the American Foundrymen's Association. Sectional Committee organized February, 1931*

A.S.M.E. Members (Total personnel, 23)

E. S. Carman, *Chairman*
E. W. Ely
F. W. Herendeen (F. B. Howell, *Alternate*)
G. F. Jenks
A. S. Phelps
†H. P. Van Cleve
O. B. Zimmerman

SPECIFICATIONS FOR LEATHER BELTING

**Sole sponsorship. Sectional Committee organized February, 1931*

A.S.M.E. Members (Total personnel, 24)

R. W. Chandler
H. T. Coates
†R. W. Drake
King Hathaway
Fred Nolde
J. E. Rhoads
C. A. Schieren
†C. O. Streeter
O. B. Zimmerman

UNIFICATION OF RULES FOR THE DIMENSIONING OF FURNACES FOR BURNING SOLID FUEL

**Sole sponsorship. Sectional Committee organized June, 1933*

A.S.M.E. Members (Total personnel, 22)

C. E. Bronson, *Temporary Chairman*
W. G. Christy
John Hunter
†V. G. Leach
T. A. Marsh
W. L. Martwick
J. F. McIntire
†John Van Brunt

CLASSIFICATION AND DESIGNATION OF SURFACE QUALITIES

**Joint sponsorship with the Society of Automotive Engineers. Sectional Committee organized May, 1932*

A.S.M.E. Members (Total personnel, 56)

C. G. Mettler, *Temporary Chairman*
John Cetrule
J. S. Chafee

(1) GENERAL INSTRUCTIONS

Appointed December, 1918

W. H. Kavanaugh, *Chairman* C. F. Hirshfeld
A. M. Greene, Jr. M. C. Stuart

(2) DEFINITIONS AND VALUES

Appointed December, 1918

F. R. Low L. S. Marks
A. C. Wood

(3) FUELS

Appointed December, 1918

W. J. Wohlenberg, *Chairman* F. G. Philo
E. G. Bailey G. S. Pope
B. L. Boye C. R. Richards
L. P. Breckenridge E. B. Ricketts
H. W. Brooks F. M. Rogers
S. B. Flagg E. X. Schmidt
D. M. Myers Nicholas Stahl
E. N. Trump

(4) STATIONARY STEAM-GENERATING UNITS

Appointed December, 1918

E. R. Fish, *Chairman* E. B. Powell
A. D. Bailey E. B. Ricketts
Alfred Iddles C. U. Savoye

(5) RECIPROCATING STEAM ENGINES

Appointed December, 1918

A. G. Christie, *Chairman* J. A. Hunter
Harte Cooke H. G. Mueller
K. S. M. Davidson B. V. E. Nordberg
Herman Diederichs J. F. M. Patitz
Henrik Greger A. V. Saharoff
Thomas Hall A. G. Witting
J. C. Workman

(6) STEAM TURBINES

Appointed December, 1918

C. H. Berry, *Chairman* V. M. Frost
I. E. Moultrop, *Secretary* A. E. Grunert
O. D. H. Bentley Francis Hodgkinson
W. E. Caldwell S. A. Moss
A. G. Christie R. O. Muller
Hans Dahlstrand T. E. Purcell
C. C. Thomas

(7) RECIPROCATING STEAM-DRIVEN DISPLACEMENT PUMPS

Appointed December, 1918

R. D. Hall, *Chairman* J. E. Gibson
C. H. Anderson G. L. Kollberg
E. H. Brown M. B. MacNeille
J. N. Chester D. W. Mead
L. A. Quayle

(8) CENTRIFUGAL AND ROTARY PUMPS

Appointed December, 1918

W. B. Gregroy, *Chairman*
Max Spillman, *Secretary*
W. C. Brown
M. B. MacNeille
L. F. Moody
F. H. Rogers
W. M. White

(9) DISPLACEMENT COMPRESSORS AND BLOWERS

Appointed December, 1918

Paul Diserens, *Chairman*
G. T. Felbeck
J. F. Huvane
R. M. Johnson
S. B. Redfield

(10) CENTRIFUGAL AND TURBO-COMPRESSORS AND BLOWERS

Appointed December, 1918

A. T. Brown, *Chairman*
E. L. Anderson
C. A. Booth
W. H. Carrier
L. E. Day
E. S. Dean
Z. G. Deutsch
S. H. Downs

Awards

The following paragraphs deal with the awards, scholarships, and loan funds which come within the jurisdiction of the A.S.M.E. The Society also participates with other engineering societies in a number of joint awards.

Honorary Membership, to which persons of acknowledged professional eminence are elected by unanimous vote of Council under the provisions of the By-Laws and Rules. A list of honorary members is given on page RI-32.

Life Membership, which may be conferred by the Council for distinguished service to the Society; or secured by a member by payment for an annuity in accordance with the provisions of the By-Laws.

A.S.M.E. Medal, established by the Society in 1920 to be presented for distinguished service in engineering and science. May be awarded for general service in science having possible application in engineering.

Holley Medal, instituted and endowed in 1924 by George I. Rockwood, Past Vice-President of the Society, to be bestowed for some great and unique act of genius of engineering nature that has accomplished a great and timely public benefit.

Worcester Reed Warner Medal, provision for which was made in the will of Worcester Reed Warner, Honorary Member of the Society, is a gold medal to be bestowed on the author of the most worthy paper received, dealing with progressive ideas in mechanical engineering or efficiency in management.

Melville Medal, established in 1914 by the bequest of Rear-Admiral George W. Melville, Honorary Member and Past-President of the Society, to be presented for an original paper or thesis of exceptional merit, presented to the Society for discussion and publication, to encourage excellence in papers. The medal may be presented annually.

Spirit of Saint Louis Medal, endowed by members of the Society and citizens residing in St. Louis, Mo., to be awarded for meritorious service in the field of aeronautical engineering. This medal will be awarded at the discretion of the Council of the Society at approximately three-year periods upon the recommendation of a Spirit of Saint Louis Medal Board of Award made up of six members, each appointed for a term of nine years and the terms of two members expiring at each three-year period. The St. Louis Section and the Aeronautic Division will each be responsible for the nomination of three members.

Junior Award, annual cash award of $50, established in 1914, from a fund created by Henry Hess, Past Vice-President of the Society, to be presented, together with an engraved certificate, for the best paper or thesis submitted by a Junior Member.

Student Awards, two annual cash awards of $25 each, established in 1914, from a fund created by Henry Hess, Past Vice-President of the Society, to be presented, together with engraved certificates, for the best papers or theses submitted by members of Student Branches.

Charles T. Main Award, annual cash award of $150, established in 1919 from a fund created by Charles T. Main, Past-President of the Society, to be awarded to a student of engineering, preferably a member of a Student Branch of the Society, for the best paper within the general subject of the "Influence of the Profession Upon Public Life." The exact subject is assigned by the Committee on Awards, subject to the approval of the Council, and is announced each year through the Honorary Chairmen of the Student Branches.

SCHOLARSHIPS AND LOAN FUNDS

Max Toltz: Loan Fund of $15,000 established by Major Max Toltz, former member of the Council of the Society, the income to be used for assistance to students.

John R. Freeman: Fund of $25,000 established in 1926 by John R. Freeman, Past-President of the Society, the income to be used for travel scholarships and research.

Woman's Auxiliary: Scholarship or Fellowship offered by the Woman's Auxiliary to the Society to assist sons and daughters of members or worthy students of mechanical engineering.

RECIPIENTS OF AWARDS

The names of the recipients of the different awards to date are given in the following lists, together with the dates of presentation, and the services or papers for which the awards were made. There were no awards for the years not listed.

A.S.M.E. Medal

1921 Hjalmar Gotfried Carlson, in recognition of the services rendered the Government because of his invention and part in the production of 20,000,000 Mark III drawn steel booster casings used principally as a component of 75-mm high-explosive shells, but also used extensively in gas shells and bombs

1923 Frederick Arthur Halsey, for his paper describing the premium system of wage payments presented before the Society at the Providence Meeting in 1891, as the adoption of the methods there proposed has had a profound effect toward harmonizing the relations of worker and employer

1923 John Ripley Freeman, for his eminent service in engineering and manufacturing by his meritorious work in fire prevention and the preservation of property

1926 R. A. Millikan, in recognition of his contributions to science and engineering

1927 Wilfred Lewis, for his contributions to the design and construction of gear teeth

1928 Julian Kennedy, for his services and contributions to the iron and steel industry

1929 William LeRoy Emmet, for his contributions in the development of the steam turbine, electric propulsion of ships, and other power-generating apparatus

1931 Albert Kingsbury, for his research and development work in the field of lubrication

1933 Ambrose Swasey, for his contributions to the advancement of the engineering profession and for his part in the development of the turret lathe and the astronomical telescope

1934 Willis H. Carrier, in recognition of his research and development work in air-conditioning.

Holley Medal

1924 Hjalmar Gotfried Carlson, for his inventions and processes which made possible the timely production of drawn steel booster casings for artillery ammunition, thereby aiding victory in the World War

1928 Elmer Ambrose Sperry, for achievements and inventions that have advanced the naval arts, including the gyroscope that has freed navigation from the dangers of the fluctuating magnetic compass

1929 Baron Chuzaburo Shiba, for his contributions to knowledge through fundamental research, including the field of aerodynamics, by the development of ultra-rapid kinematographic methods.

Worcester Reed Warner Medal

1933 Dexter S. Kimball, for his contributions to efficiency in management as exemplified by his recently revised "Principles of Industrial Organization" and by his many articles, engineering society papers, and public addresses

1934 Ralph E. Flanders, for his contributions to a better understanding of the relationship of the engineer to economic problems and social trends as exemplified by the many papers which he has presented.

Melville Medal

1927 Leon P. Alford, "Laws of Manufacturing Management"

1929 Joseph Wickham Roe, "Principles of Jig and Fixture Practice"

1930 Herman Diederichs and William D. Pomeroy, "The Occurrence and Elimination of Surge or Oscillating Pressure in Discharge Lines From Reciprocating Pumps"

1931 Arthur E. Grunert, "Comparative Performance of a Pulverized-Coal-Fired Boiler Using Bin System and Unit System of Firing"

1932 Alexey J. Stepanoff, "Leakage Loss and Axial Thrust in Centrifugal Pumps"

1933 William E. Caldwell, "Characteristics of Large Hell Gate Direct-Fired Boiler Units."

Spirit of Saint Louis Medal

1929 Daniel Guggenheim, founder of the Guggenheim Fund for the Promotion of Aeronautics

1932 Paul Litchfield, for his work in encouraging and sponsoring airship design and construction in this country.

Junior Award

1915 Ernest O. Hickstein, "Flow of Air Through Thin Plate Orifices"

1916 L. B. McMillan, "The Heat Insulating Properties of Commercial Steam-Pipe Coverings"

1919 E. D. Whalen, "Properties of Airplane Fabrics"

1921 S. Logan Kerr, "Moody Ejector Turbine"

1922 R. H. Heilman, "Heat Losses From Bare and Covered Wrought-Iron Pipe at Temperatures Up to 800 Degrees Fahrenheit"
F. L. Kallam, "Preliminary Report on the Investigation of the Thermal Conductivity of Liquids"

1923 S. S. Sanford and S. Crocker, "The Elasticity of Pipe Bends"

1924 R. H. Heilman, "Heat Losses Through Insulating Material"

1925 Gilbert S. Schaller, "An Investigation of Seattle as a Location for a Synthetic Foundry Industry"

1927 Wm. M. Frame, "Stresses Occurring in the Walls of an Elliptical Tank Subjected to Low Internal Pressure"

1928 M. D. Aisenstein, "A New Method of Separating the Hydraulic Losses in a Centrifugal Pump"

1929 Arthur M. Wahl, "Stresses in Heavy, Closely Coiled Helical Springs"

1930 Ed Sinclair Smith, Jr., "Quantity-Rate Fluid Meters"

1931 M. K. Drewry, "Radiant-Superheater Developments"

1932 Edmond M. Wagner, "Frictional Resistance of a Cylinder Rotating in a Viscous Fluid Within a Coaxial Cylinder"

1933 Townsend Tinker, "Surface Condenser Design and Operating Characteristics"

1934 John I. Yellott, Jr., "Supersaturated Steam."

Student Award

1916 Boynton M. Green, Stanford University, "Bearing Lubrication"
Howard Stevens, Rensselaer Polytechnic Institute, "An Investigation of the Dynamic Pressure on Submerged Flat Plates"
M. Adam, Louisiana State University, "The Adaptability of the Internal Combustion Engine to Sugar Factories and Estates"

1917 H. R. Hammond and C. W. Holmberg, Pennsylvania State College, "Study of Surface Resistance With Glass as the Transmission Medium"

1919 C. F. Leh and F. G. Hampton, Stanford University, "An Experimental Investigation of Steel Belting"
W. E. Helmick, Stanford University, "An Experimental Investigation of Steel Belting"

1920 Howard G. Allen, Cornell University, "Wire Stitching Through Paper"

1921 Karl H. White, University of Kansas, "Forces in Rotary Motors"
Richard H. Morris and Albert J. R. Houston, University of California, "A Report Upon an Investigation of the Herschel Type of Improved Weir"

1923 Charles F. Olmstead, University of Minnesota, "Oil Burning for Domestic Heating"
H. E. Doolittle, University of California, "The Integrating Gate: A Device for Gaging in Open Channels"

1924 George Stuart Clark, Stanford University, "Two Methods Used for the Determination of the Gasoline Content of Absorption Oils in Absorption Plants"
L. J. Franklin and Charles H. Smith, Stanford University, "The Effect of Inaccuracy of Spacing on the Strength of Gear Teeth"

1925 Harry Pease Cox, Jr., Rensselaer Polytechnic Institute, "A Study of the Effect of End Shape on the Towing Resistance of a Barge Model"
W. S. Montgomery, Jr., and E. Ray Enders, Jr., Pennsylvania State College, "Some Attempts to Measure the Drawing Properties of Metals"

1926 R. E. Peterson, University of Illinois, "An Investigation of Stress Concentration by Means of Plaster of Paris Specimens"
Cecil G. Heard, University of Toronto, "Pressure Distribution Over U. S. A. 27 Aerofoil With Square Wing Tips Model Tests"

1927 Alfred H. Marshall, Princeton, "Evaporative Cooling"
Roger Irwin Eby, University of Washington, "Measurement of the Angular Displacement of Flywheels"

1928 Clarence C. Franck, Johns Hopkins University, "Condition Curves and Reheat Factors for Steam Turbines"

1929 Frank Vernon Bistrom, University of Washington, "An Investigation of a Rotary Pump"
William Wallace White, University of Washington, "An Investigation of a Rotary Pump"

1930 Gerard Eden Claussen, Polytechnic Institute of Brooklyn, "High-Temperature Oxidation of Steel"
Harold L. Adams and Richard L. Stith, University of Washington, "A Wind Tunnel for Undergraduate Laboratory Experiments"

1931 Jules Podnossoff, Polytechnic Institute of Brooklyn, "Pressure and Energy Distribution in Multi-Stage Steam Turbines Operating Under Varying Conditions"

1932 H. E. Foster, Jr., University of Tennessee, "Factors Affecting Spray Pond Design"
William A. Mason, Stanford University, "An Experimental Investigation of the Flame Propagation in Internal-Combustion Engines"

1933 Hugo V. Cordiano, Polytechnic Institute of Brooklyn, "Thermal Analysis of Lithium-Magnesium System of Alloys"
James A. Ostrand, Jr., Princeton University, "Sudden Enlargement in the Open Channel"

1934 H. Reynolds Hudson, Georgia School of Technology, "Dynamic Balance and Functional Utility Applied to Automotive Design."

Charles T. Main Award

1925 Clement R. Brown, Catholic University of America. Subject: "The Influence of the Locomotive on the Unity of the United States"

1926 W. C. Saylor, Johns Hopkins University. Subject: "The Effect of the Cotton Gin Upon the History of the United States During Its First Seventy Years"

1927 No award. Subject: "Scientific Management and Its Effect Upon the Industries"

1928 Robert M. Meyer, Newark College of Engineering. Subject: "Scientific Management and Its Effect Upon Manufacturing"

1930 Jules Podnossoff, Polytechnic Institute of Brooklyn. Subject: "The Value of the Safety Movement in the Industries"

1931 Robert E. Klise, University of Michigan. Subject: "Interchangeability—Its Development and Significance in Industry"
1932 Marshall Anderson, University of Michigan. Subject: "Apprenticeship and Vocational Training"
1933 George D. Wilkinson, Jr., Newark College of Engineering. Subject: "Progress in the Prevention of Smoke and Atmospheric Pollution"
1934 Philip P. Self, Colorado State College, "Air Conditioning—Its Practicability and Relation to Public Welfare."

Freeman Travel Scholarship

1927 Herbert N. Eaton
1928 Blake R. Van Leer
1929 Robert T. Knapp
1931 Reginald Whitaker
1932 G. Ross Lord
1933, 1934 H. J. Casey.

Honorary Members

HONORARY MEMBERS IN PERPETUITY

Alexander Lyman Holley, Founder of the Society. Died 1882.
John Edson Sweet, Founder of the Society. Died 1916.
Henry Rossiter Worthington, Founder of the Society. Died 1880.

DECEASED HONORARY MEMBERS

	ELECTED	DIED
Horatio Allen	1880	1889
Sir William Arrol	1905	1913
Sir Benjamin Baker	1886	1907
Johann Bauschinger	1884	1893
Sir Henry Bessemer	1891	1898
Sir Frederick Joseph Bramwell	1884	1903
John Alfred Brashear	1908	1920
Gustave Canet	1900	1908
Andrew Carnegie	1907	1919
Daniel Kinnear Clark	1882	1896
Rudolph Julius Emmanuel Clausius	1882	1888
Sir John Coode	1889	1892
Peter Cooper	1882	1883
Carl Gustaf Patrick de Laval	1912	1913
Rudolph Diesel	1912	1913
James Dredge	1886	1906
Victor Dwelshauvers-Dery	1886	1913
Thomas Alva Edison	1904	1931
Alexandre Gustave Eiffel	1889	1923
Marshal Ferdinand Foch	1921	1929
Sir Charles Douglas Fox	1900	1921
John Ripley Freeman	1932	1932
John Fritz	1900	1913
Major-General George Washington Goethals	1917	1928
Franz Grashof	1884	1893
Rear-Admiral Robert Stanislaus Griffin	1920	1933
Otto Hallauer	1882	1883
Charles Haynes Haswell	1905	1907
Friedrich Gustav Herrmann	1884	1907
Gustav Adolph Hirn	1882	1890
Joseph Hirsch	1889	1901
Ira N. Hollis	1928	1930
Robert Woolston Hunt	1920	1923
Benjamin Franklin Isherwood	1894	1915
Henri Léauté	1891	1916
Erasmus Darwin Leavitt	1915	1916
Anatole Mallet	1912	1919
Charles H. Manning	1913	1919
Rear-Admiral George Wallace Melville	1910	1912
The Honorable Sir Charles Algernon Parsons	1920	1931
Charles Talbot Porter	1890	1910
Auguste C. E. Rateau	1919	1930
Sir Edward J. Reed	1882	1906
Franz Reuleaux	1882	1905
Calvin Winsor Rice	1931	1934
Palmer C. Ricketts	1931	1934
Henri Adolphe-Eugene Schneider	1882	1898
C. William Siemans	1882	1883
Viscount Ei-ichi Shibusawa	1929	1931
Henry Robinson Towne	1921	1924
Henri Tresca	1882	1885
William Cawthorne Unwin	1898	1933
Oskar von Miller	1912	1934
Francis A. Walker	1886	1897
Worcester Reed Warner	1925	1929
George Westinghouse	1897	1914
Sir William Henry White	1900	1913
Sir Alfred Fernandez Yarrow	1914	1932

LIVING HONORARY MEMBERS

	ELECTED
Sir John Audley Frederick Aspinall	1911
William Wallace Atterbury	1925
Mortimer Elwyn Cooley	1928
William Frederick Durand	1934
Charles de Fréminville	1919
Nathanael Greene Herreshoff	1921
Herbert Clark Hoover	1925
David Schenck Jacobus	1934
Masawo Kamo	1929
Henri Le Chatelier	1927
Grande Ufficiale Ing. Pio Perrone	1920
Charles M. Schwab	1918
Ambrose Swasey	1916
Elihu Thomson	1930
Samuel Matthews Vauclain	1920
Right Honorable Lord Weir	1920
Orville Wright	1918

Past-Presidents

A list of past vice-presidents, managers, treasurers, and secretaries will be found in the 1930 Record and Index, pages 10–12. Dates in parentheses denote year of death.

Alexander Lyman Holley, *Chairman of the Preliminary Meeting for Organization of The American Society of Mechanical Engineers* (1882)

1880–1882 Robert Henry Thurston (1903)
1883 Erasmus Darwin Leavitt (1916)
1884 John Edson Sweet (1916)
1885 Josephus Flavius Holloway (1896)
1886 Coleman Sellers (1907)
1887 George H. Babcock (1893)
1888 Horace See (1909)
1889 Henry Robinson Towne (1924)
1890 Oberlin Smith (1926)
1891 Robert Woolston Hunt (1923)
1892 Charles Harding Loring (1907)
1893–1894 Eckley Brixton Coxe (1895)
1895 Edward F. C. Davis (1895)
1895 Charles Ethan Billings (1920)
1896 John Fritz (1913)
1897 Worcester Reed Warner (1929)
1898 Charles Wallace Hunt (1911)
1899 George Wallace Melville (1912)
1900 Charles Hill Morgan (1911)
1901 Samuel T. Wellman (1919)
1902 Edwin Reynolds (1909)
1903 James Mapes Dodge (1915)
1904 Ambrose Swasey
1905 John Ripley Freeman (1932)
1906 Frederick Winslow Taylor (1915)
1907 Frederick Remsen Hutton (1918)
1908 Minard Lafever Holman (1925)
1909 Jesse Merrick Smith (1927)
1910 George Westinghouse (1914)
1911 Edward Daniel Meier (1914)
1912 Alexander Crombie Humphreys (1927)
1913 William Freeman Myrick Goss (1928)
1914 James Hartness (1934)
1915 John Alfred Brashear (1920)
1916 David Schenck Jacobus
1917 Ira Nelson Hollis (1930)
1918 Charles Thomas Main
1919 Mortimer Elwyn Cooley
1920 Fred J. Miller
1921 Edwin S. Carman
1922 Dexter Simpson Kimball
1923 John Lyle Harrington
1924 Frederick Rollins Low
1925 William Frederick Durand
1926 William Lamont Abbott
1927 Charles M. Schwab
1928 Alex Dow
1929 Elmer Ambrose Sperry (1930)
1930 Charles Piez (1933)
1931 Roy V. Wright
1932 Conrad N. Lauer
1933 A. A. Potter
1934 Paul Doty

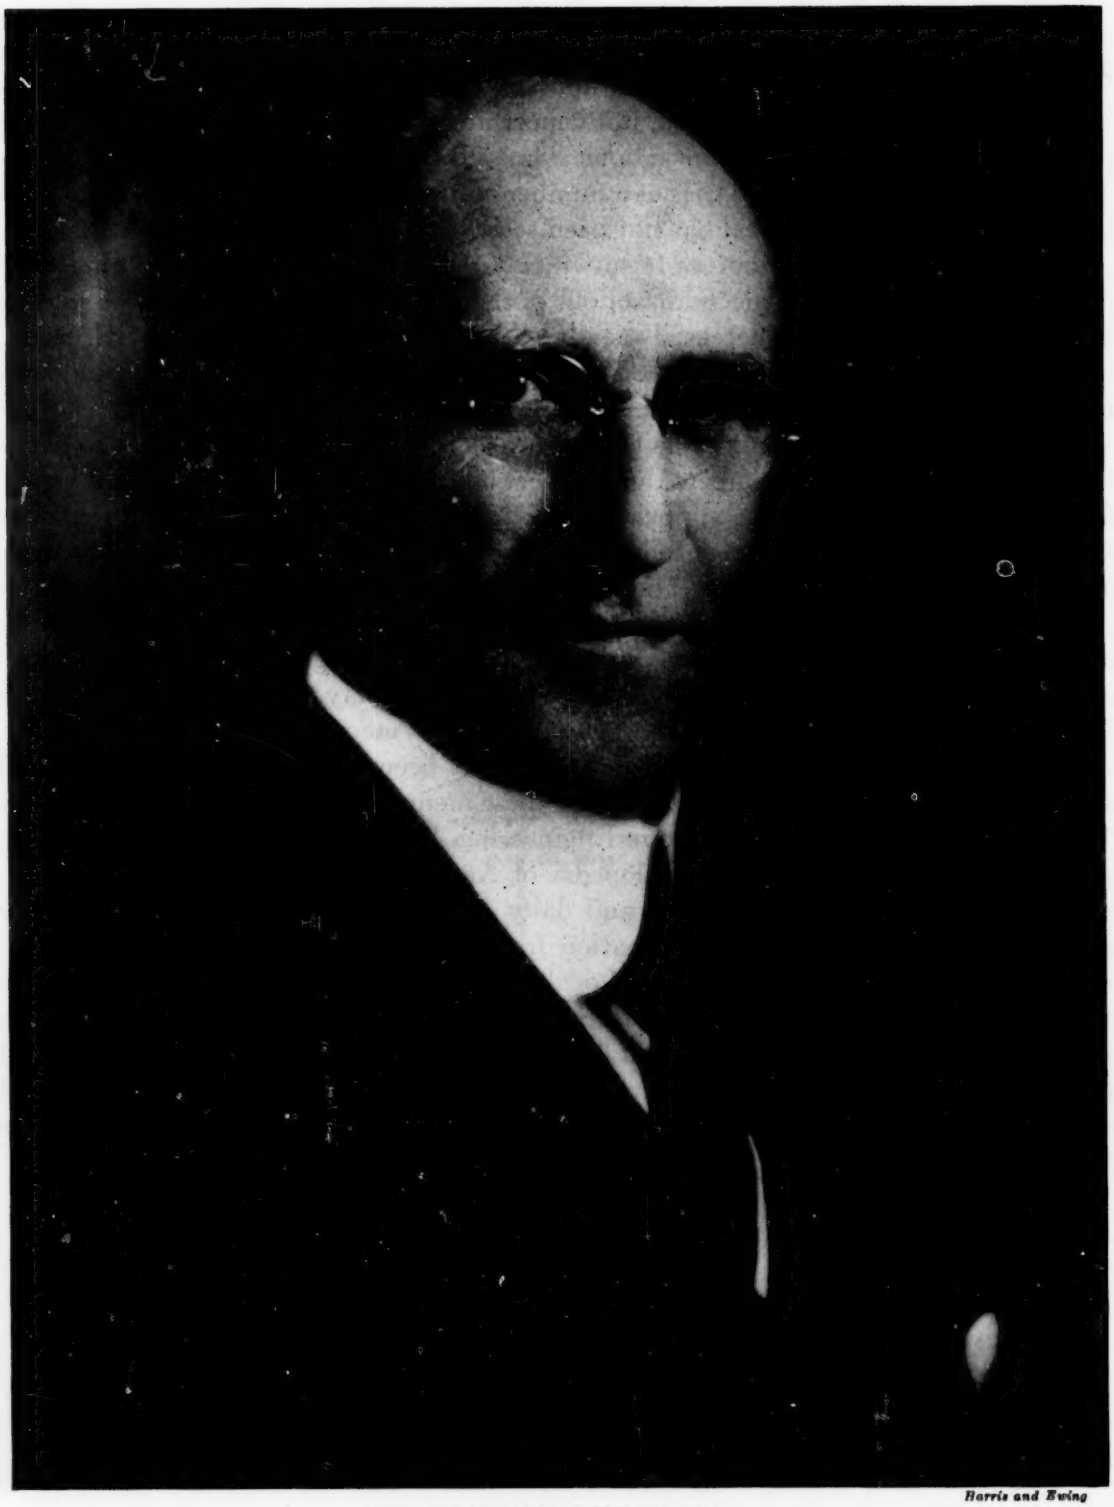
Memorial Notices



THIS group of memorial notices contains records of members of the Society whose deaths occurred prior to 1935, but concerning whom material was not ready for publication when the 1934 Transactions was issued. In fact, it is still necessary to delay the publication of obituaries of a number of members who died in 1933 and 1934 because sufficient information has not been secured.

There are a number of sources from which biographical material concerning engineers may be secured, but the Transactions of the A.S.M.E. is naturally the only place in which obituaries of all deceased members of the Society appear. Special care is therefore given to the preparation of these memorials and no obituary is published until as complete a record as possible has been secured.

The first source of information is the application file of the Society. In the case of those who have become members during recent years, the applications usually yield fairly complete records. The applications of those who became members in the early days of the Society are not as detailed, however, and these are the cases which often present considerable difficulty. The member may have been retired for some years prior to his death, so that business associates cannot be located, and in some cases members of his family cannot be found. Only by following up every slightest lead can even the main facts be assembled, and a long period may therefore elapse between the time of a member's death and the completion of his memorial.

The Society appreciates the assistance that has been given by relatives, business associates, and friends in the preparation of these memorials. It also acknowledges its debt to such sources as Who's Who in Engineering, Who's Who in America, and similar publications; the National Cyclopedia of American Biography and New International Year Book; the technical and daily press; and to engineering and other societies which have supplied information from their records.

Relatives, business associates, and Local Section and Student Branch officers are urged to notify the Society promptly of the deaths of members. Newspaper clippings or obituaries in any other form should be sent whenever available and the names and addresses of those who can supply further information should be furnished. A special form for supplying complete details will be forwarded by the Office of the Society upon request.

Harris and Ewing

CALVIN WINSOR RICE, 1868–1934

SECRETARY OF THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS
1906–1934

Life of Calvin Winsor Rice

STRICKEN at his desk in the midst of his daily work, and in the building which his vision, enthusiasm, and energy had greatly helped to bring into being as a headquarters for the professional engineering societies of the United States, Calvin Winsor Rice, honorary member and for twenty-eight years secretary of The American Society of Mechanical Engineers died as a result of cerebral hemorrhage on October 2, 1934, a few hours after his removal to a nearby hospital.

Although he had won distinction as an electrical engineer in the practice of that profession prior to 1906, he will be most widely remembered for his services to The American Society of Mechanical Engineers as its secretary and for his vision and leadership in that office, which not only developed the Society greatly in numbers and in virility, but the entire engineering profession as well. For the spirit of cooperation with which he worked brought together the numerous individually organized groups of engineers in joint activities for common purposes. Of this spirit, the Engineering Societies Building in New York is a substantial and glorious monument, the physical embodiment of that vision and idealism that were Dr. Rice's most abundant gifts.

His Qualities in Professional-Society Organization

At the time Dr. Rice was made an honorary member of The American Society of Mechanical Engineers, in December, 1931, Dr. Karl T. Compton, president, Massachusetts Institute of Technology, delivered an address on his work in professional-society organization and paid a splendid tribute to this phase of his career. In the address, which was published in the January, 1932, issue of MECHANICAL ENGINEERING, Dr. Compton listed six essential qualifications for leadership in engineering-society organization which Dr. Rice possessed to a marked degree: (1) The ability and desire to cooperate with others; (2) the ability and judgment to recognize a good project when it was suggested; (3) initiative and drive to carry a project through to completion; (4) daring to undertake an audacious project, once convinced of its merit; (5) originality of thought; and (6) ability to organize, to delegate authority, and to spur others on to take active part in the affairs of the Society. Dr. Compton listed in addition four principles that were basic to Dr. Rice's philosophy of society organization and operation: (1) Unselfish cooperation with related societies; (2) planning actively for the future, so that development might not be haphazard, and so that opportunities for development in the desired direction might be quickly and firmly grasped when they presented themselves; (3) giving the most effective service to the members of the profession; and (4) leading the profession in rendering the most valuable possible service to society. The great number of engineers who knew Dr. Rice were conscious of these elements of his character and these principles of his philosophy.

His International Reputation

One characteristic feature of his career, resulting from these personal qualities, brought distinction to him, to the society he served, to his country, and to the profession of engineering. This was his relationship with engineers in this and other countries. In Great Britain, in Europe, in Mexico and South America, and in the Orient, Dr. Rice was well known in engineering circles. He traveled frequently in the discharge of his duties, and his office in New York was a focal point upon which converged the paths of engineers, eminent and obscure, who came to the United States. He was never too busy to give letters of introduction to engineers from abroad, or to engineers of this country planning to travel in Europe. Members of the Society frequently found that letters from Dr. Rice were more effective in gaining for them admission to some foreign plant or factory than similar letters from business men and engineers in the country they were visiting. The bread of hospitality and service he continually cast upon the waters wherever he happened to be returned in abundant measure to him by way of courtesies shown all over the world to those for whom he bespoke consideration. In students coming to this country Dr. Rice had great interest, going out of his way to have arranged for them itineraries of plant visits and advising them on educational and professional programs. These active international relationships brought Dr. Rice into high esteem, both here and abroad, and year by year added to the list of those beholden to him for help, advice, and innumerable lesser courtesies.

Significant Events in His Career

Dr. Rice was born at Winchester, Massachusetts, on November 4, 1868, the son of Edward Hyde and Lucy J. (Staples) Rice. After attending public schools in Boston, New Haven, and Winchester, he spent four years as a student in the Massachusetts Institute of Technology, from which he was graduated in 1890 with the degree of bachelor of science in electrical engineering. He then held, successively, positions as assistant engineer in the power and mining department of the Thomson-Houston Company in Lynn; as engineer in the General Electric Company in Schenectady; district engineer for that company in Cincinnati; engineer with the Silver Lake Mines in Colorado; consulting engineer for the Anaconda Copper Mining Company in Anaconda, Montana; electrical engineer of the Kings County Electric Light and Power Company, and later with the New York Edison Company and the Consolidated Subway Company; vice-president of the Nernst Lamp Company; consulting engineer with the General Electric Company in New York. It was from this rich and varied experience in electrical, hydraulic, and steam engineering, combined with managerial and administrative work, that Dr. Rice was called to the secretaryship of the A.S.M.E. in 1906.

The Engineering Societies Building in New York

Dr. Rice became a member of the A.I.E.E. in 1897, and was active in its affairs. In 1900 he joined the A.S.M.E. The story of his part in the bringing together of the engineering societies in a common headquarters building in New York and of the manner in which the funds were secured was told by Dr. Compton in his tribute to Dr. Rice previously referred to. Dr. Compton said:

> In 1902, as chairman of the Building Committee of the A.I.E.E., he called a dinner meeting of the committee, together with the president of the A.I.E.E., Prof. Charles F. Scott, and several others, to discuss plans for a modest building for the Institute, primarily to house the Latimer Clark Library, which had been presented to the Institute by Dr. S. S. Wheeler on the condition that a fireproof building be secured to house it. The Committee had, at that time, definite prospects of only about $250,000. When President Scott suggested that consideration be given to the possibility of a building for housing the four National Engineering Societies, with a common library and a common auditorium and individual rooms for the headquarters of each society, doubts were expressed as to whether the four societies could be brought into such a cooperative project.
>
> Strenuous efforts, which were at the last minute successful, were made to get Mr. Andrew Carnegie as a guest at the next annual dinner of the Institute. At this dinner President Scott outlined his ambitious plan and pointed out its fine features—including the library.
>
> The next day Mr. Carnegie asked Dr. Rice to come to his residence at five o'clock, and Dr. Rice, with characteristic thoughtfulness for others, as well as admiration for the lofty character of his president,

brought with him Professor Scott. There Mr. Carnegie asked them further about the work of the Institute, about the finances of the engineering societies, about the relation of the proposed building to the Engineers' Club (of which he was a member). Dr. Rice cleverly inferred that an obstacle in Mr. Carnegie's mind was the securing of the land, for the latter was not in the habit of buying the land on which the libraries which he donated were built. Dr. Rice then optimistically remarked that the Engineering Societies would be able to provide the land, whereupon Mr. Carnegie gave a cheerful smile and said, "If you can provide the land, I will put up the building." Dr. Rice was made chairman of the building fund.

Then the money had to be raised to buy the land; complications and difficulties in perfecting the organization and developing the plans had to be overcome. In the words of Professor Scott, "Mr. Rice's devotion to the idea of a building for the Institute and his skill in directing the early conference with Mr. Carnegie and his enthusiastic and faithful assistance in subsequent service to the Institute in carrying out the project were fundamental factors in the creation of the Engineering Societies Building and the separate building for the Engineers' Club."

The Kelvin Memorial

Among other incidents that illustrate Dr. Rice's faculty of initiating projects that bore fruitful results may be mentioned the Kelvin Memorial Window, in Westminster Abbey, told by Dr. Compton in the A.S.M.E. address, and the establishment of the Officers' Reserve of the United States Army, a brief account of which was contained in a letter by the late Gen. William Barclay Parsons published in *The Military Engineer* for March-April, 1931. Dr. Compton's account of the Kelvin Memorial Window is as follows:

> In 1910 Dr. Rice had a most unique experience, an account of which has never before been published. That year the A.S.M.E. made a return visit to the Institution of Mechanical Engineers at their Birmingham meeting. Remembering that in a modest way the A.S.M.E. had contributed to the memorial window in Westminster Abbey to Sir Benjamin Baker, honorary member, A.S.M.E., Dr. Rice wrote to the Dean asking if it would be permissible for the members of the A.S.M.E. when passing through London on a certain Sunday, to visit the Abbey and view the window. Not only was permission granted but a special service was arranged, with a sermon on engineering by the Bishop of Lewes, and on this occasion the "Hallelujah Chorus" was rendered by the full surpliced choir. The event was further made memorable by having the A.S.M.E. audience arranged in a semi-circle about the memorial window, the movable pulpit having been placed beside it.
>
> Dr. Rice noticed that every window in the entire Abbey, save one, was a memorial window. The unappropriated window was apparently an original plain-glass window and was very dull by comparison. The next day Dr. Rice called on the Dean to express gratitude, and in conversation commented on the unoccupied window. The Dean immediately responded that the Abbey would appreciate a gift of a memorial window. Dr. Rice thereupon sensed the situation and offered a window, knowing it would be an easy matter to collect from the entire English-speaking world an amount sufficient to install a window to an engineer.
>
> Dr. Rice proposed a window to his friend Lord Kelvin as one mutually desired by the Abbey and by engineers. Consistently he arranged that this memorial be provided through the cooperation of the engineering bodies of Great Britain and the United States. Having obtained instant approval of influential persons in England, he used the same method in the United States, and, when the undertaking was assured, placed the whole proposition in the hands of the Institution of Civil Engineers, the oldest and most important engineering organization in the world, for announcement of the popular subscription.
>
> The result was so successful that not only was the window provided but the Kelvin Medal was founded. This is probably the only joint undertaking of this nature by the English-speaking world.

The Officers' Reserve

In a letter to General Parsons, Dr. Rice said that he had commenced agitation for an Officers' Reserve in 1902, when he went to Washington to take the matter up with Gen. Nelson A. Miles, then Chief of Staff. He was unsuccessful, but he kept repeating his suggestion up to 1914. From General Parson's letter in *The Military Engineer* the following passages are quoted:

> By the end of the year 1914, there were some engineers who perceived that the world was in for a long period of war and that no matter what position of neutrality the United States might for a while assume, it would probably inevitably be drawn into the conflict. Mr. Calvin W. Rice, secretary of The American Society of Mechanical Engineers, had this view and became firmly impressed with the belief that the engineers should be organized for action.
>
> After conferring with Major-General Leonard Wood, then commanding the Department of the East, Mr. Rice organized a luncheon in February, 1915, at which were present, besides Mr. Rice, Dr. Henry S. Drinker, President of Lehigh University, Mr. Elmer E. Corthell, Mr. Ralph Mershon, Mr. Bradley Stoughton, and a few others, with General Wood as the guest of honor. On being asked for advice, General Wood pointed out that for many years there had been established, as part of the Army, a Medical Officers' Reserve Corps, who were duly commissioned in the Army and who were subject to call to duty in case of war and in times of peace with their consent. This Reserve had been found to be most beneficial, as officers were drawn from it at times of emergency and then could return to private life when the stress was passed. He showed that engineers, like doctors, were always mobilized for the practice of their profession and that an Engineer Officers' Reserve, parallel to the Medical Officers' Reserve, might be established.
>
> This suggestion of General Wood's was promptly taken up, and committees were appointed on behalf of the engineering societies. . . . These committees were immediately organized and began to work, but it was found more expedient to form a central executive and operating committee of the chairmen of the separate committees. . . . The Chairman of the Joint Committee [Wm. Barclay Parsons] and the Committee proceeded to Washington to lay the proposed plan before the War Department. The Committee went with some misgivings as to how such a radical suggestion, emanating from civilians, would be received. Their misgivings, however, were quickly dispelled. The Secretary of War, Mr. Lindley M. Garrison, received them cordially and sympathetically and presented them to Major-General Hugh L. Scott, then Chief of Staff. General Scott, after hearing what the chairman had to say, introduced him to Major-General Tasker H. Bliss, Assistant Chief of Staff. General Bliss listened attentively and with much interest, and at the conclusion of a long interview sent for Major W. D. Connor, now Major-General Connor, an officer of the Corps of Engineers attached to the General Staff. General Bliss instructed Major Connor to confer with Mr. Parsons and to prepare a joint report for submission. When this was done, General Bliss studied it carefully and said, "You have proved your case for engineers, but why limit it to them? It has always been my wish that there should be established a general reserve as part of the Army of the United States." He then returned the report, asking them to make a plan for such a general reserve. . . .
>
> The outcome was that the joint committee reported to the five societies under date of June 23, 1916, that "a bill, which recently passed the Congress, has been signed by the President and will become effective July 1, 1916. This bill, known as the Army Reorganization Act of 1916, contains provisions for the organization of an Officers' Reserve, including the engineers."
>
> Thus a movement initiated by Mr. Rice, put into concrete form by General Wood, and carried into execution by the Committee of the Engineering Societies, was authorized by law.

Dr. Rice, in his modest manner, was very proud of the part he played in the establishment of the Officers' Reserve. He was commissioned a major in the Officers' Reserve Corps in 1922 and a Lieutenant-Colonel in 1929.

His Educational Affiliations

Inspired by the work and character of Dr. Oskar von Miller, distinguished director of the Deutsches Museum, for whom he had a warm affection and high regard, Dr. Rice became interested in the educational possibilities of exhibits of the industrial arts. This brought him into active working contact with a group of men of enthusiasm and vision who established what is now the New York Museum of Science and Industry. As honorary secretary and a member of the board of this institution he gave freely of his energy and advice up to the time of his death.

To his Alma Mater he gave his services as member of the Corporation of the Massachusetts Institute of Technology and chairman of the visiting committee of the department of mechanical engineering of that institution. His broad acquaintanceship

among engineers brought him into close contact with other institutions, for his advice was frequently sought when a professorship, a deanship, or a presidency was to be filled.

Honors and Professional Contacts

In addition to membership in the A.S.M.E. and the A.I.E.E., of which he was a former vice-president, Dr. Rice was a member of many other engineering and professional societies. He was an honorary member of the association of members in Argentina of the National Engineering Societies; of the Koninklijk Instituut van Ingenieurs, of Holland; of the Club de Engenharia, of Rio de Janeiro; of the American Society of Safety Engineers; of the Masaryk Academy, Czechoslovakia; and of the Deutsches Museum, Munich, Germany. He was corresponding member of the Instituto de Engenieros de Chile and of the Technisches Museum, of Vienna. In 1915 he served as a member of the Jury of Award of the Panama-Pacific Exposition. In 1922 he received a gold medal at the Centennial Exposition of Brazil. On him were bestowed the Order of the White Lion of Czechoslovakia, and the Golden Ring of Honor of Bavaria. He was a fellow of the American Association for the Advancement of Science, and a member of the Institution of Electrical Engineers, of London, and of the New York Electrical Society. His well-known interest in research won for him membership in the division of engineering and industrial research of the National Research Council, and the position of National Counselor of the Purdue Research Foundation.

As a delegate of The American Society of Mechanical Engineers to the Seventy-Fifth Anniversary of the Verein deutscher Ingenieure, held in Cologne, in 1931, he was the recipient of a medal of honor "in appreciation of his services to technical-scientific achievement, particularly in promoting the mutual international interests of the engineers of the entire world." Among other honors in Germany he received the honorary degree of Doctor of Engineering (Dr.-Ing. E. h.), from the Technische Hochschule, of Darmstadt, Germany, in 1926.

Dr. Rice married Ellen M. Weibezahn, of Winchester, Mass., August 6, 1904, who, with his children, Edward Winslow and Marjorie Charlotte, survives him.

Tribute of the A.S.M.E. Council

A tribute to Dr. Rice was presented at the Business Meeting of the Society in December, 1934, in behalf of the committee of three past-presidents, Dexter S. Kimball, chairman, D. S. Jacobus, and Alex Dow, appointed for this purpose at the October 24 meeting of the Executive Committee of the Council of the Society. The tribute follows:

In the passing of Calvin Winsor Rice this Society has suffered an irreparable loss and many of its members have lost a kind friend and a wise advisor. To some of us who have been close to him for many years it does not seem possible that we shall never again see his cheerful smile, never again feel the hearty clasp of his hand, and never again see his bold signature at the end of a letter.

The accomplishments of his long and busy life are well known and will be recorded elsewhere, but it is very fitting that we should here be reminded of the great work that he performed in building up this Society. In season and out of season he labored wholeheartedly, and much of the success and reputation of The American Society of Mechanical Engineers is due to his foresight and faithfulness. Nor has this Society alone been benefited by his work. He had long been a source of information and inspiration to all who were concerned with the affairs of the engineering profession.

Especially should we remember that the existence of the Engineering Societies Building that has done so much to stimulate and consolidate the engineering fraternity is largely the result of his enthusiasm and diplomacy. As a consistent and energetic promoter of the life within the walls of this building, his work has been preeminent and will ever be remembered.

Mr. Rice was a man of remarkably broad and sympathetic nature. All good works claimed his attention and support and his range of activities was surprisingly great, both in this country and abroad. As a natural result he had a world-wide host of friends and acquaintances. He had indeed a peculiar ability to make friends of all manner of men. Few men in any walk of life have made so many personal contacts as he, and this in no small way redounded to the credit and reputation of the Society. The loss of these many connections can never be regained.

He was particularly considerate of young men and their problems. Many such sought him out for the advice and help that never failed and which was given freely and graciously. His unfailing good humor and his patience, diplomacy, and steadfastness, even when under criticism, fitted him admirably for the great work that he accomplished as secretary of the Society.

The engineering fraternity has lost a distinguished member, the Society has lost a great leader, and many of us have lost a friend and counselor. Because of such men the race makes progress, and the world is the better for his presence. And his work will endure. The labors of no man, who builds so intelligently and industriously as he, are ever lost but become a part of the inheritance of the race. "Though he were dead, yet shall he live." It is for those of us who remain to build upon the work he directed, so long and so well, the greater and more serviceable society that he always visualized, weaving into it not only technical excellence, but also the fine human qualities that so marked his personality.

"Build thee more stately mansion, O my Soul!
As the swift seasons roll!
Leave thy low-vaulted past!
Let each new temple, nobler than the last,
Shut thee from heaven with a dome more vast,
Till thou at length art free,
Leaving thine outgrown shell by life's unresting sea!"

Dr. Calvin W. Rice's Contribution to International Friendliness[1]

By JOHN H. FINLEY[2]

IT has been announced that I am to give a lecture, but what I shall say will not deserve such a formal or didactic description. It will, I hope, the rather be but as a preface to a series of lectures to bear the name of Calvin Rice—lectures devoted to the causes to which he gave himself, soul, mind, and body. It will so be that though dead he will yet speak on through the years and even centuries, in which we cannot doubt that the earth will be under a unified planetary physical control of engineers with Rice's humanizing and coordinating spirit, so far as man is progressively able to master the forces of nature.

Prometheus, the first of engineers, the demi-god as Shelley recounts his alleviation of man's estate,

> brought the fire to man, tortured to his will iron and gold, the slaves and signs of power, found what was hid beneath the mountains and the waves . . . gave science . . . taught the implicated orbits woven of the wide-wandering stars . . . taught to rule the tempest-winged chariots of the ocean and made the Celt to know the Indian . . . Cities were built and through their snow-like columns flowed the warm winds and the azure ether shone and the blue sea and shadowy hills were seen.

But these were only the beginnings of the ministry of the engineer. He was a Titan in the Greek myth, this half-god, half-man who secreted the fire in a rod of fennel and carried it to mortals, as later the modern engineer, whose name meant originally the man of genius, caught the fire of electricity and carried it in a wire to the inhabitants of all the earth—the mythical precursor of the engineer who has equated the unknown from the known by algebraic signs and evoked the seen from the unseen by divinations of intersecting lines and incantations of logarithms.

Prometheus is no longer bound. A Titan he is free to avail of all that his mind can bring forth to light. You remember into what a rapture Shelley rises at last in his "Prometheus Unbound,"

> To suffer woes which Hope thinks infinite;
> To forgive wrongs darker than death or night;
> To defy Power, which seems omnipotent;
> To love, and bear; to hope till Hope creates
> From its own wreck the thing it contemplates;
> Neither to change, nor falter, nor repent;
> This, like thy glory, Titan, is to be
> Good, great and joyous, beautiful and free;
> This is alone Life, Joy, Empire, and Victory.

It was a Promethean labor that Calvin Rice, Engineer, protagonist of engineers, friend of all mankind, performed, yet happily without Promethean suffering or "withering in destined pain." He went in the midst of his joyous planetary employment, conscious of the appreciation and the goodwill of the world which he was leaving.

I have often used the phrase "planetary consciousness" as something deeper than international-mindedness, importing a basic human relationship without regard to race or nationality. I think from what I have heard that few possessed that consciousness more highly developed than Calvin Rice—and not merely as an official acquaintanceship. Dr. A. B. Hart, Professor of Government Emeritus in Harvard University, has sent me a letter which illustrates that particular phase of the life of Calvin Rice:

> I have received the invitation to be present at your address in the Calvin W. Rice Lecture Series on "International Friendliness." Surely that term is applicable to Mr. Rice, who belonged to the large group of international scientific men; for whatever race, condition, language, or government, there is but one world group composed of those who adhere to the principles of that modern religion which is founded on the establishment, recognition, and application of truth. A more candid man than Calvin W. Rice could not be found, and he was a remarkable example of the international spirit of personal goodwill, of recognition of achievements, and of distribution of the results of research and generalization for the common welfare of mankind.
>
> It is that universality of research, that generous distribution of the results of research throughout the world which characterizes the science of the Twentieth Century.
>
> Added to that indelible search for and acceptance of the truth was the personal side of the man—the humor, the good temper, the forecasting, the belief in the universality of research and of learning Calvin W. Rice is a shining example of that true, indivisible, and universal science which is the pride of our age.

Here are particular instances of his "international friendliness" in which his planetary consciousness of the common fate of mankind expressed itself—first from Dr. L. S. Rowe, Director General of the Pan American Union:

> Mr. Rice was a constant and enthusiastic collaborator in the work of the Pan American Union. He was particularly helpful to us in bringing about closer relations between the engineering societies in Latin America and the national engineering societies of the United States. In the furtherance of this work he made a trip through the countries of South America and was warmly received everywhere. In devising plans for the development of closer cultural ties between the United States and Latin America I constantly turned to him for advice and suggestion. In a word, he was one of the most efficient collaborators in the furtherance of the plan for closer understanding between the nations of this continent.

Next a letter from the General Secretary of the Committee on Friendly Relations Among Foreign Students, Mr. Charles D. Hurrey:

> Dr. Calvin Rice was an esteemed member of our Committee on Friendly Relations Among Foreign Students for the past six years. He was never too busy to receive foreign student callers and to advise them with reference to obtaining practical experience in engineering before returning to their native lands. I have never known a more thoughtful man in writing letters of sympathy and appreciation to foreign student leaders; because of his world travels he was literally a citizen of the world and always manifested a profound respect for our visiting students and professors from abroad.
>
> Outstanding in his international services was his support of the plan by which several hundred German graduates of technical schools came to America after the war to obtain practical training in American industry. Dr. Rice was one of the moving spirits in initiating and carrying through this plan, which has established an abiding friendship between American industrial leaders and hundreds of the brightest younger business and professional men of Germany.
>
> I have in my files many letters from Dr. Rice, and in my memory is a happy recollection of many conversations in which he expressed a conviction that an engineer must be first a real, intelligent world citizen and secondarily an efficient technician.

One more only may I read—from Dr. S. P. Duggan, Director of the Institute of International Education:

> Dr. Calvin Rice was of inestimable aid to me in establishing one of the important activities which took place almost at the beginning of this Institute's career; namely, the exchange made with France

---

[1] Extracts from address delivered on December 5, 1934, during the Annual Meeting, New York, N. Y., of The American Society of Mechanical Engineers.

[2] Associate Editor of the *New York Times*.

of engineering professors. . . . His own efforts in . . . respect (to securing funds) and others in connection with the exchange were of great value to us.

He has since been a real friend to all our undertakings, particularly to young foreign exchange students of engineering who have come to study at American colleges and universities. His advice was eagerly sought by them and we have felt it a privilege to have such an authority place himself at our disposal.

These are only several instances of his friendship; but it is difficult to enumerate all the occasions when he was helpful. It is needless to say that the Institute and myself feel that the passing of Calvin Rice is an irreparable loss.

His passing would be an irreparable loss if his life were not a prophecy of better human relations as well as physical comforts. His humanizing and coordinating spirit will live on.

Memorial Notices

HAROLD FRANCIS ADAMS (1868–1934)

Harold Francis Adams, whose death occurred at Sayville, L. I., N. Y., on January 30, 1934, was born at Tansborough, N. J., on August 3, 1868, the son of Charles Edwin and Ellen Maria (French) Adams. His early education was secured in the schools of Atlantic City, N. J. After completing high school there he studied at Pierce's Business School and the Franklin Art Institute, both in Philadelphia, Pa., and then at the University of Pennsylvania, from which he secured a certificate of proficiency in 1897.

During the next five years Mr. Adams was a practicing architect in Atlantic City. From 1902 to 1904 he was associated with Herbert D. Hale and H. G. Morse, Jr., in charge of their Philadelphia office as chief draftsman and also in charge of the work of designing the interior fittings of the S.S. *Manchuria* and S.S. *Mongolia*, built by the New York Shipbuilding Company, Camden, N. J. During the following year he was employed by Wilson Eyre, of Philadelphia, directing the construction of a large private home in Jenkintown, Pa.

From 1905 to 1907 Mr. Adams was again connected with Hale and Morse, with whom James Gamble Rogers was also associated at that time. Mr. Adams held the position of assistant chief draftsman and had charge of exterior work on a number of large buildings in New York, including the McCreery store and Engineering Societies Building.

In 1907 and 1908 he was employed by the Purdy & Henderson Co., of New York and Havana, in charge of drawings for the Custom House and other buildings in Santiago de Cuba, and from 1917 to 1920 he was chief draftsman and head of the Havana office of that company and made designs for both concrete and structural steel buildings there. During the years 1909–1917 he worked successively for Mr. Rogers, directing construction on the estate of E. S. Harkness, New London, Conn.; for Goldwin Starrett & Van Vleck, New York, on plans for the Albany (N. Y.) high school; and for Willauer, Shape & Bready, New York, as chief draftsman, working on plans for a number of large buildings in that city.

While in Havana with Purdy and Henderson Mr. Adams attracted the attention of the Royal Bank of Canada, and in 1920 he became manager of its Bank Premise Department there. Later he was transferred to Montreal, Canada. He left the bank's employ in 1923 to open an office of his own in New York, where he engaged in architectural work until his retirement in 1931.

Mr. Adams became a member of the A.S.M.E. in 1921 and also belonged to the American Institute of Architects and the American Arbitration Association, as well as to the masonic fraternity. He had served as captain of the Morris Guards of Atlantic City. He invented a honing device, which was patented in 1918, and was interested in photography. He is survived by his widow, Minnie A. (Rocks) Adams, and two sons, Harold Francis, Jr., and Lewis Edwin, all of Sayville, and a daughter, Helen B. Adams, of Baltimore, Md.

MARION EUGENE BABIONE (1908–1934)

Marion Eugene Babione, whose death occurred on June 2, 1934, was born on May 6, 1908, at Luckey, Ohio, the son of Dr. Augustus A. and Anna (Bollini) Babione. He secured an A.B. degree at Adelbert College, Western Reserve University, Cleveland, Ohio, in 1930, and two years later a B.S. degree in mechanical engineering at the Case School of Applied Science. While at Adelbert College he was elected to the Pi Kappa Alpha fraternity, and he later became a member of Sigma Xi, honorary scientific fraternity. He became a junior member of the A.S.M.E. in 1932.

For eighteen months prior to his death Mr. Babione was employed as mechanical engineer for the Hanna Coal Company, Cleveland.

JOSEPH E. BACHELDER (1868–1932)

Joseph E. Bachelder, who died in Chicago, Ill., on December 12, 1932, following two months' illness, was born at Palmyra, Maine, on November 3, 1868. At an early age his family removed to Holyoke, Mass. Following his graduation from high school, he entered the employ of the Deane Steam Pump Company of Holyoke, progressing rapidly in the organization, and from 1897 to 1901 was assistant to the superintendent of the company. He then went to Chicago to become manager of the Pump Sales Department of Fairbanks, Morse & Co., and remained in the employ of this company, with the exception of a year as vice-president and manager of the Temple Pump Company, Chicago (1914–1915) until his retirement in 1930. From 1901 to 1906 he was manager of the Pump Sales Department. He then was transferred to the Pump Manufacturing Department at Beloit, Wis., where he remained until 1914. After the year with the Temple Company he was appointed engineering salesman and New York branch manager of the Fairbanks organization. He was transferred to Baltimore in 1922 and to St. Louis in 1923, serving as manager in each city.

Mr. Bachelder became a junior member of the A.S.M.E. in 1905 and an associate of the Society in 1921. He is survived by his widow, Grace Swift Bachelder, and by a son and two daughters.

HERBERT A. BARRE (1875–1934)

Herbert A. Barre, chief engineer of the Southern California Edison Company, Ltd., died suddenly of a cerebral hemorrhage at his home in Los Angeles, Calif., on June 28, 1934. He had been in the continuous service of the Southern California Edison Company and its predecessor companies for 23 years, holding successively the positions of electrical and mechanical engineer, executive engineer, and chief engineer.

Mr. Barre was born at Pictou, N. S., Canada, on January 26, 1875, the son of John R. and Elizabeth F. (Merriman) Barre. He went to San Francisco while still a child and received his education in the schools of that city. He secured a B.S. degree from the University of California in 1897 and was a member of Tau Beta Pi, honorary engineering fraternity. He was given an honorary degree by the California Institute of Technology in 1924.

Practically all of Mr. Barre's engineering work was done in the West in connection with electric utility systems. Following his graduation in 1897 he secured employment as electric station operator for the Redlands (Calif.) Electric Light & Power Co. and subsequently held similar positions with the Los Angeles Railway and the Mt. Whitney Power Company, Hammond, Calif., and was assistant electrical engineer with the traction company at Oakland Calif. From 1900 to 1902 he was connected with the Independent Electric Light & Power Co. and Independent Gas Company, San Francisco, as inspector of construction and assistant to the chief engineer of the former, and assistant superintendent of the latter. In 1902 he returned to Los Angeles as assistant to R. S. Masson, consulting engineer of the Henry P. Huntington properties, which included the Los Angeles Railway, the Pacific Electric Railway, and the San Joaquin Light & Power Co.

In 1906, Mr. Barre became associated with the Electric Bond & Share Co., of New York, N. Y., where he was engaged in engineering valuation and operating activities. Construction of the Glenwood and Boulder plants of the Denver Gas & Electric Co. took Mr. Barre West again to Denver in 1907. He became interested in the formation of the Electric Construction Company, which built the Fossil Creek plant of the Arizona Power Company, and was actively engaged in the building of that plant.

In 1911, when the Pacific Light & Power Corp. (a Huntington property, merged in 1917 with the Southern California Edison Company) was beginning the construction of the Big Creek-San Joaquin River hydroelectric development with its 240-mile transmission lines to Southern California, Mr. Barre was engaged as electrical and mechanical engineer. It was in connection with the large hydroelectric and steam system of the Southern California Edison Company that his most outstanding achievements were accomplished. He was possessed of high engineering ability coupled with a very sound economic understanding of the utility industry. His recommendations as engineer and economist are permanently written into the great hydroelectric and steam system of the company he served. In 1911, when Mr. Barre became associated with the properties now comprising the Southern California Edison Company, this system consisted of a development of some 180,000 horsepower, represented by a plant investment of about $50,000,000. During his active participation in the development of this system, the plant capacity was enlarged to more than 1,250,000 horsepower and the investment in properties increased to $350,000,000.

Probably the most outstanding achievement of Mr. Barre's work was the successful construction and operation of the first 150,000-volt long-distance electric transmission lines in the world, transmitting energy from the water power development on Big Creek and the San Joaquin River to Los Angeles, a distance of approximately 240 miles. Later, when the construction of additional power development at Big Creek brought the need for greater transmission capacity to Southern California, Mr. Barre met the requirement by reconstructing the 150,000-volt lines for operation at 220,000 volts. These lines so converted were the first commercial lines in the world to ac-

complish electric transmission at this high voltage. These attainments brought to Mr. Barre world recognition as an engineer and attracted attention from outstanding engineers in America and foreign countries who went to Los Angeles to learn the details of construction and operation. This contribution in the field of electric transmission has not only saved many millions of investment in transmission expense on the projects with which he was associated, but has also had its influence on the development of all the large hydro developments in the world that are distant from the market to which the energy is transmitted.

Mr. Barre became a member of the A.S.M.E. in 1912. He also belonged to the American Institute of Electrical Engineers. He married Annie E. McTear, in Los Angeles, in 1904, and is survived by her and by two children, Ben E. and Ruth E. Barre, and also by his father.

WILLIAM HASTINGS BASSETT (1868–1934)

William Hastings Bassett, a pioneer metallurgist in the non-ferrous metal industry, connected since 1902 with The American Brass Company, died at his home in Cheshire, Conn., on July 21, 1934. He was born at New Bedford, Mass., on March 7, 1868, the son of William A. and Almira D. (Mayhew) Bassett. With forebears who were seafaring men and a childhood spent in such an environment as New Bedford, he had a love for the water which always made boating his favorite recreation. Until within a year of his death he spent a month annually at Martha's Vineyard.

Not choosing to follow the sea as a profession, however, he entered the Massachusetts Institute of Technology, from which he was graduated in 1891 with a Bachelor of Science degree. He spent the next five years as chemist and superintendent for the Popes Island Manufacturing Company, in New Bedford, and then taught chemistry at the Swain Free School there until 1900. During the next two years he was chief chemist at the Newark Laboratory of The New Jersey Zinc Company.

In 1902 Mr. Bassett went to Torrington, Conn., as chemist for the Coe Brass Manufacturing Company, a branch of the newly formed American Brass Company of Waterbury. The following year he was made chief chemist and metallurgist of The American Brass Company, in 1912 its technical superintendent and metallurgist, and in 1930 metallurgical manager of the company. Of his position in the non-ferrous metal industry and the achievements which led to it, Dr. H. Foster Bain, formerly secretary of the American Institute of Mining and Metallurgical Engineers, wrote in an appreciation published in *Mining and Metallurgy* for September, 1934, as follows:

"After beginning as chemist he rose through various grades of laboratory and plant service with ever increasing responsibilities until he became metallurgical manager for the entire company, itself the largest producer of brass and copper goods in the world. He was the recognized unofficial dean of metallurgists in his chosen field long before he died.

"To him, more than any other single individual, though many had part in the movement, was due the introduction and development of technical control of production in copper-alloy manufacture. When he went to Torrington, brass making was an art handed down from father to son or master to apprentice. The manager of a plant was in the hands of his melters who kept close in their own control knowledge of composition, temperature, and time necessary to produce given quantities in an alloy. Results were irregular, unexplained, and often unsatisfactory. Bassett being a chemist at once began taking samples and making analyses. Also, as Holland and Pringle have related in a most interesting chapter in 'Explorers in Science,' he had a microscope. It was at least among the first of those instruments put into effective use in the industry. The result was that composition and quality were accurately related and the metallurgist came to give directions for what went into the pots and when. . . . A firm foundation was laid for large-scale manufacture of standard goods even from high-priced metals.

"Mr. Bassett's researches in alloys were numerous and wide ranging. A large number of patents were secured in his name or in that of members of his staff and still others were bought by the company on his recommendations. It was not only in chemical matters that he was an authority but in much besides. An important reinforced hollow copper cable is one of his inventions and his wide knowledge and sound judgment of methods of testing were recognized by his professional compeers in his election to the presidency of the American Society for Testing Materials which he held at the time of his death."

Mr. Bassett was president of the A.I.M.E. in 1930. Prior to that he had served as chairman of the Institute of Metals Division of the Institute and was instrumental in bring about the merging of the older Institute of Metals with the A.I.M.E. He was awarded the James Douglas Medal by the A.I.M.E. in 1925 "for constructive research in copper and brass and other non-ferrous metals and their alloys and for his contributions to the establishment of high standards of quality."

Mr. Bassett's service in the American Society for Testing Materials was also outstanding. C. L. Warwick, secretary-treasurer of the Society, has summarized it in the following paragraph:

"In June, 1934, after serving a two-year term as vice-president, he was elected president of the American Society for Testing Materials, with which he had been affiliated since 1903. As a personal member and the official representative of his company, he participated actively in the work of a number of A.S.T.M. committees. He took a leading part in the organization in 1909 of the first two A.S.T.M. standing committees in the non-ferrous field, B-1 on Copper Wire and B-2 on Non-Ferrous Metals and Alloys, and served continuously on these committees until his death. He served as a member of the society's executive committee in 1916–1918. He always took a keen interest in advancing the knowledge of the properties of non-ferrous metals and supported actively a number of research and standardization projects in the society."

Mr. Bassett also took part in the work of the National Research Council and during the World War was a member of the War Department's Advisory Committee on Materials for Airplane Construction. He had served on the Metallurgical Advisory Committee to the Bureau of Standards and on the Army Ordnance Advisory Committee, Watertown Arsenal. He was a member of the Army Ordnance Association.

Mr. Bassett became a member of the A.S.M.E. in 1924. He was a former director of the American Institute of Chemical Engineers, a Fellow of the American Association for the Advancement of Science, and held membership in many scientific and engineering societies in this country and abroad, including the American Chemical Society, Society of Automotive Engineers, American Electrochemical Society, Mining and Metallurgical Society of America, American Foundrymen's Association, Society of Naval Architects and Marine Engineers, American Welding Society, The Franklin Institute, American Geographical Society, Institute of Metals and Society of Chemical Industry, London, and Deutsche Gesellschaft für Metallkunde. He was a 32d degree Mason and a Shriner, trustee of the public library in Cheshire, and a deacon in the First Congregational Church there since 1914. He belonged to the Engineers' and Chemists' Clubs in New York, as well as to clubs in Waterbury and Torrington.

Mr. Bassett married Sarah Hedge Whiting in 1892 and is survived by her and by two children, Alice Whiting Bassett and William Hastings Bassett, Jr., the latter technical superintendent and metallurgist for the Anaconda Wire & Cable Co., Hastings-on-Hudson, N. Y.

HENRY HOWELL BAUMGARTNER (1893–1933)

Henry Howell Baumgartner died on November 16, 1933, at his home in Belleville, N. J., of injuries sustained in an automobile accident during the summer. He was president and treasurer of the Essex Engineering Company, organized at Belleville in 1928.

Mr. Baumgartner was born at Flemington, N. J., on July 10, 1893, the son of Frederick and Marguerite (Burkitt) Baumgartner. He attended the United States Steam School at Hoboken, N. J., for five months during the winter of 1917–1918 and served in the United States Navy until early in 1920. He then spent about a year as second engineer on the Standard Oil tanker, "S. V. Harkness." He was refrigerating engineer for Swift & Co. from September, 1921, to February, 1922, and spent the remainder of that year in his former position of second engineer of Standard Oil tankers.

From then until June, 1925, Mr. Baumgartner was connected with the Public Service Gas & Electric Co., of New Jersey, as assistant boiler room engineer and technical assistant. During the next three years, until he organized the Essex Engineering Company, he was refractory and combustion engineer for the Drake Non-Clinkering Furnace Block Company, of New York, N. Y. Several patents, dealing with furnaces and combustion methods, were issued to Mr. Baumgartner.

Mr. Baumgartner became an associate-member of the A.S.M.E. in 1928, and was past-president of the National Association of Power Engineers. He belonged to the Belleville post of the American Legion. His widow, Ida E. (Hughes) Baumgartner, whom he married in 1918, and two sons, William Darrow and Richard Balz Baumgartner, survive him.

JOSEPH ROBERT BLAINE (1884–1934)

Joseph Robert Blaine died at his home in Oak Park, Ill., on December 17, 1934. He had been connected since 1913 with the Miehle Printing Press & Manufacturing Co., Chicago, in charge of the design of offset printing presses.

Mr. Blaine was born in Chicago on November 14, 1884, the son of John Smith and Frances (Birkholz) Blaine. He received a B.S. degree at the University of Wisconsin in 1905, and an M.E. degree from that institution in 1911. For two years prior to entering college he had worked in the shop and toolroom of Edward P. Allis, Milwaukee, and for a year on the erecting floor of Pawling & Harnischfeger, in that city. He spent his vacations in the latter work, also, and after his graduation in 1905 continued with the company for two years as mechanical draftsman.

From 1907 to 1913 Mr. Blaine was engaged by the Berlin Machine Works, Beloit, Wis., as designer of band-sawing machinery, spending four months of the time in Europe in special work for the company. He held some patents on woodworking machinery but his most important work was in the graphic arts field, in which he held about fifty patents for inventions on typographic and lithographic presses and other printing equipment.

Mr. Blaine became a member of the A.S.M.E. in 1917. He is survived by his widow, Mrs. Attolle (Frost) Blaine, a daughter, Virginia P. Blaine, and a son, Robert F. Blaine.

DAVID REES BOWEN (1865–1934)

David Rees Bowen, vice-president of Farrel-Birmingham Company, Inc., Ansonia, Conn., and for many years its chief engineer, died at his home in Ansonia on December 29, 1934. He played an important part in the development of machinery for non-ferrous rolling mills, sugar-cane grinding, stone and ore crushing, and for the manufacture of paper, rubber, linoleum, and other products, and was widely known in the industries where such machinery is used.

Mr. Bowen was born in Cwmavon, Wales, on October 22, 1865. He received his early education in the British national schools and at Llandovery Collegiate School. At the age of 17 he came to the United States with his parents and in 1883 entered the employ of the Farrel Foundry & Machine Co. as a machinist's apprentice. After serving his apprenticeship for three years he worked as a machinist two years longer, then entered the drafting room of the company. His exceptional ability soon led to his appointment as superintendent, then chief engineer. He held the latter position until 1930, when he was elected vice-president, in charge of engineering. In July, 1933, when ill health compelled him to relinquish the active direction of engineering, he became consulting engineer for the company, continuing also as vice-president until his death.

Mr. Bowen had been a member of the A.S.M.E. since 1899. He was also a member of the masonic fraternity and the Elks. He took an interest in civic affairs, serving as alderman of Ansonia and as a member of the board of trustees of the public library there. He was also a vestryman of Christ Episcopal Church. He was very fond of books and through his reading had acquired a fund of knowledge on many subjects. He spoke the Welsh language fluently and was deeply interested in his native land, to which he returned for many visits.

He is survived by his widow, a son, a daughter, and two grandchildren.

HENRY K. BROOKS (1869–1934)

Henry K. Brooks, president of the Capital Iron Works Company and of the Steel Fixture Manufacturing Company, of Topeka, Kan., died in that city on August 12, 1934, of a cerebral hemorrhage.

Mr. Brooks was born at Kettering, Northamptonshire, England, on January 8, 1869, and was educated in that country. His early schooling was received through private instruction and at the Wisbech Schools, Cambridgeshire. After securing government certificates in drawing, he served an apprenticeship with the firm of Gimson & Co., general engineers, of Leicester, at the same time attending the Leicester Technical Evening College. Upon the completion of his apprenticeship he continued in the employ of Gimson & Co. for several years. He also worked for a short time for the Midland Railway Company, in England, before coming to the United States.

During his first years in this country Mr. Brooks was also engaged in railroad work, being employed by the Atchison, Topeka & Santa Fe, the Southern Kansas, and the Southern Pacific railway companies. In 1895 he accepted a position as instructor at the Kansas State Agricultural College, in charge of the foundry, blacksmith, and machine departments. The following year he returned to the industrial field, in the capacity of general manager for the Capital Iron Works. A short time afterward he and his brother, George W. Brooks, purchased the company and he became its president. He spent three years with the company, during this first period, and was responsible for the work under many federal, state, and railroad contracts for structural iron and machinery.

In 1899 Mr. Brooks became interested in the electrical field and took a position with the Electric Axle Light & Power Co., of New York, N. Y., in charge of its equipment in operation on railroads. The following year he became assistant chief engineer for the Consolidated Railway Light & Equipment Co., New York, and for several months had charge of its factories in New York and Connecticut. Later in 1900, having made some improvements in electric train-lighting apparatus, Mr. Brooks was offered a position as chief engineer of the United States Light & Heating Co., New York. He remained with this company until 1908 and was in complete charge of its factory and all mechanical apparatus.

In 1908 Mr. Brooks returned to Topeka to again take over the management of the Capital Iron Works, and he and his brother also formed the Steel Fixture Manufacturing Company for the manufacture of steel office furniture. These two fabricating companies are among the largest of their kind in Kansas and their products are widely distributed.

Mr. Brooks became a member of the A.S.M.E. in 1907. He was a charter member of the Kansas Day Club, New York, N. Y., a member of the board of directors of the Kansas State Historical Society, past-president of the Associated Industries of Kansas, past-president of the Lakeview Hunting and Fishing Club of Topeka, and a Scottish Rite Mason.

Mr. Brooks married Miss Edith Harrison, of Ottawa, Kansas, in 1895. She died in 1927. He is survived by a daughter, Mrs. R. E. Kreuger, of Topeka, as well as by a number of brothers and sisters.

JAMES PARK CALDERWOOD (1884–1934)

James Park Calderwood, head of the Department of Mechanical Engineering at Kansas State College of Agriculture and Applied Science, Manhattan, Kan., died at his home there on August 9, 1934. He is survived by his widow, Coral E. (Parker) Calderwood, whom he married in 1910.

Professor Calderwood was born at Middleport, Ohio, on January 1, 1884, the son of Andrew and Christina (Thompson) Calderwood. He was graduated from the Middleport High School in 1903 and from the Pomeroy (Ohio) Academy the following year, and in 1908 secured his M.E. degree at Ohio State University. The following year he held a fellowship in experimental engineering at the university.

In 1909 Professor Calderwood became instructor in mechanical engineering at Pennsylvania State College. He was made assistant professor in charge of all heat-engine subjects the following year and in 1911 took charge of the experimental engineering laboratory. In 1913 he was advanced to an associate professorship, with the administration of the experimental engineering department, and he continued in this post until 1917. In addition to his regular teaching and administrative work he designed and installed a heating and ventilating system for new liberal arts and mining buildings.

Special research work conducted by Professor Calderwood while at Pennsylvania State College included an investigation of the effect of the velocity and humidity of air on heat transmission through building material; a study of the pounding in gas engines when using kerosene as a fuel; the development of a method of determining the ultimate from the proximate analysis of coal; and a study of the purchase of coal by specification, which was primarily a study of the methods of coal sampling. The results of all of these investigations were published by the Engineering Experiment Station of the college.

Professor Calderwood served as a member of the Pennsylvania State Board for the examination of boiler and elevator inspectors from 1916 to 1917, and was offered, but declined, an appointment as mechanical engineer for the Department of Labor and Industry of the State of Pennsylvania. In 1916 the Pennsylvania State College conferred the degree of Master of Science upon him.

In 1917 Professor Calderwood accepted a position in the Engineering and Inspection Division of the Travelers Insurance Company at Hartford, Conn. He spent a year with the company, working on special engineering problems connected with liability and indemnity insurance, including the special inspection of industrial plants, studies on accident prevention, and the development of a method for the rating of chemical risks. During this year he also served as assistant engineer for the State of Connecticut in connection with the United States Fuel Administration.

Professor Calderwood had been a member of the faculty of Kansas State College since 1918, when he became professor of steam and gas engineering there. He was made head of the Department of Mechanical Engineering the following year. Reports on some of his work there have been published by the Engineering Experiment Station of the college. He had also made frequent contributions to the technical press and was co-author of several textbooks, including "Engineering Thermodynamics," in collaboration with James A. Moyer; "Elements of Steam and Gas Power," with A. A. Potter; and "Elements of Engineering Thermodynamics," with Moyer and Potter. He had been called upon by the public service commissions

of Kansas and Missouri and the Federal Court of Nebraska in cases involving controversy over natural gas.

Professor Calderwood became a junior member of the A.S.M.E. in 1913 and a member six years later. He had served two terms on the executive committee of the Mid-Continent Section of the Society, being vice-chairman in 1925–1926 and again a member of the committee in 1929–1930. He was honorary chairman of the Student Branch of the Society at Kansas State College from 1925 to 1932.

He was also a member of the Society for the Promotion of Engineering Education, was president of its Kansas-Nebraska Section in 1930, and a member of its membership committee in 1928. He belonged to the Kansas Engineering Society and served on its legislative committee in 1925, was faculty advisor of Sigma Tau, of which he was a member, and was advisory editor of the *Kansas State Engineer*. He was also a member of the masonic fraternity, Delta Upsilon, and the honorary fraternities, Phi Kappa Phi and Sigma Xi, as well as of a number of clubs.

ADAMS BURTON CHAMBERLAIN (1875–1934)

Adams Burton Chamberlain, assistant superintendent of the Station Engineering Department of The Edison Electric Illuminating Company of Boston, died at his home in Wollaston, Mass., on January 22, 1934.

Mr. Chamberlain was born in LaCrosse, Wis., on April 1, 1875, the son of Eli and Mary L. (Porter) Chamberlain. At an early age he went to Newport, Vt., to live and was graduated from the St. Johnsbury Academy. After that he was successively employed by the Tremont and Suffolk Mills, Lowell, Mass., on cost and inspection work, by C. R. Makepeace, mill engineer, Providence, R. I., as a draftsman, and by the New England Telephone & Telegraph Co. on construction work.

In January, 1901, he entered the employ of The Edison Electric Illuminating Company of Boston in the Station Engineering Department, where he rose through various grades to the position he held at the time of his death.

Mr. Chamberlain became a member of the A.S.M.E. in 1911. He was also a member of the Engineers Club of Boston and a 32d degree Mason. He is survived by his widow, L. Josephine Eaton, whom he married in 1903, and by a daughter, Kathryn.

WALTON CLARK (1856–1934)

Walton Clark, consulting engineer and former vice-president of the United Gas Improvement Company, Philadelphia, Pa., died in that city on July 30, 1934. He was the inventor of a process for the complete gasification of coal, and contributed to the development of processes for operating water-gas sets. He was the author of numerous scientific articles.

From 1907 to 1924 he was president of The Franklin Institute and in 1926 the institute honored him with its first award of the Walton Clark Medal, for his "distinguished and outstanding contributions" to the gas industry. At the time of the presentation of the award Dr. W. C. L. Eglin, president of the institute, said that Mr. Clark was "a pioneer in the association of physical and chemical laboratories with the development work of gas companies."

Mr. Clark was born in Utica, N. Y., on April 15, 1856, the son of Erastus and Frances (Beardsley) Clark. He attended the public schools of Utica until his seventeenth year, when he entered the service of the New Orleans Gas Company, where he served in various capacities until 1886. In 1883 he was temporarily assigned to the United Gas Improvement Company to complete the installation of a water-gas plant in New Orleans, work on which had been interrupted by a yellow fever epidemic. Mr. Clark was immune to the disease, and so was able to finish the installation, which would have been impossible for an unacclimated engineer.

He served successively in gas companies in Jefferson City, La., and in Kansas City, and following the death of the assistant general superintendent of the United Gas Improvement Company, Mr. Clark was appointed, in August, 1888, to take his place. Six years later he was made general superintendent, a position which covered the duties of the chief engineer of the company and supervisor of the many enterprises under its control. He became a vice-president of the company in 1904 and held that office until he resigned from active duties in 1923. He had been consulting engineer to the company since then.

In 1904 the honorary degree of Master of Engineering was conferred upon Mr. Clark by Stevens Institute of Technology, and in 1911 he received the degree of Doctor of Science from the University of Pennsylvania.

He was past-president (1906) of the American Gas Institute, of which he was one of the founders; became a member of the A.S.M.E. in 1890; and also belonged to the American Institute of Electrical Engineers and the American Society of Mining and Metallurgical Engineers. He was chairman of the board of trustees of the Free Correspondence School for Gas Works Employees.

He also was a member of the Society of the Cincinnati, the Society of the Founders and Patriots of America, and the Sigma Psi fraternity. His clubs included the Engineers' Club, New York, and in Philadelphia the Engineers, Union League, University, and a number of country and athletic clubs. His home was at Chestnut Hill, Pa.

Mr. Clark in 1880 married Miss Alice M. Shaw, of Natchez, Miss., who died in 1882. In 1885 he married Miss Louise Beauvais, of New Orleans. Surviving him, in addition to Mrs. Clark, are Frank Shaw Clark, a son by his first marriage; and three sons and one daughter by his second marriage, Walton, Jr., Theobald Forstall, Beauvais, and Darthela Clark.

WILLIAM JAY COFFIN (1875–1934)

William Jay Coffin, connected with the New York State Department of Public Works since 1922, died at Wethersfield, Connecticut, on June 14, 1934, after several months' illness.

Mr. Coffin was born in Albany, N. Y., on December 20, 1875, the son of William Latham and Anna McHarg Coffin. He received his M.E.E. degree from Cornell University in 1898 and immediately began work as electrical repairman in the Signal Department of the New York Central Railroad, Albany. He was connected with this railroad, in various capacities, until 1914. He served an apprenticeship in the Motive Power Department in 1900 and 1901 and worked in that department successively as stationary engineer, roundhouse foreman, and mechanical foreman at Albany until 1909. He was then sent to the general manager's office in New York, N. Y., to take charge of locomotive tests and tonnage rating. After several months in that work he was made assistant to the superintendent of motive power of the Western Division, investigating mechanical problems in shops and on the road. In April, 1910, he was appointed assistant engineer in the president's office in New York, where he remained until 1914, making technical investigations dealing with locomotive operation and tonnage rating for the entire New York Central system.

In January, 1914, Mr. Coffin was appointed first deputy commissioner of Public Works and he served the City of Albany in that capacity until January, 1922, having charge of the adaptation of motor apparatus to municipal work and establishing repair facilities. He entered the employ of the New York State Department of Public Works as Fleet Commander in March, 1922, in charge of floating equipment on the state barge canal, including tugs and dredges; he also supervised dredging work and wrecking operations. He was made assistant civil engineer in February, 1923, and continued in that capacity until his death. He was assigned to the division of highways of District No. 1, and had charge of several highway construction projects.

Mr. Coffin became a member of the A.S.M.E. in 1923. He also belonged to the masonic fraternity. He is survived by a sister, Helen Coffin, of Hartford, Conn., and by a daughter, Lois Lilian Coffin, of Brooklyn, N. Y. His wife, Selora (Gaskill) Coffin, died in 1922.

SAMUEL DUNLAP COLLETT (1868–1933)

Samuel Dunlap Collett, whose death occurred on December 26, 1933, was born on October 25, 1868, at Newport, Ind. He attended the public schools there and secured his B.S. and M.S. degrees at Rose Polytechnic Institute, where he studied mechanical, electrical, and civil engineering.

Before completing his college work Mr. Collett worked for a short period as a surveyor on the Chicago, Evansville & Chattanooga Ry., took a training course in the factory of the Thomson-Houston Electric Company, and worked in the Boston and Pittsburgh offices of that company.

In the fall of 1895 Mr. Collett entered the employ of the Metropolitan Telephone & Telegraph Co. (now the New York Telephone Company) as engineer in the construction department and for two years was in charge of the interior block department and underground cable work. He then took the position of eastern manager of the Elevator Supply & Repair Co., New York, of which he later became vice-president. He was associated with the company until 1920, and from then until his retirement in 1925 was with the Elevator Supplies Co., Inc., Hoboken, N. J.

Mr. Collett had been a member of the A.S.M.E. since 1902. He was also a member of the American Institute of Electrical Engineers.

ERNEST HARRY CORNELIUS (1890–1934)

Ernest Harry Cornelius, president of the Oklahoma Steel Castings Company, Tulsa, Okla., died in Cleveland, Ohio, on May 8, 1934,

from complications following an operation for appendicitis. The son of Harry B. and Georgiana (Phillips) Cornelius, he was born on October 28, 1890, at Hastings, Neb., and received his early education there. He entered Northwestern University, at Evanston, Ill., at the age of 17, but because of an injury sustained in a fall during his junior year, he was obliged to leave college. After spending about a year and a half in California, he returned to Nebraska and entered the state university at Lincoln, from which he was graduated with a B.S. degree in 1913.

Following his graduation Mr. Cornelius engaged for a time in sales work for the Jacques Steel Company, in northern Texas. During the first part of 1914 he assisted in appraisal work in Kansas City and then took a position with the Metropolitan Street Railway in that city inspecting construction of new trackage and rehabilitation of existing lines. He also made special designs for cars and did other drafting work, remaining with the company for about two years. He spent part of 1916 with the Kansas City Southern Railway Company, as assistant to the bridge engineer. He then moved to Tulsa, and during the next two years was connected with the Oklahoma Structural Steel Company, subsidiary of the Oklahoma Iron Works, as chief engineer and sales manager the greater part of the time.

In January, 1918, Mr. Cornelius began private practice in the design and construction of steel structures, chiefly for the oil industry. This business was incorporated as the Industrial Construction Company two years later, with Mr. Cornelius as president. In 1922 he also organized the Oklahoma Steel Castings Company, which he had since served as president, greatly developing the size of the plant and extending the territory it serves.

Mr. Cornelius took a keen interest in civic affairs and the development of industry in Oklahoma. He was a past-president and for some years had been a director of the Associated Industries of Oklahoma. He had also served as president of the Public Welfare Society of Tulsa, director of the Tulsa Community Fund and the Tulsa Chamber of Commerce, member of the Board of Trustees of the University of Tulsa, president of the Rotary Club in Tulsa, and Member of the Board of Trustees and chairman of the Financial Committee of the Boston Avenue Methodist Episcopal Church. Just previous to his illness he had been appointed to the NRA Code Authority for the steel-castings industry.

Mr. Cornelius became a member of the A.S.M.E. in 1927 and was a former director of the American Iron and Steel Institute. He belonged to Sigma Nu and the masonic fraternities, and to the Tulsa Club and Tulsa Country Club.

In addition to all these activities he found time to take up flying, first as a hobby and later as a means of transportation for business trips.

Mr. Cornelius is survived by three children, Marjorie Ann and Ernest H. Cornelius, Jr., and Mrs. Virginia (Cornelius) Eby. His wife, Virginia Moseley, whom he married in Lincoln, Neb., in 1914, died in 1923.

ALBERT NELSON CRAMER (1883–1934)

Albert Nelson Cramer, whose death occurred on June 21, 1934, was born in Philadelphia, Pa., on March 27, 1883, the son of Harry Howell and Fannie H. (Slack) Cramer. After attending the Manual Training School in Philadelphia for three years, he entered the employ of the Baldwin Locomotive Works there, and for five years worked on detail drawings for the company. He subsequently spent a year and a half each in similar work for the Link-Belt Engineering Company, Nicetown, Pa., and W. E. Hamilton, Columbus, Ohio, and about six months with the Schoen Steel Wheel Company, Philadelphia. In 1908 and 1909 he was engaged in field engineering for P. A. Kley, Philadelphia, and layout work for the Jeffrey Manufacturing Company, Columbus.

During the next ten years Mr. Cramer was designer in charge of experimental development and construction for the Federal Glass Company, Columbus. He then went to Toledo, Ohio, to take the position of assistant engineer, in charge of special engineering development, with the Owens Bottle Company. He left there in the spring of 1929 and spent the next two years as assistant engineer in the research department of the American Optical Company, Southbridge, Mass.

Since July, 1931, Mr. Cramer had devoted all his time to developing inventions of his own. Prior to that date he had already taken out more than twenty patents on glass-making machinery, including blowing, molding, and cutting machines, feeders, and handling apparatus. Subsequently he developed additional equipment for the glass industry, including a number of machines for forming tumblers and hollow glass articles, patents on some of which were pending at the time of his death.

Mr. Cramer became a member of the A.S.M.E. in 1929 and was active in the masonic fraternity in both Columbus and Toledo. He is survived by his widow, Mrs. Alice P. (Bietsch) Cramer, and by a daughter, Elizabeth B. Cramer.

RALPH CROOKER (1854–1934)

Ralph Crooker, a member of the A.S.M.E. since 1890, died at his home in Acton, Mass., on June 2, 1934. He is survived by his widow, Louise C. (Little) Crooker, whom he married in 1905.

Ralph Crooker (3d) was born in South Boston on December 25, 1854, the son of Ralph and Ann A. (Bailey) Crooker. He was graduated from the English High School of Boston with the class of 1872, and had always kept in touch with the members of that class through its annual reunion dinners in Boston.

At the age of eighteen he entered training as a draftsman at the Bay State Iron Works, Boston, under the direction of his grandfather, who was a member of the firm and superintendent of the works. He remained with that company until 1879, when he went to Springfield, Ill., where he spent about six months with the Springfield Iron Company. From 1880 to 1884 he served as engineer and superintendent with the Colorado Coal & Iron Co.

In 1885 Mr. Crooker entered the employ of the Jones & Laughlin Steel Co., Pittsburgh, Pa., and between then and 1907 he spent the greater part of his time with that company, the last period being from about 1903 to the latter part of 1907. His other connections were with the Bessemer Works of the Springfield Iron Company in 1887 and 1888, with the Johnson Company, Lorain, Ohio, during part of 1894, and with the Lorain Steel Company, about 1900.

He had made his home in Acton since 1907 and had not been active in business except for a little consulting work and a few months in 1919 making alterations in piping for T.N.T. for Mackintosh-Hemphill & Co., Pittsburgh. His chief pastime during his latter years was the study of maps and of plans for ocean liners and boats. He also liked to study the rock formations and wild life in the woods near his home.

Mr. Crooker was a Legion of Honor member of the American Institute of Mining and Metallurgical Engineers and also belonged to the Engineers' Society of Western Pennsylvania.

FRANK GARFIELD CUTLER (1881–1934)

Frank Garfield Cutler, of Birmingham, Ala., died on June 17, 1934, at the Manhattan Eye, Ear and Throat Hospital, New York, N. Y., of complications following a mastoid operation.

Mr. Cutler was born on May 13, 1881, at Fort Scott, Kan., the son of Samuel and Ella B. (Dickerson) Cutler. He studied manual training in Louisville, Ky., and then entered the University of Kentucky, from which he received his Bachelor's degree in mechanical engineering in 1901, and the degree of Mechanical Engineer three years later. He was graduated with highest honors and in 1902, when the honorary engineering fraternity, Tau Beta Pi, was organized there, he was made a member.

Immediately upon leaving college in 1901 Mr. Cutler went to Chicago to become assistant in the steam engineering department at the South Works of the Illinois Steel Company. He remained in that position until the fall of 1906, then took charge of the steam engineering department of the Ensley Division of the Tennessee Coal, Iron & Railroad Co. He was made chief of the Bureau of Steam Engineering of the company in 1914 and held that position until his death.

Mr. Cutler was considered an authority on steam power-plant design and construction and especially its application to steel mills. In 1928 he completed studies for and wrote a paper on "Combination Firing of Blast-Furnace Gas and Pulverized Coal," which was presented at the Semi-Annual Meeting of the A.S.M.E. in Pittsburgh in May of that year.[1] These studies were carried on as new boilers and equipment were put in at the mill, and continued practically up to his death.

Mr. Cutler became a member of the A.S.M.E. in 1914 and had served several years on the Executive Committee of the Birmingham Section of the Society, being chairman in 1921. He was secretary in 1917–1918 and president in 1921 of the Alabama Technical Association, and in 1922 was vice-chairman of the Association of Iron and Steel Electrical Engineers. He had also served as chairman of the Jefferson County Orphans Home Association and as a director of the Ensley Rotary Club and a member of the board of governors of the Woodward Gold Club. His hobbies were golf and contract bridge, and especially long automobile trips in both the North and South. He is survived by his widow, the former Blanche B. Duffy, of Chicago, whom he married in 1909, and by three children, Mary E., Samuel M., and Grace L. Cutler.

[1] Trans. A.S.M.E., vol. 49–50, 1927–1928, FSP-50-35, pp. 102–106.

ORTON GOODWIN DALE (1870–1934)

Orton Goodwin Dale was drowned in Barnegat Bay on February 18, 1934, when ice broke beneath him as he was walking on the bay near his summer home at Mantoloking, N. J. Mr. Dale was consulting engineer to the Texas Gulf Sulphur Company, of New York, and a director of the New York & New Jersey Steamboat Company. He is survived by his widow, the former Miss Amy Slade, of Trenton, N. J., whom he married in 1896, and by a daughter, Mrs. D. R. Abbes, of Burlingame, Calif., and two sons, F. Slade Dale, yachtsman, Bay Head, N. J., and Orton G. Dale, Jr., vice-president of Bowne & Co., financial printers, New York.

Mr. Dale was born in Helensburgh, Scotland, on November 8, 1870, but had lived in the United States since he was ten years old. He was graduated from the Stevens Institute of Technology in 1893 and spent the following year in the drawing room of the National Sugar Refining Company, Yonkers, N. Y. He then became New York manager of the Mead-Morrison Manufacturing Company. In 1918 he was connected with the Singer Manufacturing Company, Elizabeth, N. J., and for the next two years was assistant chief engineer of the American International Shipbuilding Corporation, Philadelphia, Pa. He had been with the Texas Gulf Sulphur Company since that time.

Mr. Dale resided in Plainfield, N. J., for some years, but moved to New York in 1916. It was his custom to spend the weekends at his Mantoloking home and he had recently been elected to the Mantoloking Borough Council. He became a junior member of the A.S.M.E. in 1894 and was promoted to the grade of member in 1909. He was appointed a member of the Committee on Publications of the Society in 1922 and served as its chairman in 1925 and vice-chairman the following year.

CYRUS EATON DAVISON (1890–1934)

Cyrus Eaton Davison, formerly chief research engineer for Martin Motors, Inc., New York, N. Y., died on March 8, 1934, after a year's illness. He is survived by his widow, Anna R. (Tong) Davison, whom he married in 1918, and by a son, Robert C., and daughter, Ruth B. Davison, residing at Stapleton, S. I., N. Y.

Mr. Davison was born at Huntsport, Nova Scotia, Canada, on August 26, 1890, the son of Cyrus C. and Laura (Eaton) Davison. He attended the Huntsport High School and at the age of twenty-one entered the employ of the Southern Pacific Company. He served as assistant engineer and chief engineer on various ships of that company until December, 1917. He then entered the United States Navy as an engineer officer, with the grade of lieutenant, serving, during the next year and a half, aboard the U.S.S. *Lakewood* and U.S.S. *Montclair*. During the summer of 1919 he was connected with the United States Shipping Board in the capacity of assistant machinery inspector and chief machinery inspector, supervising the installation of boilers, turbines, and reciprocating engines, and all other mechanical equipment on ships being built by the Federal Shipbuilding Company for the Emergency Fleet Corporation. He was graduated from the Naval Turbine School at Carnegie Institute of Technology, Pittsburgh, Pa., in 1919.

In the fall of 1919 Mr. Davison took charge of the Educational Department of the Ocean Association of Marine Engineers, of which he was a member, and was instructor of its engineering classes for three years. During the following year he was assistant engineer for the French Company, directing the operation and repair of turbo-generators and electric motors.

Mr. Davison again became an instructor in marine engineering in July, 1923, when he took the position of chief engineer and senior engineering instructor at the New York State Nautical School, New York, N. Y. He continued in that work until January, 1926, then spent two years as assistant superintendent of buildings and grounds at Columbia University. He had been with Martin Motors, Inc., since that time, located at the research laboratory in East Rutherford, N. J., at first. He was engaged in the design and construction of internal-combustion engines for test purposes, and in running power and efficiency tests.

Mr. Davison became an associate-member of the A.S.M.E. in 1926 and a member three years later. He also belonged to the masonic fraternity.

WILLIAM EDWARD DEAN, JR. (1888–1933)

William Edward Dean, Jr., who died of pneumonia at Hamilton Ontario, Canada, on December 11, 1933, was a native of Minneapolis Minn., where he was born on June 12, 1888. His parents were William Edward and Elmina (Clapp) Dean. He attended grammar and high school at Los Angeles, Calif., and then served a four-year apprenticeship with the Southern Pacific Company, of that city. In 1910 he entered the University of California, from which he was graduated with a B.S. degree in mechanical engineering in 1914. During his summer vacations he did drafting-room and testing-laboratory work.

Immediately following his graduation Mr. Dean took a position in the Engineering Department of the Westinghouse Air Brake Company, Wilmerding, Pa., and in the fall of that year was made personal assistant to the manager of engineering, to work on the design, manufacture, and performance of air brakes and related devices, such as automatic train control.

In August, 1917, Mr. Dean entered the Second Officers Training Camp at Fort Oglethorpe, Ga. He was commissioned second lieutenant in the Signal Reserve Corps, Aviation Section, and served five months at Park Field, Tenn., and five at Langley Field, Va., as engineer officer in charge of installation and operation of machine, motor-repair, and blacksmith shops. He was then promoted to first lieutenant in the Air Service and until January, 1919, was stationed at Washington, D. C., in the engine and plane maintenance branch of the service.

Upon his return to civilian life, Mr. Dean was made assistant engineer of tests by the Westinghouse Air Brake Company, continuing to carry on research on air brakes. Early in 1921 he was sent to Kingston, Jamaica, on special consulting work for the Jamaica Government Railways. Upon his return he was appointed engineer of tests, and at the beginning of 1926 assistant chief engineer in charge of tests and inspection.

At the close of 1928 Mr. Dean was appointed chief engineer of the Westinghouse Brake Company of Australasia Ltd., and for several years was located in New South Wales, Australia. In August, 1932, he was transferred to the position of chief air-brake engineer of the Canadian Westinghouse Co. Ltd., at Hamilton, Canada, the position he held at the time of his death.

Mr. Dean became a junior member of the A.S.M.E. in 1921 and a member four years later. He also belonged to the Air Brake Association and to the honorary fraternities, Tau Beta Pi and Sigma Xi. He had patented many air-brake system devices.

Surviving Mr. Dean are his widow, Doris (Brown) Dean, whom he married in 1923, and three sons, Frederick Brown, William Corner, and Robert Stanley Dean.

GEORGE PASS DeHAVEN (1886–1934)

George Pass DeHaven, son of William Henry and Margaret M. (Pass) DeHaven, both descendants of old Pennsylvania families, was born at Harrisburg, Pa., on September 3, 1886. His early education was secured in the schools of that city. After his graduation from high school there he studied for two years at the Stevens Institute of Technology, Hoboken, N. J., and two years at Drexel Institute, in Philadelphia. He then entered the employ of the Pennsylvania Steel Company, at Steelton, where he spent a year each in the pattern and machine shops, and about six months each in the iron and steel foundries.

In January, 1914, he took a position in the engineering department of the Bethlehem Steel Corporation, Steelton, where he remained for four years, working on the design of rolling mill machinery. From then until the summer of 1923 he was connected with the Harrisburg Foundry and Machine Works, spending four years on the design, testing, and preparing specifications and estimates for steam engines, then serving successively as assistant purchasing agent, assistant works manager, and production manager.

He was next employed for about a year as designer and checker for the Koppers Company, Pittsburgh, working on gas producers and machinery for operating them, and during the winter of 1924–1925 designed rolling-mill machinery for the Birdsboro Steel Foundry & Machine Co., Birdsboro, Pa. He then became assistant chief engineer for the Taylor-Wilson Manufacturing Company, McKees Rocks, Pa., with which he remained until he was appointed chief engineer, General and Maintenance Employees, of the Bureau of Public Grounds and Buildings of the Commonwealth of Pennsylvania. He subsequently was made superintendent of the Bureau of Maintenance of Public Grounds and Buildings, the position he held at the time of his death, which occurred on February 19, 1934, at his home in Harrisburg.

Mr. DeHaven became an associate-member of the A.S.M.E. in 1926 and in that year he also took some courses in the shaping of steel and roll pass design at the Carnegie Institute of Technology. He had served as corporal and quartermaster sergeant on the Governor's Troop of the Pennsylvania National Guard and belonged to the masonic fraternity and the Elks. He is survived by his widow, Margaret M. (Edwards) DeHaven, whom he married in 1906, and by their son, Charles A. DeHaven.

EDWARD H. J. DILLON (1887–1934)

Edward H. J. Dillon, who died in Philadelphia, Pa., on March 28, 1934, was born in Brooklyn, N. Y., on April 15, 1887, the son of John and Anna (Mohan) Dillon. He attended the public and high schools there, and subsequently studied for two years at Brooklyn Polytechnic Institute and St. John's University, Brooklyn.

At the age of seventeen Mr. Dillon entered the employ of the Griscom-Russell Company, of Philadelphia, marine and stationary power plant engineers and manufacturers, and had spent his entire professional life with that company, rising to the position of manager of the Philadelphia office.

Mr. Dillon became an associate of the A.S.M.E. in 1920 and belonged to the Knights of Columbus. He is survived by his widow, Margaret Dillon, whom he married in 1915.

FRED DOEPKE (1862–1934)

Fred Doepke, founder and president of the Wrought Washer Manufacturing Company, Milwaukee, Wis., died in Los Angeles, Calif., on April 23, 1934, after having been in failing health for several years. Mr. Doepke became a member of the A.S.M.E. in 1922 and since 1926 had served as secretary of the Sectional Committee on the Standardization of Plain and Lock Washers, for which the A.S.M.E. and the Society of Automotive Engineers are joint sponsors. He was also a past vice-president of the Engineering Society of Milwaukee and belonged to a number of social clubs in Milwaukee and vicinity.

Mr. Doepke was born at Rockford, Ill., on March 28, 1862, the son of Gotlieb and Bertha (Smith) Doepke. The family later moved to Milwaukee and he attended school there from 1879 to 1883, at the same time serving an apprenticeship in the machine shops of the old Filer & Stowell Co. After working for a time in 1883 in machine shops in Cleveland, Ohio, he went to New York, where he studied at Cooper Union nights and was employed by E. W. Bliss Co., the North River Iron Works, and the Freeland Tool Works. Subsequently he went to Philadelphia, where he likewise studied evenings, taking courses offered by The Franklin Institute, and worked in the daytime.

During these years Mr. Doepke became interested in automatic machinery and conceived the idea of automatic washer-making machinery. He returned to Milwaukee in 1885 and started in business with A. J. Read. The Wrought Washer Manufacturing Company was founded about 1887 and he served as vice-president of the company until 1910, when he became its president. He not only designed and built the plant itself, but also practically all of its special machinery. Under his guidance the plant became one of the largest in the world devoted to the production of washers.

Mr. Doepke had traveled extensively, visiting many foreign countries, and was widely known in engineering circles and throughout the metal industries. For some years prior to his death he had made his home in St. Petersburg, Fla. He is survived by his widow, Anna M. (Disch) Doepke, whom he married in 1892, and by one son, Fred C. Doepke, of Milwaukee.

ROSCOE IRVING DUNTEN (1888–1934)

Roscoe Irving Dunten, whose death occurred on June 17, 1934, was born at Calcium, N. Y., on April 13, 1888, the son of Milton Thomas and Anna Elizabeth Dunten. To supplement his high-school education he took courses in steam and electrical engineering through the International Correspondence School, completing these studies in 1907. He then secured work as assistant at the steam power plant of the St. Regis Paper Co. at Deferiet, N. Y., where he remained for two years, part of the time being chief engineer.

From 1909 to 1912 Mr. Dunten was in charge of the steam-electric power plant of the Delaware & Hudson R. R. Co. at Oneonta, N. Y., and during the next year directed the operation and maintenance of an 80-ton ice-making plant of the Tampa Ice Company, at Palmetto, Fla.

In 1913 the Southern Utilities Company, of Palatka, Fla., engaged Mr. Dunten as engineer in its electric plant at Bradentown, Fla. After three years there he was transferred to the combined ice and electric plant at West Palm Beach as chief engineer. Something over two years later he was made supervising engineer of all of the company's properties, consisting of more than twenty plants located at different points in Florida and Georgia. He remained with the company until the latter part of 1921, his work including not only the supervision of existing plants but also the design, layout, and erection of new plants and research on burning oil fuel under power boilers.

During the next seven years Mr. Dunten was vice-president and general manager of the San Juan Ice and Refrigeration Company, in Porto Rico. He directed the reconstruction and enlargement of the company's plant at San Juan, greatly increasing the output and reducing fuel consumption. He returned to Florida in 1928 to become manager of the Caribbean Division of Pan-American Airways, Inc., with headquarters at Miami, and held that position at the time of his death.

Mr. Dunten joined the A.S.M.E. with the grade of associate-member in 1921 and was promoted to full membership three years later. He was Rear Commodore of the Biscayne Yacht Club and a member of the masonic fraternity. He is survived by his widow, Luvenia M. (Wood) Dunten, whom he married in 1909, and by a daughter, Florence A. (Dunten) Foster.

GEORGE C. FARKELL (1872–1934)

George C. Farkell, superintendent of the rail and blooming mills, at the Lorain, Ohio, works of the National Tube Company, died at St. Joseph's Hospital in that city of pneumonia on October 22, 1934. He had been connected with the Lorain Works since early in 1905, when he became assistant superintendent of the skelp mills. The following year he was advanced to the position of superintendent of the skelp mills, and in 1907 was made superintendent of the rail and mechanical departments of the works. He held this position for ten years, then was superintendent of the rolling mills until April, 1934, when he was further promoted to the position he held at the time of his death.

Mr. Farkell was born on January 12, 1872, at Canajoharie, Montgomery County, N. Y., the son of John and Catherine Farkell. He was graduated in 1887 from the local high school and entered Cornell University from which he was graduated in 1892 with an M.E. degree in electrical engineering. While at Cornell he was elected to membership in the honorary scientific fraternity, Sigma Xi.

For two years after leaving college Mr. Farkell was engaged in electrical construction work for H. Ward Leonard & Co., New York, and from then until the end of 1895 was on the staff of the Physical Testing Laboratory of the Lukens Iron & Steel Co., Coatesville, Pa. During the next five years he was assistant engineer with the United States Revenue Cutter Service, for three years of that period assistant to the engineer-in-chief detailed for inspection duty and for engineering work in connection with the construction of steam machinery for new revenue cutters.

Mr. Farkell became assistant chief inspector of the Homestead Steel Works of the Carnegie Steel Company in January, 1901. In October of that year he was made assistant to the superintendent of the 128-in. plate mill, the 42-in. universal, and the 30-in. slabbing mill of the Homestead works, where he remained until May, 1904. Between then and his connection with the Lorain Works, he held the position of assistant superintendent of the slabbing, plate, rail, and structural mills of the Lackawanna Steel Company, Buffalo, N. Y.

Mr. Farkell contributed greatly to the development of rolling-mill practice and held patents on a manipulator used in handling rolled-metal shapes; a speed-controlling apparatus for electrically driven rolling mills (joint patent with Edwin S. Lammers); a method of rolling T-shaped rails; and a device for tightening nuts on screw-threaded ends of bolts.

Mr. Farkell had been a member of the A.S.M.E. since 1913. He also belonged to the American Society for the Advancement of Science, the American Iron and Steel Institute, and the masonic fraternity. He was very active in community affairs in Lorain. He was one of the founders of the local Red Cross chapter and served on its executive committee from 1917 to the time of his death, part of the time as chairman. He had been a member of the board of directors of the Lorain Y.M.C.A. since 1925 and was chairman of the committee which had charge of erecting a new Y.M.C.A. building. He was a member of the board of directors of the Lorain Community Fund during the last five years of his life. In recognition of these services he was selected in 1933 for the *Lorain Journal* Achievement Award, as the citizen who during the year had performed the most noteworthy service to the community.

Radio construction was his special hobby and golf his favorite pastime.

His widow, the former Miss Ouida E. Pease, whom he married in 1909, survives him.

THOMAS FARMER (1852–1934)

Thomas Farmer, a member of the A.S.M.E. since 1891, died of pneumonia at the United Hospital in Portchester, N. Y., on November 6, 1934. He is survived by his widow, formerly Miss Maud H. White, whom he married in 1879, and by a daughter, Elizabeth G. (Farmer) Kelsey, and a son, Thomas, the fourth in line to bear that name.

Mr. Farmer was born in Boston, Mass., on October 12, 1852, his

mother being Henrietta B. (Cobb) Farmer. After his graduation from high school in Roxbury in 1869 he learned the machinist's trade at the shops of A. Leitelt Co. in Grand Rapids, Mich. He spent three and a half years there, then went to Aurora, Ill., where he worked in the locomotive shops of the Chicago, Burlington & Quincy R.R. He next returned East, working for a time on erecting for the Providence Machine Company. During these years he studied drawing and other engineering subjects.

In 1874 he returned to Grand Rapids, where he obtained the position of superintendent of the city water works, which he held for five years, resigning to go into business for himself. Owing to lack of capital his venture was not successful and he went to Chicago, where he was employed for a time as tool saleman. He did not find this work congenial, however, and took a position as general superintendent of the Somersworth Western Manufacturing Company of Bloomington, Ill. During two years spent with this company he built new shops and designed special tools. He resigned that position to become superintendent of the Detroit Radiator Company (which later became a part of the American Radiator Corporation). He directed the laying out and building of a new plant and had charge of the design of new tools and the operation of all departments of the plant.

Mr. Farmer's next connection was with the Russel Wheel & Foundry Co. of Detroit, for which he built a new plant and served as its superintendent for a time. About 1894 he became chief engineer of the Detroit Citizens Railway, with which he remained for nine years. From Detroit he went to Cleveland, Ohio, where he was associated for ten months with the Kuhlman Car Company. He then opened an office for consulting work in the street-railway field. He gave this up to rebuild and electrify the plant of the United States Heater Company (subsequently known as the United States Radiator Corporation) in Detroit, after which he became sales manager of the Detroit office of the Warner & Swasey Co. He spent nine years in that capacity, prior to becoming manager of the Detroit office of Manning, Maxwell & Moore, Inc. He had not been active in business since 1925.

EDWIN E. A. FISHER (1870–1934)

Edwin E. A. Fisher was born in Providence, R. I., on August 31, 1870, the son of James Potter and Caroline Martha (Butts) Fisher. He attended Cooper Union, New York, then entered Cornell University, from which he was graduated in 1891 with an M.E. degree. He specialized in electrical engineering during his senior year and his first position after graduation was with the Field Engineering Company, working on the installation of an electric railway between Paterson and Passaic, N. J. After a year in that connection he went to Lynn, Mass., to take a course at the General Electric Company works there. In 1893–1894 he engaged in electric-railway installation for the Union Railway Company, Providence, R. I., and the following year was instructor in physics and electrical engineering at Lehigh University.

From 1895 to 1912 Mr. Fisher was located the greater part of the time outside the United States. He studied physics, chemistry, and mathematics for a year at the University at Göttingen, Germany, after which he was located in England and Canada. For ten years beginning in 1901 he was connected with the Bureau of Education in the Philippine Islands, as division superintendent of schools, superintendent of the Philippine School of Arts and Trades, and acting assistant director of education in charge of schoolhouse construction in the Philippines, and devised the unit system for schoolhouses there. He next spent a year as assistant commissioner of the interior of Porto Rico.

Since his return from Porto Rico Mr. Fisher had been engaged in technical and statistical research in relation to life insurance. He was in the statistician's department of the Prudential Insurance Company, Newark, N. J., from 1912 to 1921 and since then, until his death on March 3, 1934, had been in the risk classification department of the John Hancock Mutual Life Insurance Company, Boston, Mass.

Mr. Fisher became a member of the A.S.M.E. in 1922 and also belonged to the American Statistical Association, American Association for the Advancement of Science, and Boston Life Underwriters Association. He was vice-president and director of Fisher & Thompson, Inc., New York. In Dover, Mass., where he made his home, he was treasurer of the First Parish of Dover and vice-president of the Dover Historical and Natural History Society. He married Sophie L. Armington, of Providence, in 1907, and is survived by her and by three sons and a daughter.

STANLEY GRISWOLD FLAGG (1860–1934)

Stanley Griswold Flagg, president of Stanley G. Flagg & Co., Philadelpha, Pa., died of a heart attack on March 14, 1934, just a week after the death of his wife, Elizabeth (Windrim) Flagg. He is survived by his son, Stanley Griswold Flagg, 3rd, of Philadelphia, and his daughter, Mrs. Edward S. Nugent-Head, of London.

Mr. Flagg was born in Philadelphia on January 21, 1860. His mother was Adelaide (Gordon) Flagg and his father Stanley Griswold Flagg, founder of the company, which manufactures malleable-iron, cast-iron, and brass fittings, brass valves, and specialties. He learned the business under his father and succeeded him to the presidency of the company.

Mr. Flagg was one of the early advocates of standardization in the valve and fittings industry. As a member of the A.S.M.E., which he joined in 1891 and of which he was a manager for the term 1910–1913, he was appointed a representative on the American Engineering Standards Committee soon after its formation in 1918. He continued to serve on that body, later reorganized as the American Standards Association, until 1930.

For some years prior to the formation of the A.E.S.C. he served on special A.S.M.E. committees on pipe and screw threads. He represented the Society on the Sectional Committee on Standardization and Unification of Screw Threads from the time of its organization in 1921 until 1930, and was also the Society's representative on the Sectional Committee on Pipe Threads. He also represented the Manufacturers Standardization Society of the Valve and Fittings Industry on the Sectional Committee on Pipe Flanges and Fittings.

He was a most active worker on these and other committees to which he was appointed by the various technical organizations to which he belonged, losing no opportunity to cooperate in the sound development of the industry as a whole. He made frequent trips abroad, promoting standardization at international conferences and through his many personal contacts.

Mr. Flagg was a past-president of the American Foundrymen's Association and a member of the American Institute of Mining and Metallurgical Engineers, the American Society for Testing Materials, and the Iron and Steel Institute. He had also served as president of the Pennsylvania Society of Sons of the Revolution, vice-president of the General Society of the Sons of the Revolution, and treasurer of the Society of Colonial Wars in the Commonwealth of Pennsylvania. One of his pastimes was the collecting of rare books.

WILLIAM FRAY (1865–1934)

William Fray, who died at the Bridgeport (Conn.) Hospital, on July 22, 1934, after a two years' illness, was born at Cornwall, England, on July 2, 1865, the son of Samuel and Emma (Sweet) Fray. He came to the United States as a boy and attended the Bridgeport public schools. At the age of sixteen he was apprenticed to the machinist and toolmaking trade and he worked up in that field, studying mechanical drawing, mathematics, and other subjects evenings, until he became assistant foreman at the Farrel Foundry & Machine Co., Waterbury, Conn., in 1890, and foreman two years later.

He resigned in 1900 to take the position of superintendent of the wire mill of the Benedict & Burnham Manufacturing Co., Waterbury, with which he remained four years. He then became production superintendent for John S. Fray & Co., Bridgeport, manufacturers of small tools for mechanics. He was there until 1910 when he became superintendent of the Standard Brass & Copper Tube Co., New London, Conn. After two years he was made secretary of the company, as well as superintendent, and two years later became its president and general manager. He greatly enlarged the plant during his connection with it. After the sale of the business in 1917 Mr. Fray retired from active business, but from time to time acted as a consulting engineer on brass and copper-tube manufacture, serving, among others, the Bridgeport Brass Company, Wheeler Condenser & Engine Co., Detroit Brass & Copper Co., Scovill Manufacturing Company, Dominion Copper Products Company, and Philadelphia Roll & Machine Co.

Mr. Fray became a member of the A.S.M.E. in 1920 and was treasurer of the Bridgeport Section of the Society from 1926 to 1931. He was also a member of the Bridgeport Engineers Club and the masonic fraternity. After his retirement he spent some time in travel. He is survived by his widow, Minnie J. (Steiber) Fray, whom he married in 1883, and by a son, George H. Fray, and daughter, Florence (Fray) Clark.

DAVID WILLIS FRENCH (1860–1934)

David Willis French, retired superintendent of the Hackensack (N. J.) Water Company, died at his home in Englewood, N. J., on August 9, 1934, following a few days' illness. He is survived by his widow, Wilburta F. French, and by a sister, Mrs. Laura E. Libby of Boston. His first wife, Amelia (Eddy) French, whom he married in 1884, died in 1929.

Mr. French was born at North Weymouth, Mass., on March 24, 1860, his father's name being John French. At the age of sixteen he entered upon a three-year apprenticeship in the shops of the Whittier Machine Company, Boston, during which period he also attended night school four evenings a week. The following year he took a special course at the Massachusetts Institute of Technology. In 1881 he became associated with the Henry R. Worthington hydraulic works in South Brooklyn, N. Y., as erecting engineer. In 1882 the firm contracted to install a pump for the Hackensack Water Company at the New Milford plant. Mr. French supervised this installation and upon its completion was retained by the Hackensack Water Company. In 1883 he had charge of installing the plant for the high service system at Weehawken, and subsequently was engaged to operate it for a year under Charles B. Brush, chief engineer and superintendent. He was engineer in charge of the high service system for eight years, then was made deputy assistant superintendent of the company, and after the death of Mr. Brush in 1896 was made superintendent of the company, the position he held until his retirement in 1928.

Some of his major projects were the reconstruction of the New Milford pumping plant, the installation of the present great filter system, construction of the sub-pumping station at North Bergen, and the extension of the water system to supply about sixty towns in Hudson and Bergen counties. In 1900 he recommended to the board of directors of the company the purchase of a subsidiary water company located at Spring Valley, N. Y., and in 1912 he reconstructed this plant to supply ten towns in Rockland County.

In 1913 Mr. French perfected a machine which makes it possible to install a line gate without the interruption of service, a machine now widely used throughout the United States.

Mr. French became a member of the A.S.M.E. in 1916. He was also a member of the American Water Works Association, which he served as president in 1909, was a director of the Hoboken Savings Bank, a member of the Union City Masonic Lodge, member of the board of the First Presbyterian Church, Englewood, director of the New Jersey Utilities Association for twenty years, superintendent of the Grove Church Sunday School for a number of years, member of the Executive committee of the Boy Scouts, North Hudson County Council, and a former member of the Board of Education of Union City.

A. O. FRICK (1852–1934)

A. O. Frick, chairman of the board of the Frick Company, Waynesboro, Pa., and active in the affairs of the firm for more than sixty years, died at a hospital in Baltimore, Md., on April 20, 1934.

Mr. Frick was born on June 16, 1852, at Ridgeville (now Ringgold), Md., where his father, George Frick, a native of Switzerland with a genius for mechanical things, then had his engine shop. The family having moved to Waynesboro in 1861, Mr. Frick's education was completed in the public schools of that town. At the age of fifteen he began work as an apprentice in the Frick shops under his father, later becoming foreman, then draftsman, then mechanical engineer.

In the late 60's and the 70's Mr. Frick, with an engineering insight years ahead of his time, improved the designs for the Frick portable steam engines and boilers. Some of his early drawings for these engines, bearing the date 1869, are still preserved, and illustrate with their fine, accurate lines, the craftsmanship he displayed in all his work.

Between 1876 and the early 80's he developed the Frick steam traction engine, doing the ground work which led through such steps as steering by a team of horses, chain drive from the engine shaft to the gearing, the use of a train of small gears to replace the chain, devices for springing the rear axle, feedwater heaters, etc. He also patented an improved balanced slide valve, some of his early drawings showing the adaptability of this valve to locomotive practice.

In 1882 and 1883 Mr. Frick made the drawings for the original refrigerating machines with which the firm pioneered in this field, and he subsequently assisted in enlarging the line of ice-making equipment. About 1889 he spent a year in Springfield, Mo., building and operating an ice plant. Following this he devoted himself particularly to managing the engineering work of the company. He was made vice-president in 1896 and elected to the presidency of the company in 1904, but continued to serve as consulting engineer on all of its work.

Mr. Frick had been chairman of the board since 1924, and though in recent years he had retired from active work, he always took the keenest interest and pride in the company's progress. When he was past the age of 75 he took over the duties of chief engineer for several months, during his absence. He was the last living member of a group of thirteen men who banded together in 1873 to save the firm from the effects of the panic of that year.

In addition to his connection with the Frick Company, Mr. Frick was a director of the Citizens National Bank & Trust Co., a director of the Chamber of Commerce and of the Beneficial Fund Association of Waynesboro, a member of the board of managers of the Waynesboro Hospital, a member of the Waynesboro Country Club, and charter member of the local masonic lodge. He became a member of the A.S.M.E. in 1885.

He is survived by his widow, the former Miss Margaret Mehaffey, a sister, and two brothers, Amos and Ezra Frick.

ALFRED BROOKS FRY (1860–1933)

Alfred Brooks Fry, Commodore, U.S.N.R. (Retired), died in Coronado, Calif., on December 4, 1933. Mr. Fry entered Government service in 1886 as inspection engineer of public buildings under the Supervising Architect's Office of the Treasury Department and held many important posts in civil and naval service prior to his retirement in 1927.

Mr. Fry was born in New York, N. Y., on March 3, 1860, a son of Major Thomas William G. Fry (U.S.V.) and Frances (Olney) Fry, and a great-grandson of Captain Benjamin Fry, who served in the Continental Army. He attended private schools and Morse's School in New York and studied engineering at Columbia University. He spent several years at sea as an oiler and assistant engineer and also had shop experience with the Corliss Engine Company, Providence, R. I., and at Portland, Me., and Boston, Mass., with the Portland Company and Globe Mill Company. He was captain of the Boston Fire Department from 1882 to 1886.

In civil service in the Treasury Department Mr. Fry was advanced from inspection engineer to chief engineer and supervising chief engineer. He had charge of the construction, engineering operation, and repairs of United States public buildings and their mechanical and electrical plants. Much of his time was spent on work at New York but he also had assignments in Boston, Chicago, Washington, New Orleans, and Galveston and on the Pacific Coast and in connection with quarantine stations and marine hospitals on the Atlantic, Gulf, and Pacific Coasts. From 1916 to 1926 he was consulting engineer for the U. S. Immigration Service, in charge of the construction and maintenance of immigration buildings. He served on a Congressional Commission on the mechanical transmission of mails in 1913.

By order of the President Mr. Fry served as a member of the Board of Consulting Engineers for the Improvement of State Canals in New York from 1904 to 1912, and he also studied and reported on European and Egyptian canal, river, and port improvements in 1909 and 1918. He was an engineer member of the Special Panama Canal Commission in 1921.

Mr. Fry was consulting engineer for the Association for the Protection of the Adirondacks, from 1908 to 1920, and for the Department of Water Supply, Gas, and Electricity of the City of New York, from 1914 to 1917. He was a member of the Committee on Water Storage and Waterways of the Merchants' Association of New York from 1918 to 1926.

In 1892 and 1893 he organized the first Engineer Division of the United States Naval Militia at Boston and New York. He served as engineer lieutenant and engineer lieutenant-commander from 1892 to 1910 and as commander and chief of staff of the Naval Militia, New York, from then until 1923, when he was made commodore. He was retired in 1924 with the rank of rear-admiral.

In the U.S.N.R. he was advanced through the ranks from lieutenant to commodore, retiring in 1927. He was acting chief engineer in the U.S.N. during the Spanish-American War, 1898, and engineer-aide to Rear-Admiral Burd, industrial manager of the Third Naval District and New York Navy Yard, during the World War. He was engineer-observer on the first run of the U.S.S. *Leviathan* in 1917 and also saw duty at sea and at English and French ports. He was consulting marine engineer for the U.S. Army Transport Service in 1922. He was a member of the International Congresses of Navigation.

Since his retirement Mr. Fry had served on the Harbor Committee of the San Diego Chamber of Commerce in 1929 and on the City Council of Coronado in 1929–1930 and was mayor pro-tem of Coronado in 1930–1931, and mayor from then until the time of his death. He served on the employment committee of Southern California in 1931.

Mr. Fry became a member of the A.S.M.E. in 1892. He was also a member of the American Society of Civil Engineers, American Society of Naval Engineers, Society of Constructors of Federal Buildings, of which he had been president. He was a member of a committee of engineers representing the National Engineering Societies at the New York Constitutional Convention in 1915. He belonged to the Society of Colonial Wars, The Society of the Cincinnati of the Providence Plantations, and the Military Order of the Spanish-

American War, and his clubs included the Columbia University, New York, and Army and Navy, Washington. He was an honorary member of the Yachting Department of the New York Athletic Club.

Surviving Mr. Fry are his widow, Emma V. (Sheridan) Fry, whom he married in 1890, and their son, Sheridan Brooks Fry.

GEORGE WARREN FULLER (1868–1934)

George Warren Fuller, who became internationally known as a sanitary engineer and expert on water supply and sewage disposal died at his home in New York, N. Y., on June 15, 1934. He was born at Franklin, Mass., on December 21, 1868, and was the son of George Newell and Harriet (Craig) Fuller. After his graduation from the Massachusetts Institute of Technology in 1890 with an S.B. degree, he studied for about a year at the University of Berlin and in the private office of the engineer of the Berlin water works. He then devoted about nine years to research work in water purification, chiefly at the Lawrence Experiment Station of the Massachusetts State Board of Health, and at Louisville, Ky., and Cincinnati, Ohio, where his work on coagulation and rapid sand filtration laid the basis for American water purification practice.

Since 1899 Mr. Fuller had engaged in consulting work, with his headquarters in New York. From 1901 to 1911 he was in partnership with Rudolph Hering under the firm name of Hering & Fuller. During the next few years he continued practice under his own name. In 1916 he formed a partnership with James R. McClintock, under the firm name of Fuller & McClintock, of which he was senior member at the time of his death.

Mr. Fuller served as consulting engineer for major water works and sewerage improvements in more than 150 large cities in this country and abroad. He had been consultant to the New York Board of Water Supply since 1906. In connection with the development of the Catskill reservoirs and supply systems he made an intensive study of the principal systems in Wales and Scotland which led to the installation of aerating stations below the Ashokan and Kensico reservoirs. He also served as consultant to the Metropolitan Sewage Commission and in 1928 and 1929 reported to the city upon the Wards Island sewage-treatment project, plans for which were subsequently drawn by his firm.

In 1917 and 1918, during the World War, Mr. Fuller was a member of a central committee at Washington having to do with the engineering, planning, and sanitation of various army camps, and he was also consulting engineer to the Construction Division of the Army. Directly after the Armistice he served as a member of the Franco-American Engineering Congress which convened at Paris to consider reconstruction and economic problems in France.

One of the many important posts held by Mr. Fuller since the World War was that of chairman of the Engineering Board of Review for the Sanitary District of Chicago, which was formed in 1924 to consider a new sewage-disposal system in that city. The recommendation of the board to draw sufficient water from Lake Michigan to carry sewage in satisfactory dilution through the Illinois Canal to the Mississippi River was adopted and successfully carried out. In 1934 he was recalled to advise a special board of review in regard to additions to this system.

Mr. Fuller had always taken a keen interest in public-health work. He was consulting engineer to the United States Public Health Service in connection with municipal improvements necessary to public health, contributed largely to the development and adoption of the Standard Methods of Analysis for Water and Sewage sponsored by the American Public Health Association, and as chairman of its Council on Standardization, helped the American Water Works Association in the publication of its Manual of Water Works Practice.

Mr. Fuller was a member and chairman of an engineering advisory committee of the Reconstruction Commission of the State of New York, and advisor to the International Joint Commission on Boundary Waters between the United States and Canada. Among the projects on which the advice of his firm was sought during recent years were water works for Shanghai, China; the Wanaque aqueduct, for the New Jersey Water Policy Commission and the North Jersey District Water Supply Commission; new water supply and purification systems for Kansas City, Mo., Memphis, Tenn., and Wilmington, Del.; sewage-treatment works at New Haven, Conn., and Lexington, Ky.; a comprehensive system of intercepting sewers and sewage treatment for the Hackensack Valley Sewerage Commission of New Jersey involving some fifty communities bordering on the Hackensack River and its tributaries; the collection and treatment of sewage and industrial wastes reaching Narragansett Bay from the city of Providence and neighboring municipalities, a study of which was made for the Metropolitan Sewerage Commission of Rhode Island; and the future water supply of the Minneapolis-St. Paul district, a report on which was completed just prior to his death.

Mr. Fuller's work was not entirely in the hydraulic and sanitary fields, however. He was an expert in the valuation of public utilities and in adjusting disputes on rates and charges by utilities supplying water and other services. During the World War he was a member of the Pittsburgh valuation board, appraising the street railways in that city. He had also been a member of the valuation committee handling street-railway adjustments in Philadelphia and was consulting expert for the International Railways Company, owner of the street-car system in Buffalo, N. Y., and its suburbs on both sides of the Niagara Valley.

In addition to his consulting work Mr. Fuller found time to write many papers in his field, and three books: "Water Purification at Louisville," published in 1898; "Sewage Disposal," 1912; and "Solving Sewage Problems," 1926, of which his partner, James R. McClintock, was co-author.

At the time of his death Mr. Fuller was chairman of the board of The Engineering Foundation. He was appointed a member of the board by the American Society of Civil Engineers in 1931, served as vice-chairman the following year, and was elected chairman in 1933. He was a past-president and director of the American Society of Civil Engineers and a past-president of the American Water Works Association and the American Public Health Association. He became a member of the A.S.M.E. in 1910 and belonged to many other professional and scientific societies, including the Institution of Civil Engineers, Verein Deutscher Ingenieure, Association Generale des Hygienistes et Techniciens Municipaux, of France, Engineering Institute of Canada, The Franklin Institute, American Chemical Society, American Institute of Consulting Engineers, and the American Society of Bacteriologists. He was chairman of the Committee on Promotion and Attendance for the World Engineering Congress at Tokio, Japan, in 1929.

Among Mr. Fuller's clubs were the Engineers' and Machinery, New York; University, Chicago; Cosmos, Washington; Seaview Golf, Absecon, N. J.; Everglades, Palm Beach; Canoe Brook Country, Summit, N. J.; and the Pleiades Club, New York, of which he was president at the time of his death.

He is survived by his widow, Eleanor Todd Fuller; three sons by previous marriages: Myron E., Kemp G., and Asa W. Fuller; and three step-sons, Kenneth B., Gordon B., and George B. Fuller; and a sister, Mrs. Carl W. DeVoe, of Jerome, Idaho.

THAYER PRESCOTT GATES (1879–1934)

Thayer Prescott Gates, manager of the Finishing Department of the Riverside and Dan River Cotton Mills in Danville, Va., died suddenly of angina pectoris on the evening of January 1, 1934, while in Richmond, Va.

Mr. Gates was born in Lowell, Mass., on May 14, 1879, the son of Prescott Coburn and Ellen (Kittridge) Gates. He prepared for college at Phillips Andover Academy and took a mechanical engineering course at the Massachusetts Institute of Technology. He was vice-president of his class there one year and a member of Sigma Chi fraternity.

Textile manufacturing had been Mr. Gate's work ever since he left the Institute. After some early experience under his father at the mill of Josiah Gates & Sons, in Lowell, he was employed on the construction of mills and layout and erection of machinery at the Lawrence, Mass., mills of the American Woolen Company in 1902–1903. During the next year he secured drafting-room and shop experience with the Jeffrey Manufacturing Company, Columbus, Ohio.

In February, 1904, Mr. Gates became master mechanic for the Wilkes-Barre (Pa.) Lace Manufacturing Company, where he remained for two years. He then took the position of foreman of the J. and W. Lyall Machine Works and master mechanic of the Brighton Mills at Passaic, N. J. In 1907 he became efficiency engineer for the Sayles Bleacheries at Saylesville, R. I., and continued with that mill and the Glenlyon Dye Works, reorganizing them along the lines of scientific management and handling all engineering problems in connection with construction, power supply, maintenance, and operation until 1917. The following year he was connected with Collins and Aikman, of Philadelphia, manufacturers of plushes.

In the fall of 1918 he opened an office in Providence, R. I., as a consulting engineer and textile specialist. He transferred his office to New York in 1930, and continued in practice until 1932, when he took the position he held at the time of his death.

Mr. Gates became a junior member of the A.S.M.E. in 1906 and a member in 1913, and was a Knight Templar in the masonic fraternity. He was a contributor to the textile press and had worked on an emulsifier for use in textile manufacture.

Surviving Mr. Gates are his widow, Cecile (Lovell) Gates, whom he married in 1904, and a daughter, Marjorie (Gates) Alley.

FREDERICK TAYLOR GAUSE (1866–1934)

Frederick Taylor Gause, for nearly forty years connected with the Standard Oil Company of New York, died in San Diego, Calif., on October 17, 1934.

Mr. Gause was born at Kennett Square, Chester County, Pa., on March 16, 1866, son of S. Irwin and Edith (Taylor) Gause. After leaving public school he served an apprenticeship with the Harlin & Hollingsworth Co., and secured drafting and shop experience with that company and at the Trenton Iron Works. He then entered Stevens Institute of Technology, from which he was graduated in 1891.

From the time of his graduation until his retirement in 1930, Mr. Gause was in the employ of the Standard Oil Company. The first few years were spent mainly on experiments to determine the merits of pure petroleum oil for lubricating reciprocating marine engines. In 1894 he was sent to the Far East to report on the possible demand for heavy petroleum products in the principal commercial centers there, particularly at the seven centers in India, China, and Japan where the company had opened offices the previous year to sell kerosene oil. As a result of his investigation the company added to these offices organizations to market heavy petroleum products, and Mr. Gause was assigned to supervise their establishment. Later he made similar trips to South America, South Africa, Australia, New Zealand, etc., establishing marketing branches at many points and otherwise assisting in the conduct of the Export Marketing Department of the company.

Mr. Gause became a member of the A.S.M.E. in 1893, belonged to the Engineers' Club, New York, and was a former member of the American Association for the Advancemnt of Science. He is survived by his widow, Gertrude (Grier) Gause.

FREDERICK AUGUST GEIER (1866–1934)

Frederick August Geier, president of the Cincinnati Milling Machine Company, Cincinnati, Ohio, died suddenly of a heart attack at his home in that city on March 27, 1934.

Mr. Geier was born in Cincinnati on June 23, 1866, the son of Philip and Sophia L. (Otten) Geier. He was graduated from the Woodward High School there in 1884, and for a time worked in a bank in Newton, Kansas. At the age of 21 he became associated with the Cincinnati Screw & Tap Co., which in 1889 became the Cincinnati Milling Machine Company. He served as manager of the company for a time, was made secretary and treasurer, and finally became president.

Within a few years after Mr. Geier's affiliation with the company, increased business necessitated the removal of the plant from Second and Plum Streets, where it had been established in 1884, to new quarters at Spring Grove Avenue and Alfred Street. By this time the company had entered the foreign trade field and exhibited a revolutionary milling machine at the Paris World Fair in 1900.

After 19 years at Spring Grove Avenue and Alfred Street, the company was housed in a plant at Oakley where Mr. Geier was a moving spirit in organizing a factory colony that did much to make the suburb one of the leading machine-tool centers of the world.

Mr. Geier was also president of the Factory Power Company, Factory Colony Company, Cincinnati Grinders Incorporated, Cincinnati Rubber Manufacturing Company, and Cincinnati Morris Plan Bank. He was a director of a number of other companies and institutions, including the Cincinnati Bickford Tool Company, Central Trust Company, Lincoln National Bank, and the Children's Home, all of Cincinnati. He was a leader in promoting vocational education in Cincinnati and aided in the establishment of the cooperative engineering system at the University of Cincinnati when he was a trustee and president of the board of the university. He also established a loan fund for cooperative engineering students. At the time of his death he was president of the Ohio Mechanics Institute.

From 1913 to 1915 Mr. Geier was chairman of the Council of Social Agencies for Cincinnati, from 1915 to 1917 chairman of the Central Budget Committee, and from 1917 until his death, a member of the Executive Committee of the Cincinnati Community Chest.

Other organizations in which Mr. Geier was actively interested included the Cincinnati Bureau of Governmental Research, the National Crime Commission, and the Ohio Valley Improvement Association.

Mr. Geier became an associate of the A.S.M.E. in 1900. He served as chairman of the Cincinnati Section in 1917 and was a manager of the Society from 1917 to 1920. He was interested in the standardize tion and research work of the Society and contributed to the support of the work of the Special Research Committee on Gears.

Mr. Geier was an early advocate of the eight-hour day and helped to organize the National Metal Trades Association. In 1910 and 1911 he was president of the National Machine Tool Builders' Association and in 1933 he helped to organize the Machinery and Allied Products Institute. He was also a member of the American Academy of Political and Social Science, American Institute of Banking, National Municipal League, National Society for Promotion of Industrial Education, Chamber of Commerce of the United States, Cincinnati Chamber of Commerce, and many other such organizations. His clubs included the Engineers, Commercial, Queen City, Camargo, and others in Cincinnati and vicinity.

Surviving Mr. Geier are his widow, Juliet (Esselborn) Geier, formerly of Portsmouth, Ohio, whom he married in 1904, and two sons and two daughters.

HAROLD LOTHROP GOODWIN (1897–1933)

Harold Lothrop Goodwin was born in Roxbury, Mass., on November 14, 1897, son of Homer and Mabel A. (Bates) Goodwin. He was graduated from the Roxbury Latin School in 1916 and received an S.B. degree in mechanical engineering from the Massachusetts Institute of Technology in 1921. Following his graduation he engaged in construction work in Boston with L. P. Soule, soon securing a position with Stone & Webster, Inc. In 1924 he was sent to Philadelphia, Pa., in connection with the construction of a building for the Insurance Company of North America, and in the following year worked on a power-plant building for the Savannah Light & Power Co., and on construction at Davis Islands, Tampa, Fla.

He returned to Boston in 1928 and was associated with L. P. Soule again in constructing an addition to the John Hancock Life Insurance Company building there. In 1930 he took a position in the Generating Office Department of the Edison Electric Illuminating Company of Boston, where he was employed at the time of his death on December 4, 1933.

Mr. Goodwin became a junior member of the A.S.M.E. in 1921. He is survived by his widow, the former Miss Martha L. Dewey, of Great Barrington, Mass., whom he married in 1925.

SAMUEL MARTIN GREEN (1864–1934)

Samuel Martin Green was born at Benton Harbor, Mich., on April 13, 1864, son of Martin Green, a civil engineer well-known for his connection with some of the greatest engineering projects in the United States. His mother was Mary Frances Stuart (Hathaway) Green.

Mr. Green was graduated from the course in mechanical engineering at Worcester Polytechnic Institute in 1885. Following his graduation he was draftsman for about a year with each of the following companies: F. E. Reed Company, Worcester, Mass., machine-tool manufacturers; the John T. Noye Manufacturing Co., Buffalo, N. Y.; the Deane Steam Pump Company, Holyoke, Mass.; and the Merrick Thread Company, Holyoke. He then became master mechanic of the last-named company, which permitted him to do outside consulting work. About 1898 the American Thread Company was formed and the Merrick Thread Company merged with it. He served as consulting engineer to the company until he organized his own business in the fall of 1908 at Springfield, Mass., under the firm name of Samuel M. Green Company.

Among the numerous companies which Mr. Green served as consulting engineer prior to the establishment of his own company were the Union Metallic Cartridge Company, Bridgeport, Conn., and the United States Envelope Company. For the latter company he designed and supervised the construction of a three-story factory building at Waukegan, Ill., and a five-story structure at Springfield in connection with which he designed and supervised the installation of a steam boiler and power plant and electrified the entire plant.

In connection with Mr. Green's work for the Union Metallic Cartridge Company, the following is taken from a memoir prepared by Harry B. Hopson, of Springfield, for the American Society of Civil Engineers, of which Mr. Green was also a member:

"In 1906, Mr. Green designed a steam boiler and turbine plant for the Union Metallic Cartridge Company. When this work was completed, the company requested him to make an examination of its primer loading plants after a disastrous explosion. He revised the method of loading primers entirely; built a new primer-loading plant; and devised an entirely new method of handling and mixing fulminate, which, to that time, had been an exceedingly dangerous operation. Since the revision of the method by Mr. Green the company has never had an explosion in its plant.

"About that time, the company had a disastrous explosion in its powder-storage farm where many tons of powder had been stored. Mr. Green was given the problem of designing a powder-storage farm that would be safe. He designed roads, bunkers, and small storage houses for powder, and supervised the installation of this equipment.

The Union Metallic Cartridge Company was the owner of the Remington Arms Company, at Ilion, N. Y. This latter company was not making a profit, and Mr. Green was given the commission of investigating the entire process of manufacturing arms. He spent two or three years at the Remington plant, designing new equipment and re-arranging machinery, until, finally, it was operating on a profitable basis."

Concerning Mr. Green's work after 1908, Mr. Hopson writes: "Among his more important clients was the Farr Alpaca Company, of Holyoke, which spent under his direct supervision and charge from $12,000,000 to $15,000,000.

"In 1911, he was given a commission by Max Henkels, who had come to the United States from Germany to engage in the lace-manufacturing business, at Bridgeport. Mr. Green designed and supervised the construction of a weave shed; a two-story and basement brick mill building; and in 1915, a three-story building of reinforced concrete. The design of this latter building was rather extraordinary because the posts had to be located so that Nottingham-lace looms could be installed in the building. The floors of the building were of the mushroom type of construction.

"In 1912 and 1913, Mr. Green designed and supervised the construction of a paper mill for the Strathmore Paper Company, at Woronoco, Mass., together with its power plant, filter plant, etc. For this same company, in 1923, he designed a reinforced-concrete bridge across the Westfield River, a span of approximately 400 ft, supported by three high arches.

"In 1915, he designed and supervised the construction of the plant of the Warner-Klipstein Chemical Company, at South Charleston, W. Va. This was a caustic-chlorine plant consisting of many buildings, including a power plant of about 2000-kw capacity, a plant for the production of carbon tetrachloride, carbon bi-sulphide, chlorine, and caustic soda.

"In 1918, Mr. Green was awarded the contract by the United States Government to design and supervise the construction of the large chlorine plant at the Edgewood (Md.) Arsenal. This chlorine plant was the largest of this character that had ever been built to that time. Its capacity was 100 tons of chlorine gas and caustic soda per 24 hr. Mr. Green's work consisted in designing all the buildings which were of brick and wood construction. This plant consisted of a building for chlorine cells; a salt-treating plant; a boiler plant, of approximately 2000 boiler-hp; an evaporator plant for salt caustic evaporation, containing eight double-effect evaporators; and a caustic fusion plant. He designed all the machinery and supervised its installation, and was under contract with the Government to supervise the installation of all the equipment and the starting of its operation. This plant was successfully constructed, and operation was started before the end of the World War, or in approximately six months.

"In 1926, Mr. Green designed a new boiler plant for the Fitchburg Paper Company, of Fitchburg, Mass. This work consisted of a complete revision of an old boiler-house and the installation of one 1000-hp, 250-lb pressure boiler, with complete pulverized-coal equipment, superheaters, and piping system. In connection with this work he also designed a high-pressure steam line, with all the supports, about 1200 ft long, running from this boiler plant to one of the other mills over a bridge, about 100 ft long, also designed by Mr. Green. This work was entirely under his supervision; he let all the contracts and supervised the completion of the work.

"In 1927, he designed a new boiler installation for Joseph Bancroft and Sons Company, at Wilmington, Del. This work consisted in the removal of two old boilers and the installation of one 1000-hp, 250-lb pressure boiler, together with all its auxiliary equipment, stokers, etc., and a revision of the boiler-house for this installation.

"During 1927 and 1928, Mr. Green also engineered and supervised the construction of the Integrity Trust Building in Philadelphia, Pa."

Mr. Green had been a member of the A.S.M.E. since 1890, and in addition to his membership in the A.S.C.E., belonged to the Engineering Institute of Canada, Engineering Society of Western Massachusetts, and the American Geographical Society. He was a member of the Chamber of Commerce and Taxpayers' Association of Springfield, and president of the latter at the time of his death. He also belonged to the Constitutional Liberty League of Massachusetts, National Economy League, and Navy League of the United States. He was a member of all the branches of the York Rite and of the Scottish Rite of the masonic fraternity, being a Knight Templar, a Thirty-second Degree Mason, and a member of the Shrine.

Mr. Green's death occurred at Springfield on March 22, 1934. He is survived by his widow, formerly Miss Ida McKown, of Holyoke, and by their two married daughters, Mrs. Mildred (Green) Page, of Longmeadow, Mass., and Mrs. Lydia (Green) Meadows, of New York, N. Y.

JOSEPH RUDD GREENWOOD (1883–1934)

Joseph Rudd Greenwood, who retired in 1930 as president and treasurer of the New York Vitreous Enamel Products Corporation, Flushing, L. I., N. Y., died in New York on March 2, 1934.

Mr. Greenwood was born in New York on May 27, 1883, the son of Isaac J. and Mary A. (Rudd) Greenwood. He attended the Collegiate and Halsey schools in New York and the Hill School at Pottstown, Pa., and was graduated as a civil engineer from Princeton University in 1905. After serving as an instructor in civil engineering at Princeton in 1905–1906, he took a position as assistant engineer with The Ballwood Company in New York, manufacturers of single- and four-valve engines, high- and low-pressure and mixed-flow turbines, and high-pressure pipe joints and bends. He was made superintendent of the pipe shop in 1908, superintendent of construction in the field in 1910, general superintendent in 1911, and general manager in 1914.

In 1916 Mr. Greenwood left The Ballwood Company to be mechanical engineer in the office of Charles H. Higgins, but the following year entered the World War as a driver and section leader in the American Ambulance Field Service in France. He rose to the rank of captain in the service.

After the close of the War he returned to the employment of Mr. Higgins, with whom he remained for several years before becoming connected with the New York Vitreous Enamel Products Corporation.

Mr. Greenwood became a member of the A.S.M.E. in 1920, and belonged to the Sons of the Revolution, and the University and Princeton clubs. He is survived by his widow, Ruth M. (Dayton) Greenwood, whom he married in 1919.

ELWOOD GRISSINGER (1869–1934)

Elwood Grissinger, of Buffalo, N. Y., whose death occurred on October 8, 1934, was born at Mechanicsburg, Pa., on March 3, 1869. After completing his high school course there he studied telegraphy in the ticket office of the Cumberland Valley Railroad at Mechanicsburg. At the age of 17 he secured an appointment as a telegraph operator on the Norfolk & Western R.R. Subsequently he studied stenography at Chaffee Institute, Oswego, N. Y., and worked in the general passenger office of the New York, Ontario & Western R.R. and for the Pennsylvania Railroad, at Harrisburg, Pa.

In 1890 Mr. Grissinger entered Lehigh University, from which he was graduated four years later with a degree in electrical engineering. His scholastic standing was such that he was appointed orator for Founder's Day and commencement. He was elected to membership in Tau Beta Pi, honorary engineering fraternity, as well as in Delta Upsilon. In 1916 the university conferred an honorary M.S. degree upon him.

After his graduation from Lehigh University Mr. Grissinger worked for two years in the shops of the Westinghouse Electric & Manufacturing Co., and for three years was district engineer and salesman for the company at Syracuse and Buffalo. From 1899 to 1906 he was commercial engineer for the Buffalo General Electric Company and the Cataract Power & Conduit Co. The following year he was general agent for the Niagara Falls Power Company and the Canadian Niagara Power Company.

Since 1906 Mr. Grissinger had engaged in consulting engineering in the mechanical and electrical fields, and in research work. He patented a complete system of long-distance telephony, including telephonic speech amplifiers and the only known operable method of associating them with the speech transmission circuits. This system has been adopted for use on transcontinental lines and all classes of long-distance circuits, the United States patents having been purchased by the American Telephone & Telegraph Co., and was used in Europe by the United States Army and its Allies during the World War. He also patented a method of sound amplification as exemplified by phonograph horns.

Mr. Grissinger became a member of the A.S.M.E. in 1912. He was a Fellow of the American Institute of Electrical Engineers and a member of The Franklin Institute. He had contributed special articles on electric railroading to the journals of the Brotherhood of Locomotive Engineers and Firemen.

Mr. Grissinger married Lucy Martin Ash, of Oil City, Pa., in 1897, and is survived by her and a son, Elwood.

CONRAD VELDER HAHN (1890–1933)

Conrad Velder Hahn, associate professor of mechanical engineering at Drexel Institute, Philadelphia, Pa., and head of the mechanical engineering department of the Drexel Evening Diploma School, died on December 3, 1933, at the Temple University Hospital.

Dr. Hahn was born in Philadelphia on May 9, 1890, the son of John G. and Elizabeth (Velder) Hahn. He attended the Central Manual Training High School in Philadelphia and was graduated from the University of Pennsylvania with a B.S. degree in engineering in 1908. An M.E. degree was conferred upon him by the same university four years later and San Jose University gave him the degrees of Doctor of Engineering and Doctor of Philosophy.

Dr. Hahn was a member of the faculty of the civil engineering department of Temple University Evening School from 1910 to 1912 and of the mechanical engineering department of the University of Pennsylvania during the next two years. He had been connected with Drexel Institute since 1919, when he became director of the mechanical engineering department of the evening school.

He had also carried on a consulting practice since 1910 as managing director of the Hahn Company, Philadelphia. He was also a director and associate engineer of the International Development Company, Washington, D. C., consulting mechanical engineer for the Turbo Motor Company, East Radford, Va., and a member of N. T. Whitaker & Co., Washington.

During the World War he served in the Ordnance Department, as first lieutenant and captain, and received special mention for technical service at the Army Ordnance Base Depot, France, and the Aberdeen Proving Ground, Scotland. He held the rank of major in the Ordnance Reserve Corps.

Dr. Hahn became a junior member of the A.S.M.E. in 1915. He also belonged to The Franklin Institute, National Philosophical Society, masonic fraternity, and a number of fraternal orders and clubs, including the honorary engineering fraternities, Sigma Xi, Tau Beta Pi, and Pi Tau Sigma.

He is survived by his widow, Lillian (Roth) Hahn, and by his mother, a brother, and a sister.

THEODORE COMMODORE HAILES, JR. (1883–1934)

Theodore Commodore Hailes, Jr., field engineer for the New York State Temporary Emergency Relief Administration, Binghamton, Division Office, died in that city on October 29, 1934.

Mr. Hailes was born in Albany, N. Y., on September 15, 1883, the son of Theodore Commodore and Elizabeth (Brooks) Hailes. After his graduation from the Albany High School he entered Rensselaer Polytechnic Institute, from which he received a C.E. degree in 1907. He took part in practically all extra-curricula activities while at the Institute and was one of the founders of the Rensselaer Technical Society, which later became Pi Kappa Phi fraternity.

From the time of his graduation until the United States entered the World War, Mr. Hailes engaged in the general practice of engineering and contracting, with an office in Albany. His work included examinations and reports on a number of hydroelectric-development projects; the design and installation of signal equipment on the Erie Canal; construction of several telephone lines; destruction by dynamite of ice gorges in the Hudson River several years; supervision of construction of state highways, and quarrying and crushing of stone for them; and investigation and reports as expert witness in many cases involving engineering.

In 1917 he accepted a position as superintendent of the Neemes Brothers Iron Foundry, at Troy, N. Y., which was engaged in war work. He continued with that company for several years after the close of the war, then became manager for the Tool & Device Corp., of Troy. More recently he had been secretary and treasurer of the Engineering Service Corporation, Albany.

Mr. Hailes became a member of the A.S.M.E. in 1922 and was a 32d degree Mason. He is survived by his widow, Charlotte S. (Welch) Hailes, whom he married in 1909, two sons, Theodore C. Hailes, 3d, and Gardner M. Hailes, and three sisters.

FRANCIS EDWARD HALLORAN (1882–1932)

Francis Edward Halloran was born on June 5, 1882, in Brooklyn, N. Y., the son of Patrick and Anne (Burke) Halloran. He was graduated in 1900 from the Boys High School in Brooklyn and later continued his studies through the International Correspondence Schools.

The greater part of Mr. Halloran's engineering work was for the E. W. Bliss Co., Brooklyn. He was associated with this company from early in 1902 until after the close of the World War with the exception of about a year during which he worked for C. J. Regan, Maspeth, L. I., designing dies for sheet-metal ware and attachments for spinning lathes. His first assignments for the Bliss company were in the general drafting room. He was then transferred, upon his request, to the drafting room of the die department. After the year at Maspeth he began his most important work for the company, in connection with torpedoes. In the capacity of mechanical draftsman in the torpedo drafting room at the main works of the company he worked from 1906 to 1910 laying out the mechanisms in the Bliss-Leavitt torpedo; helping to develop the outside superheater system; experimenting with gyroscopic steering, hydrostatic depth regulating, and reducing-valve gears; redesigning dynamometers; and developing new tools and fixtures for the manufacture of torpedo parts. He was made chief draftsman in 1910 and during the next three years was engaged in the design and construction of an "angle-fire" gyroscope, depth mechanism, steering engines, launching tubes, and high-pressure air accumulators for the company's proving steamer *Emblane*.

In 1913 the torpedo department was relocated at the 53d Street works of the company and for about ten years longer Mr. Halloran devoted himself to supervising all the experimental and research work incident to further increasing the speeds, range, and reliability of torpedoes.

After leaving the Bliss company Mr. Halloran was mechanical designer first at the Edison Lamp Works of the General Electric Company at Harrison, N. J., and then with the Trans-Lux Daylight Picture Screen Corporation, Brooklyn. He helped to perfect the machinery for manufacturing frosted bulbs, in the former position, and in the latter worked on the Trans-Lux stock quotation projection machine and motion picture projection. Poor health forced his retirement from the Trans-Lux company, and his death from heart disease occurred on March 20, 1932, at the home of his sister, Mrs. M. Gertrude Quinn, Corona, L. I., N. Y.

Mr. Halloran became a member of the A.S.M.E. in 1920.

JOHN HANKIN (1865–1933)

John Hankin, for nearly forty years president of John Hankin & Brother, consulting engineers, New York, N. Y., died at his home in Passaic, N. J., on November 30, 1933.

Mr. Hankin was born on September 21, 1865, in Farnworth, Lancashire, England, the son of William and Susannah Hankin. He came to the United States with his parents in 1874 and secured his early education in the public schools in Rome and Watertown, N. Y. Subsequently he attended the Brooklyn Evening High School for one year and took mechanical and scientific courses at Cooper Institute.

Mr. Hankin's first employment was in Watertown, N. Y., in the shops of the Davis Sewing Machine Company, in 1880. He then served a four-year apprenticeship at the Steam Engineering Works there, after which he was employed as a journeyman machinist at the works and by the Eames Vacuum Brake Company, Watertown, the James Brady Manufacturing Company, Brooklyn, and Arnoux & Hochausen Electric Co., New York. For two years, beginning in March, 1888, he was draftsman for the Buffalo Forge Company, and for the next three years engaged in sales engineering for the Akron Heating & Ventilating Co., Akron, Ohio, and Cook & Co. and Jas. Beggs & Co., New York.

From August, 1893, to a year from that time Mr. Hankin was a partner in the Armstrong Engineering Company, New York. He then went into the general engineering business for himself. The firm of John Hankin & Brother was established in 1900.

Mr. Hankin became a member of the A.S.M.E. in 1913 and belonged to the National Association of Heating and Piping Contractors, American Society of Professional Engineers, American Institute of the City of New York, and Building Trades Employers' Association of New York. He was also a member of the masonic fraternity, the Blizzard Men of 1888 Club, and the Transportation Club, New York.

Surviving Mr. Hankin are his daughter, Mrs. E. Hans Jacob, of New York; a brother, Dr. Walter Hankin, of Bisbee, Ariz.; a stepson, Dr. John Townsend, of Passaic, a son of his deceased wife, the former Mrs. Ida Dieter Townsend, of Buffalo; and two grandsons, Robert Earl and John Edward Jacob.

JAMES HARTNESS (1861–1934)

The American Society of Mechanical Engineers lost one of its most honored members, and the profession one of its most distinguished engineers, in the death of Ex-Governor James Hartness, of Springfield, Vermont, after a long illness, on February 2, 1934. His loss will be deeply felt by all who have ever known him.

James Hartness was born in Schenectady, N. Y., on September 3, 1861. His father, John W. Hartness, a man of dry, salty humor and keen understanding of human nature, moved to Cleveland in 1863, where he was a foreman in various machine shops. James Hartness was educated in the Cleveland public schools and began learning his trade at sixteen, at a wage of 45 cents a day, first with Younglove, Massey, and Company, of Cleveland, where his father was superintendent, and then in the machine shop of the Union Steel Works. In the latter shop he first came into contact with close, accurate work

under Jason A. Bidwell, one of the fine New England mechanics of the older generation. Later, Mr. Hartness went to the Lake Erie Iron Works as a toolmaker. In 1882 he secured a position, through correspondence, as foreman of the Thomson, Stacker Bolt Company in Winsted, Conn. When he reached there the superintendent exploded at the youth of the man whom he had hired. Hartness waited until the storm was over and then offered to release the firm from its contract but to stay until his successor was installed. He remained three years. In 1885 he went to the Union Hardware Company, of Torrington, Conn., manufacturers of gun implements, first as toolmaker, then foreman, and later as inventor. During the year 1888 he worked for a few months each at the Pratt & Whitney Company in Hartford, at Scottdale, Pa., and with the Eaton, Cole, and Burnham Company in Bridgeport.

Connection With Jones & Lamson Machine Company Established in 1889

He went to the Jones & Lamson Machine Company in March, 1889, the year in which the company moved from Windsor to its present location at Springfield, Vermont. He was at first superintendent until 1893, then manager until 1900, and president from then until his retirement last year. Mr. Hartness' going to the Jones & Lamson Machine Company added another to the list of great mechanics who made the history of this company, or rather the succession of companies of which it is a part. It began about 1838 at Windsor, Vermont, as the Robbins and Lawrence Company, and through the middle of the century, under Richard S. Lawrence, Frederick W. Howe, and Henry D. Stone, this small shop made engineering history. The ever-widening influence of their work is felt to this day. Here was developed and first manufactured the hand-operated turret lathe, the beginnings of the milling machine later known as the Lincoln miller, drop hammers, and many tools adapted to arms manufacture and other types of accurate work. Through various changes the firm became Lamson, Goodnow, and Yale, E. G. Lamson and Company, the Windsor Manufacturing Company, and in 1879 the Jones & Lamson Machine Company. Mr. Hartness brought with him the fundamental ideas of the Hartness flat turret lathe which he had had in his mind for a number of years. He undertook, as superintendent, to develop and manufacture this machine, and in so doing opened up a new period in the history of the company. Like other shops of the time, the successive companies at Windsor had scattered their energies over a wide line. An old "poster" of the Windsor Manufacturing Company shows them offering engine lathes, turret lathes, planers, saw-mill and quarrying machinery, engines and boilers, trip-hammers, sewing machines, rifles, "etc., etc." Things had improved somewhat in this respect, but with the removal of the company to Springfield and the coming of Mr. Hartness there was a radical change. He concentrated its activities on a single size of the flat turret lathe, and the tools for it, dispensed with agents and sold direct, and instituted a new type of sales literature. Under his leadership the company rapidly acquired a world-wide recognition. This is all the more remarkable for its being located in a small town in a Vermont valley six miles off a minor railway, a location, by the way, which he always defended and said he would in no wise change.

Services to A.S.M.E. and the Public

Mr. Hartness joined The American Society of Mechanical Engineers in 1891. He was a manager from 1909 to 1912, and vice-president in 1912 and 1931. On the German trip of the Society in 1913, President Goss was unable to go and Mr. Hartness, as senior vice-president, acted as head of the party on all the formal occasions. He did this so acceptably to all that he was elected president of the Society in the following year, 1914. He was president of the American Engineering Council from 1924 to 1926, and as a past-president, served as a member of its Assembly for the six years following his presidential term. He therefore held the highest elective positions in the gift of his profession.

In 1912 he was appointed a member of the A.S.M.E. Special Committee on Tolerances in Screw-Thread Fits, and he served for many years on this and other committees on screw-thread standardization.

His public services were as distinguished as those for the engineering profession. He served his state as chairman of the State Board of Education for six years (1914–1920), was chairman of the Committee of Public Safety during the War, and also Federal Food Administrator, and, in 1921 to 1923, served as the sixty-first governor of Vermont. In national affairs he was a member of the commission which represented the United States at the Inter-Allied Air Craft Standardization Conferences in London and Paris; and was vice-chairman of the Congressional Screw-Thread Standardization Committee from 1918 to 1920.

He was a member of the Society of Automotive Engineers, the Aero Club of America, the American Astronomical Society, a Fellow of the American Association for the Advancement of Science, the Royal Astronomical Society, the Royal Society for Encouragement of Arts, the Royal Societies Club of London, and the Institution of Mechanical Engineers in London. In 1921 he was awarded the John Scott Medal by the Board of Directors of the City Trusts of Philadelphia, and the Edward Longstreth Medal by The Franklin Institute of Philadelphia.

He is the author of a number of papers before the A.S.M.E., including his presidential address on "The Human Element, The Key to Economic Problems." He also wrote two books, "The Human Factor in Works Management" which was widely distributed, and translated abroad, and "Machine Building for Profit."

He was given the honorary degree of M.E. by the University of Vermont in 1910, honorary M.A. by Yale University in 1914, and LL.D. by the University of Vermont in 1921.

In 1885 he married Lena Sanford Pond, of Winsted, Conn., who died in March, 1933. He is survived by two daughters, Anna Jackson, who married Dr. William H. Beardsley, and Helen Edith, who married Mr. Ralph E. Flanders.

Mr. Hartness a Prolific Inventor

Mr. Hartness was a prolific inventor and he held patents in this country and abroad for more than 100 inventions. Among these was the flat turret lathe which he began developing from the time of his first coming to Springfield. In the old type of high turret lathes, developed originally by the Robbins and Lawrence Company, the turret revolved about a large vertical pin and all subsequent development had followed that design. Mr. Hartness felt that a stiffer and more accurate construction was possible and investigated the disk turret, the barrel turret, and the flat turret. He settled finally upon the flat turret which appealed to him as offering all the advantages of the old type with possibilities of greater stiffness and precision. It was low, could be clamped at points far apart, and permitted the location of the locking pin directly under the cutting tool. Following out this general design, he developed a lathe which has found wide use here and abroad for the large output of accurate work. Among the improvements were the cross-sliding head in 1903, the double-spindle type in 1910, and the Hartness automatic lathe.

The Lo-Swing and Fay automatic lathes are two more machines invented by him, or greatly influenced by his work. In connection with lathes, he developed many special tools to be used in connection with them, and among these were the well-known Hartness threading dies, which became an important element in the company's business. Associated with these was the Hartness thread comparator, a refined method for the gaging of screw threads by optical means, which not only tells whether the threads are off standard, but precisely wherein they depart from it. He also invented the Hartometer, another type of gage for screw-thread inspection.

His Interest in Astronomy

Mr. Hartness' avocations were as interesting as his vocation. He spent four summers on a yacht following down the coast as far as Chesapeake Bay. In 1916 he learned to fly and won an amateur pilot's license. His interest in aviation continued throughout his whole life and he was largely influential in establishing a landing field at Springfield as a memorial to the soldiers and sailors of the World War. It was at this field that Lindbergh landed for his stop in Vermont during the tour of the country after his Paris flight.

For years astronomy claimed his attention. After suffering from a cold acquired in using the old-fashioned type of telescope, he devised the turret equatorial telescope, which was an adaptation of the fundamental idea of the flat turret lathe, wherein a large ring was substituted for one of the axes in the usual equatorial type. This permitted the observer to work inside, under warm and comfortable conditions at all times. One of the happy incidents of the A.S.M.E. trip in 1913 was to run into a model of this type of telescope in the astronomical section of the Deutsches Museum at Munich. This invention was the subject of a valuable paper before the Society at its Annual Meeting in 1911, and gained for him membership in both English and American astronomical societies. It was mounted over an underground room, one of a long series, running under the lawn in front of his home, connected by a heated and air-conditioned tunnel, and containing workrooms, library, and lounging room. Here he did much of his later work, and it formed a unique feature of the home whose charming hospitality will long be remembered.

His interest in astronomy aroused many others, so that there is probably no community of size similar to Springfield where there is such widespread interest in astronomy and in the building of amateur telescopes.

His Influence on Other Men

An outstanding characteristic of Mr. Hartness' life was his influence on and encouragement of young men. A number of impor-

tant machines have been developed by men connected with his company and are now being manufactured by other firms. He discovered and helped in various ways many men now well known in the engineering profession, among whom are George O. Gridley, inventor of the Gridley automatic, and vice-president of the New Britain-Gridley Machine Company; Edwin R. Fellows, inventor of the gear shaper, and president of the Fellows Gear Shaper Company; the late William L. Bryant, who was president of the Bryant Chucking Grinder Company; Frederick P. Lovejoy, president of the Lovejoy Tool Company; and Ralph E. Flanders, who succeeded Mr. Hartness as president of the Jones & Lamson Machine Company. Mr. Hartness' concentration on his own machines was so great that he would not be diverted in his own work by the inventions and ideas of these younger men, but as they brought their ideas to him he freely gave them help and encouragement and was a factor in their success.

Though Springfield is a small country town, there has grown up there a large group of important tool-building plants, largely through his influence.

Governor Hartness was one of the foremost mechanical engineers of this country and generation, and a splendid example of the engineer in public life. The Society holds him in affection and honor as an engineer and as a citizen.—J. W. Roe.[1]

WILLIAM JOSEPH HENNESSY (1873–1934)

William Joseph Hennessy, a veteran of the Spanish-American War, died in Washington, D. C., on November 26, 1934, and was buried in Arlington Cemetery with military honors. When war was declared with Spain Mr. Hennessy was employed by the American Line Steamship Company on the *St. Paul*, which was taken over by the Navy Department and placed under the command of Captain Charles D. Sigsbee, who had commanded the battleship *Maine*. Mr. Hennessy enlisted as a chief machinist and served on the *St. Paul* until the close of the war.

He was born at Jersey City, N. J., on September 27, 1873, son of Michael J. and Ellen T. (Clancy) Hennessy. His father was chief engineer in the United States Navy. After he had completed his high-school course in Jersey City he became an apprentice machinist with the William Cramp & Sons Ship & Engine Building Co. and during his apprenticeship also took evening courses in mechanical engineering at The Franklin Institute, and correspondence courses in marine engineering through the International Correspondence School.

He entered the employ of the American Line in 1895, and with the exception of his six months in the Spanish-American War, was connected with the company for five years, serving from junior to second engineer on vessels between the United States and England. In 1901 and 1902 he was a machinist in the Construction and Repair Department at the United States Navy Yard, New York, engaged for the most part in experimental work. During the next two years he was first assistant engineer for the Mallory Steamship Company, on boats running between New York and Georgia, Florida, and Texas cities.

He returned to Government service in November, 1905, as chief engineer in the United States Coast and Geodetic Survey. During about eight of the twelve years he spent in this service he was connected with important surveying expeditions in the Philippines, Alaska, and the West Indies, as well as work on the Atlantic Coast. Four years were spent in shore duty in the office of the Survey at Washington, and in different parts of the United States. One of his assignments was the inspection of the steam yacht *Isis* in 1915, which was taken over by the Navy upon his recommendation. He designed, wrote the specifications,and supervised the construction of the boilers, engines, and auxiliaries of the steamer *Surveyor*, built in 1917 for the Survey at the works of the Manitowoc Ship Building Company in Wisconsin, and served as chief engineer on its maiden trip to Washington and Norfolk.

During the World War Mr. Hennessy was inspector of engines and boilers for the Emergency Fleet Corporation of the United States Shipping Board, in connection with work being done in the Central States area.

Subsequently he was superintendent, for a time, of marine engine construction for the Dodge Manufacturing Company, in Indiana, and more recently had served as chief engineer in charge of the plants at Woodstock College, Gonzaga College, and St. Aloysius Church, Washington. He was in poor health the last few years of his life.

Mr. Hennessy received medals from the United States Navy and Shipping Board, and from the State of New Jersey for his war service.

Mr. Hennessy was not married. He is survived by a brother, the Reverend Charles J. Hennessy, of Woodstock, Md., and by two sisters, Miss Ella Hennessy and Mrs. Lydia Bahlman, both of Washington. He became an associate-member of the A.S.M.E. in 1918.

[1] Professor of Industrial Engineering, New York University, New York, N. Y., and author of "English and American Tool Builders," McGraw-Hill Book Co., 1926. Mem. A.S.M.E.

WILLIAM THOMAS HENRY (1845–1933)

William Thomas Henry, of Fall River, Mass., died in that city on July 22, 1933. He was born there on February 27, 1845, son of James and Martha (Whitaker) Henry, and received his early education in local schools. He took courses in civil and mechanical engineering with the class of 1870 at the Massachusetts Institute of Technology. He then entered the employ of Josiah Brown, civil engineer, Fall River, and upon his death five years later took over the business, which he continued until his retirement from business. He was connected with the design and construction and engineering problems of many of the textile mills in that part of the country and the inventor of a belt-driving mechanism patented in 1910.

Mr. Henry became a member of the A.S.M.E. in 1887 and belonged to the American Historical Society in Fall River and the Methodist Episcopal church there. His first wife, S. Louise Hadcock, whom he married in 1884, died nine years later. He is survived by his widow, Carrie S. Henry, whom he married in 1898.

FREDERICK WILLIAM HESPE (1889–1934)

Frederick William Hespe, whose death occurred on April 16, 1934, was born in Jersey City, N. J., on July 27, 1889. He attended the Stevens School and Stevens Institute of Technology, Hoboken, N. J. His first position was with the Public Service Corporation of New Jersey, Newark, where he worked on machine design and in the claims department from 1911 to 1918. The next year was spent as chief inspector of metal parts for the Standard Aircraft Corporation, Elizabeth, N. J. In 1919–1920 he was machine designer for the American Sawmill Machinery Company, Hackettstown, N. J., and from 1920 to 1923 held a similar position at the Picatinny Arsenal, Dover, N. J. He became co-partner of the Wharton (N. J.) Foundry in 1923 and owner in 1926, and engaged in the manufacture of gray iron castings until 1928. He then went to the Fokker Aircraft Corporation of America, Passaic, N. J., where he worked first as machine designer and subsequently as supervisor of the shop of the research department. More recently he had been supervisor of research at the General Aviation Manufacturing Corporation, Passiac.

Mr. Hespe became a member of the A.S.M.E. in 1931. He is survived by his widow, Rita Hespe.

FRANK JOSEPH HESS (1896–1934)

Frank Joseph Hess, instructor at Brooklyn (N. Y.) Technical High School from 1926 until the time of his death on December 26, 1934, was born in Buffalo, N. Y., on August 17, 1896. His parents were Frank William and Mary H. (Schroeder) Hess. He secured his early education in the schools of Clifton, N. J., then attended the Stevens Institute of Technology for two years. He secured a B.S. degree from New York University in 1920 and his M.E. degree two years later. Columbia University conferred a posthumous M.A. degree upon him in February, 1935.

Mr. Hess was an assistant superintendent with the Tidewater Oil Company in Bayonne, N. J., from 1920 to 1924. He was an engineer at Columbia University between then and the time he joined the faculty of the Brooklyn Technical High School.

Mr. Hess became a junior member of the A.S.M.E. in 1921 and also belonged to the masonic fraternity. He was an ensign in the United States Naval Reserve in 1918 and a sergeant in field artillery in the United States National Guards, in New York, from 1926 to 1930. He is survived by his widow, Edna M. (Flewelling) Hess, whom he married in 1924.

EDWARD MARRIOTT HEWLETT (1866–1934)

Edward Marriott Hewlett, an electrical engineer and inventor for many years associated with the General Electric Company and known for his connection with important engineering projects, died at his home in Schenectady, N. Y., on May 24, 1934, of a cerebral hemorrhage.

Mr. Hewlett was born at Cold Spring Harbor, L. I., N. Y., on September 14, 1866, a son of Edward T. and Eliza (Marriott) Hewlett. He was educated in private schools and by private study in civil and mechanical engineering and physics. From 1884 to 1890 he was general manager and civil engineer of the Cascade Town Improvement Company, Cascade, Colo. In 1888 he surveyed and laid out the first road to the top of Pike's Peak.

Mr. Hewlett took up electrical engineering in April, 1890, when he

went to work for the Thomson-Houston Electric Company, at Lynn, Mass., where he assembled, tested, and repaired electrical machinery. After about a year there he was sent to South River, N. J., where he worked until March, 1892, on the design and construction of embroidery machinery. He was then transferred to the New York office of the Thomson-Houston company and assisted in the installation of a focusing lamp and strings of incandescent lamps on the Statute of Liberty for the Columbian Exposition. After this work was completed he returned to Lynn, where he assisted in designing electrical switchboards for railways.

In 1894 Mr. Hewlett went to Schenectady as assistant design engineer for the General Electric Company, which had taken over the Lynn plant. Two years later he was advanced to the position of design engineer in the railway department, and when the switchgear department was organized in 1898 he was appointed its head. He was active in the work of this department until 1927, when he became consulting engineer for it. He retired from service in 1931.

Mr. Hewlett designed switchboards for the control of the locks of the Panama Canal and for the Metropolitan Street Railway Company, New York Edison Company, Manhattan Elevated Railway, Interborough Rapid Transit Company, and Grand Central Terminal, all in New York. He also handled the electric lighting of Tiffany's store in New York and designed special electrical effects for outdoor displays.

Between 1905 and 1907 Mr. Hewlett, in association with H. B. Buck, then engineer of the Niagara Falls Power Company, evolved the Hewlett suspension insulator, which made possible the transmission of voltages between 100,000 and 220,000 and higher, as against about 60,000 volts which could be sent with the earlier pin-type insulator. In 1906 he received a silver medal at the St. Louis Exposition for the development of the oil switch, from which sprang the entire modern line of oil circuit breakers, operating at high interrupting frequencies. He also originated the electrical relay, an indispensable factor in electrical control systems. He received the Coffin Award of the General Electric Company for special marine apparatus. He proposed and designed the modern fire-control system of the United States Navy, and during the World War was chief engineer of the Navy Experimental Station at New London, Conn. Altogether, Mr. Hewlett held about 160 patents for his inventions.

Mr. Hewlett became a junior member of the A.S.M.E. in 1897 and a member three years later. He was a Fellow of the American Institute of Electrical Engineers, and belonged to the masonic fraternity as well as to a number of clubs in New York and Schenectady, including the Engineers' in New York and the Mohawk and Electrical in Schenectady.

Surviving Mr. Hewlett are his widow, Mrs. Susan (Mauger) Hewlett, who resides with her son, John Mauger Hewlett, of Teaneck, N. J.; and two other sons, Edward P. Hewlett, of Schenectady, and Paul Marriott Hewlett, of Albany, N. Y.

LOUIS JOSEPH HIRT (1854–1933)

Louis Joseph Hirt, retired consulting engineer, New York, N. Y., died in that city on September 20, 1933. He was born in Paris, France, on September 26, 1854, and was educated in that country. He served as an apprentice in the shop of his father, Joseph Hirt, for two years and secured further experience in the marine shop of Esher Wyss & Co., Zurich, Switzerland, and with the Northern Railroad of France. He went to London in 1876 and was employed successively by Leger & Co., manufacturers of mathematical and optical instruments, and by J. Moore as general workman on watchmaker's tools. In 1878 and 1879 he was foreman, first at the Keystone Valve Company in Wolverhampton, England, and then at the steam-pump works of J. Evans & Son there.

Mr. Hirt came to the United States in July, 1880, and until the fall of 1882 was employed as foreman at the machine shop of Hanan & Lewes, New York. From then until 1885 he was superintendent of the machine shop of Merrill Bros., Brooklyn. He went to Rochester, N. Y., in 1885 and for two years was master mechanic of the Standard Nail Company there. During the next year he was chief draftsman at the Walker Manufacturing Company, Cleveland, Ohio, and from 1888 to 1890 traveling engineer for the Hill Clutch Works of that city.

From 1890 to 1896 Mr. Hirt was connected with the West End Street Railway, Boston, Mass., as master mechanic and chief engineer. He then returned to New York, taking the position of mechanical engineer for the New York Cable Railroad (later known as the Metropolitan). After two years with that company he became chief engineer for the New England Gas & Coke Co., Everett, Mass.

In 1900 Mr. Hirt took a position as mechanical engineer for the Pearson Engineering Corporation, New York, later becoming its vice-president and continuing in that capacity until 1920. In 1906 he took up consulting work for the Toronto Power Company, Toronto, Canada, and the Winnipeg Electric & Manitoba Power Companies, Winnipeg, Canada, which he served until 1926. In 1910 he also became consulting engineer for the Brazilian Traction, Light & Power Co., Ltd., Mexican Light & Power Co., Ltd., and Barcelona Traction, Light & Power Co., Ltd., the head offices of all of which were located in Toronto. His service to these companies continued until his retirement in 1925, and he therefore played an important part in the inception and development of their hydroelectric properties. On the occasion of the golden wedding anniversary of Mr. and Mrs. Hirt in 1925 they were presented with a gold bowl from these three companies, the inscription on which included a tribute to the skill and technical ability of Mr. Hirt.

Mr. Hirt held many patents in the street-railway field and on gas engines. He had been a member of the A.S.M.E. since 1894, and had belonged to the New York Athletic Club and Lawyers Club prior to his retirement. He is survived by a son, Edward L. Hirt, of Toronto, and by two daughters, Mrs. Sidonia (Hirt) Jackson, of South Orange, N. J., and Mrs. Florence (Hirt) Ellis, of Longmeadow, Mass. His wife, Alice M. (Flammand) Hirt, whom he married in 1875, died in 1934.

PLINY EASTMAN HOLT (1872–1934)

Pliny Eastman Holt, director of the Caterpillar Tractor Company, San Leandro, Calif., died of heart disease at his home in Stockton, Calif., on November 18, 1934. He will be remembered not only for his inventions and improvements in tractors, harvesters, and other farm equipment, and for his service to the city of Stockton as chairman of its Port Commission; but more widely for his developments in the field of ordnance.

In this field Mr. Holt's achievements were threefold. During 1917 he assisted the Ordnance Department of the United States Army in the development of $2^1/_2$-, 5-, and 10-ton artillery tractors, at the Peoria, Ill., plant of the Caterpillar Tractor Company. He was appointed chairman of the Motor Artillery Board and during the remainder of the War was located in Washington, declining a commission and serving without a salary. He completed the designs for a one-man tank, supervised the design of a 150-ton tank, and had begun work on a much larger unit when the War ended. Perhaps his most outstanding achievement was the caterpillar gun mount, the design for which he completed shortly before the close of the War. Subsequently he supervised the construction and testing of a working model. The design provided for the mounting of light- and medium-weight field guns directly on a caterpillar chassis, armed and equipped for military service, and capable of traversing terrain utterly impassable to anything except a track-laying tractor. The design was accepted and the mount has become a standard part of army equipment.

Mr. Holt was born at Loudon, near Concord, N. H., on August 27, 1872. He was the son of William Harrison Holt, who, with his brothers, Charles and Benjamin Holt, started the firm of Holt Brothers in San Francisco in 1869. His mother was Clara Susan (Cate) Holt. His education, secured in the schools of Minneapolis, Minnesota, included three years' special work in mechanical and electrical engineering at the University of Minnesota.

At the age of 23 Mr. Holt took a position with the Carter Brake Company, in Chicago, Ill., as superintendent, and for about a year was engaged in the manufacture of a special street-car brake. In 1896 he became a draftsman for the Holt Manufacturing Company at the Stockton plant. He was made superintendent in 1903, vice-president in 1906. He was also president of the Aurora Engine Company and treasurer of the Houser & Haines Manufacturing Co. He resigned these positions in 1909 to establish the Holt Caterpillar Company at Peoria, but after serving the new company as president and general manager for about a year he was forced to resign because of ill health. In 1912 he became vice-president and general manager of the Holt Manufacturing Company, at Stockton, with which had been consolidated the Holt Caterpillar Company, Aurora Engine Company, and Houser & Haines Manufacturing Co. Ill health again necessitated his retirement as manager in 1916, but he retained the office of vice-president, and since the close of the War had served the company as director.

The inventive ability of Mr. Holt accounted in a large measure for the success of the Holt company and the industrial growth of his community. Nearly all of the agricultural machinery manufactured by the company was designed by him or had met improvement at his hands.

In recent years Mr. Holt had given much of his time to civic activities, and particularly to the Stockton Port Commission, of which he had been chairman since its formation. His careful, first-hand study of the industrial and technical details of the development of the port

were invaluable. He was a member of the Statewide Water Commission and had sponsored the movement for the construction of the Central Valley Water Project. He belonged to the San Francisco and Stockton Chambers of Commerce, was a director of the Stockton Land, Loan and Building Association, and a member of the advisory board of the Bank of America.

Mr. Holt became a member of the A.S.M.E. in 1915 and also belonged to the Society of Automotive Engineers, Society of Agricultural Engineers, Institute of Radio Engineers, American Association for the Advancement of Science, and other engineering and scientific organizations, as well as to the masonic fraternity and to many clubs. He was a director of the Army Ordnance Association and president of the San Francisco post of the Association.

In addition to his widow, Mrs. Florence (Guernsey) Holt, whom he married in 1909, he is survived by three sons and a daughter, Pliny Guernsey Holt, Frank Harrison Holt, Richard Eastman Holt, and Miss Harriet Holt.

BRONSON LOVETT HUESTIS (1890–1934)

Bronson Lovett Huestis, who died on May 29, 1934, was born in Long Island City, N. Y., on June 15, 1890, the son of Robert Sidney and Hanna M. (Isberg) Huestis. He attended the Erasmus Hall High School and Brooklyn Polytechnic Institute, receiving his mechanical engineering degree in 1913. Prior to his graduation, in the summer of 1912, he worked as a patent draftsman.

During the latter part of 1913 and early 1914, Mr. Huestis taught evening classes in machine design at Brooklyn Polytechnic Institute and was employed daytimes by the Stresau Engineering Company, Brooklyn, on the design of special machinery. He was next employed by the International Callophone Corporation, New York, N. Y., first as draftsman on new types of telephone apparatus and later in charge of a small machine shop for developing this apparatus. Later in the year he assisted his father in connection with plumbing and wiring for new residences. After a period of illness he again became connected with Brooklyn Polytechnic Institute, as instructor in machine-shop practice and toolmaker for laboratory apparatus.

At the close of the school year in 1915, Mr. Huestis entered the employ of Westinghouse Church Kerr & Co., New York. He was connected with that company until November, 1917, working as draftsman on sanitation, heating, and ventilation layouts for plants, and testing materials of construction, principally concrete and steel.

In November, 1917, Mr. Huestis became assistant inspector of ordnance matériel for the Ordnance Department of the United States Army, and until April, 1919, was stationed in Connecticut, his duties being at the New Britain Machine Company and the Winchester Repeating Arms Company, New Haven. He was in charge of a division of ballistic tests of small-arms ammunition, and the selection of all Government test specimens at the Winchester company.

In the fall of 1919 he returned to civilian work with the Pratt Engineering & Machine Co., New York, in charge of the mechanical design department, working particularly on chemical plants and equipment. This led to his connection two years later with the Dorr Company, New York, as designer of chemical plants and equipment and the following year as designer of sugar-mill equipment and plants for the Francisco Sugar Company, New York.

Beginning in December, 1922, Mr. Huestis was employed by the American Railway Association, New York, until his death. He was first connected with the Freight Container Bureau, inspecting methods of fruit packing all over the United States, and also carrying on independent research work on freight handling and preparing articles for the technical press on this subject. His book on "Shipping Containers" was published in 1925. In 1923 he became supervisor of the Accident Department of the Bureau of Explosives and subsequently was editor of the "Accident Bulletin" published by the Bureau.

Mr. Huestis became a junior member of the A.S.M.E. in 1913, an associate-member in 1917, and a member in 1923. He was particularly interested in photography, including motion-picture photography. He was unmarried.

EDWARD WALTER JONES (1889–1934)

Edward Walter Jones, vice-president and manager of the Laclede Stoker Company, St. Louis, Mo., died in that city on March 24, 1934. He is survived by his widow, Marguerite (Rickert) Jones, whom he married in 1920, and by two children, Edward R. and Marion F. Jones.

Mr. Jones was born in Chicago, Ill., on March 10, 1889, son of Lewis F. and Margaret (Goss) Jones. After securing a B.S. degree at the University of Illinois in 1911 he became testing engineer for the Commonwealth Edison Company, Chicago, and remained in that position until 1916. He then worked for the American Tar Products Company, Chicago, as fuel and power engineer for about three years. In 1919 he became chief engineer of the Stoker Department of Laclede-Christy Clay Products Company in St. Louis. He supervised the design and development of the Laclede chain-grate, forced-draft stoker. He became vice-president and manager of the Laclede Stoker Company in 1924. He was also active in smoke-abatement work in St. Louis.

Mr. Jones became a member of the A.S.M.E. in 1930 and belonged to the Prairie Club in Chicago.

ALFRED JOHN JUPP (1875–1934)

Alfred John Jupp, a vice-president of The Lunkenheimer Company, Cincinnati, Ohio, died of a cerebral hemorrhage at the Roosevelt Hospital, New York, N. Y., on April 10, 1934, while in the city on business.

Mr. Jupp was born in Cincinnati on June 25, 1875, son of Basil John and Rosina (Kolker) Jupp. He entered the employ of The Lunkenheimer Company at the age of fifteen. In 1896 he was made New York representative and continued in that position until 1913. He then returned to the home office, becoming a vice-president and director of the company.

Mr. Jupp was active in the Manufacturers Standardization Society of the Valve and Fittings Industry and in the Valve and Fittings Institute, and for a number of months prior to his death had contributed much of his time to code work on behalf of the Institute, under the National Industrial Recovery Act. He was a member of the American Committee to the World Power Conference in 1930.

He became an associate of the A.S.M.E. in 1917 and also belonged to the American Society for Testing Materials, Society of Naval Architects and Marine Engineers, American Petroleum Institute, Zoological Society of Cincinnati, American Red Cross Society, masonic fraternity and Elks, and the Engineers', Cincinnati, Queen City, and Cuvier Press Clubs in Cincinnati. He was unmarried and made his home with his sister, Mrs. Sarah J. Rice.

HERBERT EUGENE KAIGHN (1875–1934)

Herbert Eugene Kaighn, consulting engineer, Wilmington, Del., died on March 18, 1934. He was born at Washington, D. C., on August 19, 1875. During his high-school vacations he secured practical experience in the ordnance drafting room at the Navy Yard at Washington, and subsequently took instruction in ordnance construction and electrical engineering there and at the Naval Torpedo Station, Newport, R. I. He also took private lessons in electrical and mechanical engineering.

From 1894 to 1896 Mr. Kaighn was in charge of an electrical course for officers at the Naval Torpedo Station at Newport, and the next year was assistant engineer for the Newport Illuminating Company. In 1898–1899 he was in charge of electrical equipment, marine district, for the New York, New Haven, and Hartford Railroad. From 1900 to 1904 he was again at the Naval Torpedo Station, as ballistic engineer in charge of the powder factory and naval magazine, and the following two years he held a similar position at the Naval Proving Ground, Indian Head, Md. During the early part of 1907 he was at Philadelphia, Pa., in charge of manufacture of powder for the army and navy and the design of machinery for that purpose, and was also inspector of ordnance at the Midvale Steel Works.

Later in 1907 Mr. Kaighn entered the employ of the E. I. du Pont de Nemours Powder Co. at Wilmington as ballistic and experimental engineer in charge of all ballistic and physical tests of powder and the design and improvement of methods and apparatus used in this connection. He remained with the company until 1917, when he established a consulting practice, specializing in designing wiring systems for hospitals and other institutions. Since 1926 he had specialized in radio and acoustic and amplifying systems. He was also consultant for the American Car & Foundry Co. on marine installations.

Mr. Kaighn became a member of the A.S.M.E. in 1913. He also belonged to the American Institute of Electrical Engineers and the United States Naval Institute.

FREDERICK KAREL (1882–1934)

Frederick Karel, appointed car designer by the Board of Transportation of the City of New York in 1927, died on December 8, 1934, after a short illness.

Mr. Karel was born in New York on February 26, 1882, the son of William and Antoinette (Pekarek) Karel. He attended Cooper Insti-

tute from 1902 to 1905 and later took a course in mechanical engineering through the International Correspondence School. Between 1905 and 1920 he was employed nearly all the time by the Central Railroad of New Jersey as locomotive and car designer. Between 1909 and 1916, while serving as senior mechanical draftsman in the office of the superintendent of motive power he instructed apprentices in mechanical drawing and elementary mechanics. He was boiler and construction engineer for the company from 1916 to 1920.

During the next four years Mr. Karel was inspector of locomotives and equipment for the United States Railroad Administration and the Interstate Commerce Commission, and from then until his appointment by the Board of Transportation was chief draftsman in the office of the superintendent of motive power of the Long Island Railroad Company. He did important design work for the Board of Transportation on the 207th Street Shops, Concourse, and Jamaica Yards and in 1911 patented a coupling carry-iron.

Mr. Karel became an associate-member of the A.S.M.E. in 1921 and belonged to the masonic fraternity. He is survived by his widow, Louise (Vanek) Karel, whom he married in 1908, and by a daughter, Mrs. Frances (Karel) Connolly, and two sons, Frederick and Arthur Karel.

EDWARD J. KEARNEY (1868–1934)

Edward J. Kearney, secretary and treasurer of the Kearney & Trecker Corporation, Milwaukee, Wis., died in that city on January 12, 1934, of pneumonia, after having been in failing health for several months.

Mr. Kearney was born at Little Cedar, Mitchell County, Iowa, on April 7, 1868, the son of James Hamilton and Emeline (Smith) Kearney. Left an orphan at the age of 12, he began work as an engine wiper in a roundhouse on the Chicago, Milwaukee & St. Paul R.R. at Egan, S. D. He continued in the employ of the road, working in various capacities, until a year after his graduation, in 1893, from Iowa State College, from which he received the degree of Bachelor of Mechanical Engineering. During the year following his graduation he was located in the West Milwaukee locomotive shops.

In June, 1894, Mr. Kearney took a position as draftsman with the Kempsmith Machine Tool Company, Milwaukee, manufacturers of milling machines. Here he met Theodore Trecker and in 1898, during the Spanish-American war, the two friends decided that if Admiral Dewey were victorious they would start in business together. On May 17, 1898, therefore, a partnership was formed under the name of Kearney & Trecker for the manufacture of milling machines. The business was incorporated under its present name in 1906.

Mr. Kearney became a member of the A.S.M.E. in 1913. He served a five-year term on the Society's standing committee on standardization, terminating as chairman of the committee during 1930. He then became chairman of the Sectional Committee on Allowances and Tolerances for Cylindrical Parts and Limit Gages. After serving the National Machine Tool Builders' Association as vice-president for four years he was elected its president in 1922. He was also secretary and treasurer of the Kearney & Trecker Investment Co., a director of the LeRoi Company, a trustee of Milwaukee Downer College, and one of the original members of the Wisconsin State Board of Vocational Education. During the World War he acted as Director of Sales for the Liberty Loan drives in the Seventh Federal District. He belonged to the Delta Tau Delta fraternity and to a number of clubs in Milwaukee and vicinity.

Mr. Kearney married Ella B. Norton in 1895, and is survived by her and by two daughters, Katherine (Kearney) Carpenter and Alice (Kearney) Fuldner.

WILLIAM THOMAS KEOUGH (1866–1933)

William Thomas Keough, whose death occurred on January 20, 1933, was born in Boston, Mass., on December 22, 1866. He was graduated from the special course in marine engineering and naval architecture at the Massachusetts Institute of Technology in 1888, and after taking post-graduate work and lecturing at the Institute he entered the employ of the Atlantic Works in East Boston. He remained there nine years, the last five as chief engineer.

For the next ten years he carried on work in his own private office as consulting engineer in marine engineering and naval architecture. Then he was elected a member of the Boston School Committee and from 1907 to 1924 held the position of business agent for the school board, establishing modern and efficient business methods. He was appointed a member of the Boston Finance Commission by Governor Allen in 1930 and held that position until his death.

Mr. Keough became a member of the A.S.M.E. in 1900 and belonged also to the Society of Naval Architects and Marine Engineers and the American Society of Marine Engineers. He was a trustee and member of the board of investment of the Home Savings Bank and a director and vice-president of the Enterprise Cooperative Bank. He was a member of the Charitable Irish Society and president of the Catholic Alumni Sodality. He is survived by his widow, who was Rose Butler, of Boston, and by two sons, Paul and John, and a daughter, Katherine.

JAMES WALTER LAWRENCE (1858–1933)

James Walter Lawrence, emeritus professor of the Colorado Agricultural College, Fort Collins, since his retirement in 1917, died on April 3, 1933.

He was born on December 14, 1858, at Toronto, Ontario, Canada, the son of George and Honora (Naughton) Lawrence. His early education was secured in the public schools of Boston, and he subsequently attended the Massachusetts Institute of Technology. After working for several years at the Pacific Mills, Lawrence, Mass., he became a member of the faculty of the Colorado Agricultural College, teaching mechanical engineering and directing the shops and laboratory. He was acting president in 1892 and dean of the faculty from 1907 to 1913. The college conferred an M. E. degree upon him in 1902.

Professor Lawrence also served as president of the Fort Collins School Board from 1902 to 1912. He belonged to the Fort Collins Lodge of Masons and the Colorado School Masters Club, and was treasurer of the Fort Collins Pioneer Society and a member of the St. Lukes Episcopal Church of Fort Collins. He became a member of the A.S.M.E. in 1892.

Professor Lawrence is survived by his widow, Elizabeth (Coy) Lawrence, whom he married in 1890, and by a son, George Coy Lawrence, of Rochester, N. Y.

RUSSELL ELLSWORTH LAWRENCE (1889–1934)

Russell Ellsworth Lawrence, founder of the Lawrence Institute of Technology, located at Highland Park, Mich., died at his home in Redford, Mich., on June 15, 1934. He founded the Institute in 1932 and headed it as president and dean. It was his wish that the school, which in 1933–1934 had an enrolment of more than eight hundred students, be continued as an institution where any student, regardless of financial status, religion, or nationality, may secure engineering training.

He was born in Terre Haute, Ind., on November 4, 1889, a son of Ellsworth Lyman and Mary C. (Holmes) Lawrence. He received a B.S. degree in mechanical engineering from Rose Polytechnic Institute in 1913 and during the next three years was employed in steam-turbine research for the General Electric Company at Lynn, Mass. He then took graduate work at Rose Polytechnic Institute for his master's degree, which he received in 1916. Subsequent work toward his doctor's degree at the University of Cincinnati was interrupted by the World War, and he served in 1918–1919 as a sergeant in the Signal Corps, Aviation Section, United States Army.

From 1919 to 1922 he taught mechanical engineering at the University of Detroit and was acting dean of the College of Engineering. He became dean in 1922 and held that position until he founded the Lawrence Institute of Technology in 1932. He also did a great deal of consulting work while at the University of Detroit.

He became a member of the A.S.M.E. in 1929 and also belonged to the Society of Automotive Engineers and The Franklin Institute, and was a member of the masonic order and Phi Kappa Upsilon fraternity. He is survived by his widow, Mrs. Frieda Lawrence, and by two daughters.

WILLIAM STATES LEE (1872–1934)

William States Lee, inventor of the "Lee pin," an insulator pin used to support large insulators in the transmission of power, and a noted figure in the industrial development of the Carolinas, died at at his home in Charlotte, N. C., on March 24, 1934, of a cerebral hemorrhage. The American Institute of Electrical Engineers, of which he was a past-president, published a tribute in the July, 1934, issue of *Electrical Engineering*, which read, in part:

"Throughout his career, his ability as an engineer, his keen perception of the controlling factors in any situation encountered, and his constant attention to the human values involved made him an outstandingly effective and a highly respected leader of men.

"As president of the American Engineering Council, during the years 1932 and 1933, he worked intensively and enthusiastically to make the engineering profession as helpful as possible in all problems involving engineering and affecting the public welfare."

William States Lee was born at Lancaster, S. C., on January 28, 1872, one of nine children of W. S. and Jenny Lind (Williamson) Lee.

He attended public school at Anderson, S. C., and was graduated as a civil engineer in 1894 from the South Carolina Military Academy at Charleston, now The Citadel. He had held a scholarship in return for which he was obligated to teach for two years in the public schools of the state. In February, 1896, he secured a position with the Greenwood-Anderson & Western Railway. He spent five months in the drafting room, three months as transitman on location, and then was resident engineer on construction until March, 1897. He next became resident engineer with the Anderson Water, Light & Power Co., on a hydroelectric development on the Seneca River, about ten miles from Anderson. His first assignment was to string a transmission line across the river, a task in which others had failed. He was successful and before the close of the year had completed the plant and put it into operation. Following this he served for several months as resident engineer on construction for the Pickens Railway.

From March to November, 1898, Mr. Lee was connected with the United States Engineering Department as assistant engineer on coast defense. He helped with work on forts on Charleston Harbor and assisted in mining the harbor. He was next associated with the Columbus (Ga.) Power Company. From November, 1898, to September, 1901, he was resident engineer for the company, and from then until March, 1903, was its chief engineer. He directed a 8000-hp hydroelectric development and also the construction of a 27,000-spindle fine-yarn mill.

In 1903 Mr. Lee became chief engineer for the Catawba Power Company, Charlotte, a post which brought him into contact with James B. Duke, the tobacco manufacturer. His first task, to dam a river at a plant near Rock Hill, S. C., after three previous attempts to do so had been unsuccessful, was finished in seven months. This was the beginning of the Carolinas superpower system, financially backed by Mr. Duke and designed and built under the direction of Mr. Lee. He served as vice-president and chief engineer of the Southern Power Company, which took over the Catawba Power Company, and later became vice-president and chief engineer of the Duke Power Company, holding this position until his death.

In addition to the huge Carolina system, Mr. Lee designed and built the Isle Maligne station of the Duke-Price Power Company on the Saguenay River, in Quebec, Canada, and was associated with other projects on the Saguenay, part of the Duke system in that section.

So high was Mr. Duke's regard for him that his will provided that Mr. Lee be a trustee of the great Duke foundation of some $80,000,000.

Mr. Lee was president of the W. S. Lee Engineering Corp., of Charlotte, and was retained as consulting engineer on many hydroelectric projects throughout the East and South. He designed and built and for years had operated the Piedmont & Northern Railway, a high-speed, 1,500-volt, direct-current railroad, consisting of about 160 miles of track located in North and South Carolina, an accepted model of electric-railway design, carrying both freight and passengers.

During the World War his advice was sought in connection with plans for naval fortifications along the Atlantic seaboard. He was a director of the American Cyanamid Company, and vice-president and chief engineer of the Great Falls Power Company, Western Carolina Power Company, Wateree Power Company, Catawba Manufacturing & Electric Power Co., Duke-Price Power Company, and the Quebec Development Company, Ltd.

Mr. Lee became a member of the A.S.M.E. in 1907. He also belonged to the Engineering Institute of Canada, the American Society of Civil Engineers, the American Electrochemical Society, the masonic fraternity, and various clubs. In 1929 he was given an honorary degree of Doctor of Science by Davidson College, and he was a trustee of North Carolina State College of Agriculture and Engineering.

He married Miss Mary Martin, of Columbus, Ga., in 1901, and is survived by her and their three children, William States Lee, Jr., Mrs. William H. Williamson, and Martin Lee.

WILLIAM HENRY LEFFINGWELL (1876–1934)

William Henry Leffingwell, president of W. H. Leffingwell, Inc., New York, N. Y., died at his home in Westfield, N. J., on December 19, 1934, of pneumonia.

Mr. Leffingwell was born on June 14, 1876, in Woodstock, Ontario, Canada, the son of American parents, Wendell Phillips and Mary Catherine (Edwards) Leffingwell. After attending high school in Grand Rapids, Mich., he spent ten years as stenographer, clerk, and office manager for different companies. From 1904 to 1910 he was general manager of several large mail-order publications in New York, no longer published. From then until the outbreak of the World War he was in Europe acting as professional office organizer for various firms.

With this varied and practical background Mr. Leffingwell entered more seriously upon his career as a business efficiency expert. He was organization and management engineer at the Chicago Ferrotype Company in 1914–1915, and from then until 1918 was manager of the office-efficiency department of L. V. Estes, Inc., industrial engineers of Chicago. By 1918 he had founded the W. H. Leffingwell Company in Chicago. Two years later the name was changed to The Leffingwell-Ream Company, management engineers, and subsequently the firm was incorporated in New Jersey under its present name.

Mr. Leffingwell believed that for efficient management of an office a highly specialized knowledge was necessary. He applied scientific methods to his task by dividing office management into 93 parts, thus permitting a test rating to be given to each. Then suggestions for improvement were made on the resulting diagnosis. He considered office management inefficient unless each of the 93 parts had the best known practice.

Mr. Leffingwell was the author of a number of books and pamphlets, as well as of articles for scientific societies to which he belonged. His book on "Scientific Office Management," published in 1917, was one of the first on the application of engineering principles to the office. His "Office Management Principles and Practice," published in 1925, is used as a textbook in many schools and colleges. He contributed articles on office management and office appliances to the Encyclopedia Britannica and in 1928 was associate editor of the magazine *System*. He read papers at the Third International Congress of Scientific Management in Rome, 1927, the fourth congress in Paris, 1929, when he was official delegate from the United States, and the fifth congress in Amsterdam, in 1932. He had prepared a paper for the sixth congress to be held in London in 1935.

As aids in carrying out his principles Mr. Leffingwell invented a typewriter measuring scale, a desk and a posture chair for clerks, and a lighting-demonstration device. He enjoyed amateur photography, sculpture, handicraft, and gardening.

Mr. Leffingwell became an associate of the A.S.M.E. in 1921. He was a past-president of the National Office Management Association and was president of the Taylor Society at the time of his death. He was a member of the Society of Industrial Engineers and chairman of its New York Chapter, and belonged to the American Management Association, the Association of Consulting Management Engineers, the Engineers' and City Clubs, New York, the Union League Club, Chicago, and the Sons of the American Revolution.

Mr. Leffingwell married Miss Anna Short, of Chicago, in 1900, and is survived by her and by two daughters, Evelyn E. (Mrs. Joseph W.) Lewis and Dorothy A. (Mrs. Harold F.) Scribner, both of Westfield. His father, two sisters, and a brother, also survive him.

SYLVESTER MAURICE LEONARD (1896–1934)

Sylvester Maurice Leonard, born in Northampton, Mass., on August 16, 1896, died in the Bridgeport (Conn.) Hospital on December 31, 1934. Mr. Leonard, whose parents were James Sylvester and Felicie (Gillet) Leonard, supplemented his grammar school education with study through correspondence schools and by evening work at the New Haven College. He served an apprenticeship in drafting at the Baird Machine Company, Stratford, Conn., and worked as a special machine designer there between 1916 and 1921. Although not continuously employed during the next two and a half years he gained experience in shoe and paper machinery and miscellaneous tool work. During the summer of 1923 he was draftsman at the Continental Paper & Bag Mills, and the following winter worked on wire-drawing and wire machinery for the Waterbury Machine Company. From then until his death he was employed by the Crawford Oven Company, New Haven. He was senior draftsman for about three years and had been chief draftsman since then.

Mr. Leonard became an associate-member of the A.S.M.E. in 1930 and belonged to the masonic fraternity and Odd Fellows. He married Beatrice Hudson in 1925, and is survived by her and their son, Raymond Frederick Leonard.

EDWIN S. LORSCH (1869–1934)

Edwin S. Lorsch, whose death occurred on October 4, 1934, was born in New York, N. Y., on November 19, 1869, a son of Sigmund and Jenny (Simon) Lorsch. He was graduated from the Stevens Institute of Technology in 1891 as a mechanical engineer and during the next two years worked in the drafting, testing, and erecting departments of the Geo. F. Blake Manufacturing Co., manufacturers of pumping machinery, East Cambridge, Mass. He then returned to New York, where he was employed by the Electrical & Mechanical Engineering Co. and in the New York office of the Fort Wayne Electric Company until he became a member of the firm of Sussfeld, Lorsch & Co., in 1896.

Mr. Lorsch was responsible for the organization of the export department of the company in 1899 and for many years was in charge of this department. The firm was reorganized to Sussfeld, Lorsch, and Schimmel on January 1, 1920, and he remained a member of the firm until it was dissolved in 1929.

Mr. Lorsch became a member of the A.S.M.E. in 1903 and belonged to the North Shore Country Club and Harmonie Club of New York. He had made several trips around the world, recorded in a collection of photographs which he took. He was unmarried and is survived by his brother, Henry Lorsch, of New York.

JAMES LYMAN (1862–1934)

James Lyman, consulting engineer, retired, for the firm of Sargent & Lundy, Chicago, Ill., died on March 28, 1934, at Del Monte, Calif., where he had been spending the winter months with his son, Oliver B. Lyman.

Mr. Lyman was born at Middlefield, Conn., on September 1, 1862, the son of David and Catherine (Hart) Lyman. He was graduated from the Sheffield Scientific School of Yale University in 1883 with the degree of Ph.B. and during the summer and fall of that year was foreman of the machine shops of the Metropolitan Manufacturing Company, at Middlefield.

In December, 1883, Mr. Lyman became construction electrician for the Edison Construction Company, with which he remained about six months, assisting in the installation of a number of lighting plants in Pennsylvania and Ohio. During the next two years he was assistant superintendent of the Marr Construction Company, which was organized to take over the construction work for the Edison company. He had entire charge of the installation of plants at a number of places in Pennsylvania, including Johnstown, Wayne, and DuBois, and also gave exhibitions of incandescent lighting.

Resigning from the Marr company in 1886, Mr. Lyman returned to Middlefield as superintendent of the shops and foundry of the Metropolitan Manufacturing Company, in which his family held an interest. During the seven years he spent there the company became part of the American Wringer Company.

In 1893 Mr. Lyman took up post-graduate engineering work at Sibley College, Cornell University, and received an M.E. degree in 1894 and M.M.E. degree in 1895. He then entered the employ of the General Electric Company at Schenectady and as assistant to Dr. Charles P. Steinmetz conducted special experimental testing and designed electric apparatus. Later he was transferred to the power and mining department and in 1899 was appointed assistant engineer of the Chicago branch of the company. Three years later he became district engineer and continued in that capacity until 1911.

From 1911 until his death Mr. Lyman was associated with the firm of Sargent and Lundy, Inc., as electrical engineer, member of the firm, vice-president (1926–1930), and as consultant retired since 1930.

Mr. Lyman became a member of the A.S.M.E. in 1899, was a Fellow of the American Institute of Electrical Engineers, and belonged also to the American Electrochemical Society, Western Society of Engineers, and the Institution of Electrical Engineers. He was a member of the University and Union League Clubs, Chicago, and several clubs in Evanston, where he made his home for more than thirty years.

Mr. Lyman married Miss Anna J. Bridgman, of Boston, Mass., in 1891.

WALTER ARNOLD LYNCH (1902–1934)

Walter Arnold Lynch, who died of typhoid fever and meningitis at Carrizo Springs, Texas, on September 23, 1934, was born in Philadelphia, Pa., on August 16, 1902, the son of Edmund Wright and Alice (Clayton) Lynch. He attended high school in Darby, Pa., and received a B.S. degree in mechanical engineering at Drexel Institute, Philadelphia, in 1926.

Between the time of his graduation and 1929, Mr. Lynch engaged in farming in Carrizo Springs and was employed at different periods by the Atlantic Refining Company, Philadelphia, in the conversion of a ship from steam to Diesel-electric drive; by the Mayhue Lumber Company in the installation of deep-well pumps; and by the Central Power & Light Co. in the installation of refrigeration machinery.

In 1929 he secured employment as a junior hydraulic engineer with the Texas State Board of Water Engineers in an underground water survey, and in 1933 began similar work with the United States Geological Survey, with which he was connected at the time of his death.

Mr. Lynch had devised a portable device for testing for salt water in deep wells and for determining the position of the salt-water leaks. He also designed and constructed a wind-driven generator for charging a storage battery on his farm, and had constructed many models for airplanes. Radio was perhaps his principal hobby; he had constructed many sets and was a licensed amateur sender.

He served as chairman of the A.S.M.E. Student Branch at Drexel Institute in 1926 and became a junior member of the Society upon his graduation. He was also president of the Phoenix Club at the Institute in 1926, and served as a sergeant in the Headquarters Battery of the 108th Field Artillery of the Pennsylvania National Guard from 1921 to 1925. He was unmarried.

NELSON THEODORE MANN (1899–1934)

Nelson Theodore Mann, who had been employed as a research analyst since 1927 by Scudder, Stevens & Clark, New York, N. Y., died on February 17, 1934, of pneumonia. He is survived by his widow, Beatrice Smith Mann, whom he married in 1928, and by a son, Timothy Charles Nelson Mann.

Mr. Mann was born at Hawley, Mass., on November 10, 1899, attended the Medford (Mass.) High School, and secured an S.B. degree in Mechanical Engineering at the Massachusetts Institute of Technology in 1923. He spent one vacation as rodman for the Scully Construction Company, Boston, and several with the New York Central Railroad, working as pipefitter's helper and in other capacities in the Electrical Department. He served nine months in the United States Marine Corps during 1918.

After his graduation Mr. Mann served a special apprenticeship with the Westinghouse Air Brake Company, Wilmerding, Pa., and worked for that company as assistant to the mechanical engineer and as commercial engineer for a time prior to his connection with Scudder, Stevens & Clark. His work for the latter company had been mainly on machinery, tin containers, railroad equipment, and nonferrous metal mining, analyzing their investment possibilities.

Mr. Mann became a junior member of the A.S.M.E. in 1924, and belonged to the New Rochelle Tennis Club and the Huguenot Yacht Club.

NORMAN ISAAC MARSHALL (1865–1933)

Norman Isaac Marshall, who died in New York, N. Y., on March 28, 1933, was born at Hampstead, N. H., on December 6, 1865, the son of Isaac Hull and Julia (Bement) Marshall. He prepared for college at the Bromfield Academy, Harvard, Mass., and was graduated from Worcester Polytechnic Institute in 1886 with a B.S. degree in mechanical engineering.

For several years following his graduation Mr. Marshall was employed by the Marr Construction Company, assisting in the erection of central-station light and power plants in Pennsylvania, Ohio, and Wisconsin. He next had charge of similar work for the Westinghouse Electric & Manufacturing Co. in Texas, later becoming eastern manager for the company, with headquarters in Boston. From 1901 to 1903 he was designer of machinery and fittings and superintendent of shops for the Star Electric Company, Philadelphia, Pa., and during the next two years manager of the Iona Manufacturing Company and Anchor Electric Company, Boston.

In 1905 Mr. Marshall went into business for himself as owner and manager of the Marshall Electric Company, Boston. Subsequently he sold this business and formed the Elastoid Fibre Company, in West Newton, Mass., later located in Waltham, Mass. He was president and treasurer of the company until its sale in 1927, since when he had not been active in business except for consulting work.

Mr. Marshall held many patents in the electrical and mechanical fields. He was one of the first to manufacture sockets, switches, fuses, etc., and patented the first automatic machinery for the manufacture of incandescent bulbs. From 1916 to 1918 he was connected with the science and research department of the United States War Department, and jointly with Dr. Louis Bell invented and perfected the ultra-violet signalling apparatus for use in the Signal Corps during the World War.

Mr. Marshall served as a lieutenant in the naval militia during the Spanish-American War.

Since 1927 Mr. Marshall had spent a great deal of his time in travel. He was an excellent shot with the rifle and had hunted big game in Alaska, China, and India. He wrote several articles on hunting for publication, and had also written some short stories. He greatly enjoyed walking and mountain climbing and was an able botanist.

Mr. Marshall became a member of the A.S.M.E. in 1910 and also belonged to the American Institute of Electrical Engineers, Boston University Club, Lake Placid Club, and Appalachian Mountain Club.

He married Miss Hortense Carver in 1898 and is survived by her and by three children, Thomas C. Marshall, of Fairfield, Conn., Mrs. M. H. Hull, Still River, Mass., and Mrs. C. V. Russell, Boston.

WILLIAM CROSBY MARSHALL (1870–1934)

William Crosby Marshall, consulting mechanical and civil engineer, and former professor of machine design at the Sheffield Scientific School, Yale University, died at the Gaylord Farm Sanitorium, Wallingiord, Conn., on February 1, 1934. Mr. Marshall, a descendant of Robert Treat, an early governor of Connecticut and founder of Newark, N. J., retired in 1929 and since that time had made his home at Milford, Conn. He was born at Avon, Conn., on September 21, 1870, the son of Henry G. and Marietta (Crosby) Marshall.

After being graduated from Yale University in 1890, with a Ph.B. degree, Mr. Marshall worked for three years as a draftsman and structural engineer for the Berlin Iron Bridge Company, Berlin, Conn. He then returned to Yale to study for a mechanical engineering degree, which was conferred upon him by Sheffield Scientific School in 1894. He remained at the school, first as instructor and later as professor in machine design, until 1913. He was given a civil engineering degree there in 1900. He studied at the École des Beaux Arts and École du Genie Maritime, in Paris, in 1907–1908.

For a year after he left Yale in 1913 Mr. Marshall was chief engineer for the Federal Sugar Refining Company, New York, N. Y. He then became research engineer at the Union Metallic Cartridge Company, Bridgeport Works of the Remington Arms Company. During the early part of 1917 he was connected with the Holt Manufacturing Company, Peoria, Ill., as mechanical engineer, then served during the World War as captain in the Ordnance Department, U. S. A., in charge of twenty-five plants. He also served as trade commissioner to Italy for the U. S. Bureau of Foreign and Domestic Commerce in 1919.

Returning to civil life, Mr. Marshall was engaged as mechanical engineer for the National Spun Silk Company, New York, and carried on consulting work in that city on machine designing, testing, graphical charting, and materials handling and traveled in England inspecting various plants for new and comparative material. In 1921–1922 he was chief enginer for the U. S. Hoffman Machinery Corp., New York; 1922–1923, mechanical engineer for The Trexler Co. of America, Wilmington, Del.; 1923–1924, maintenance and plant engineer, Richard Hellman, Inc., Long Island City, N. Y.; 1924–1925, director, Yale Graduate Placement Bureau, Yale Club, New York; 1925–1926, instructor in machine drawing, Pratt Institute, Brooklyn, N. Y. From then until his retirement he was an associate editor of The Engineering Index.

While living in Milford, Mr. Marshall served as town-planning and building inspector there. He was the author of a textbook on "Descriptive Geometry," published in 1910, "Machine Drawing and Design," 1912, and "Graphical Methods," 1921, as well as of many magazine articles.

Mr. Marshall became a junior member of the A.S.M.E. in 1901 and a member in 1909. He also belonged to the Sigma Xi fraternity, Yale Engineering Association, and Yale Club, New York. He is survived by his widow, Mrs. Genevieve Holbrook Marshall, and by a son, John.

ROYAL MATTICE (1878–1934)

Royal Mattice, president of the Mattice Engineering Company, Philadelphia, Pa., died at his home in that city on February 18, 1934, and was buried with military honors in the Arlington National Cemetery. He was born at Birmingham, Ala., on July 27, 1878. At the age of 13 he began work as a water boy at the Carnegie Steel Company. He served an apprenticeship as a patternmaker and for six years took evening courses, specializing in metallurgy. In 1897 he was employed as assistant manager and metallurgical engineer for the Kokomo (Ind.) Nail & Brad Co., and after serving in the Spanish-American War in 1898, returned to that company in the position of general manager in charge of sales and production.

From 1900 to 1920, with the exception of periods of service on the Mexican Border and in the World War, Colonel Mattice was metallurgical engineer for the American Steel & Wire Co. He was division sales manager for the company at Chicago, Ill., Oklahoma City, Okla., Wichita, Kan., and Cincinnati, Ohio. Although his connection with this company, as well as with the Kokomo Nail & Brad Co., was officially in the sales department, he had practically nothing to do with selling except in a technical way. He was chiefly concerned with improvements in the firm's products and production methods.

After the World War, Colonel Mattice established the Mattice Engineering Company, devoted almost entirely to electric welding of cast iron.

Colonel Mattice became a member of the A.S.M.E. in 1924, and also belonged to The Franklin Institute, the Military Order of Foreign Wars, the Engineers Club in Philadelphia, and the masonic order. He was president of the Welding Contractors' Association of Greater Philadelphia and Camden.

He is survived by a son, Royal Mattice, Jr., and a daughter, Nancy Ellen.

DABNEY HERNDON MAURY (1863–1933)

Dabney Herndon Maury, retired consulting engineer, chiefly in the water-supply field, died at his home in Chevy Chase, Md., on May 11, 1933. Mr. Maury was born in Vicksburg, Miss., on March 9, 1863, the son of Dabney Herndon and Nannie Rose (Mason) Maury. His early education was secured in private schools in New Orleans, La., and Richmond, Va. He then attended the Virginia Military Institute, at Lexington, Va., from which he was graduated in 1882. Two years later he secured his M.E. degree from Stevens Institute of Technology, Hoboken, N. J.

Mr. Maury worked during his summer vacations while attending college. In 1881 he was rodman on surveys for a railroad bridge across the Ohio River at Point Pleasant, W. Va. The following summer he was chief of a party making preliminary surveys for the Brighthope Railway, near Richmond, Va., and draftsman at Colt's Armory, Hartford, Conn. During the summer of 1883 he was draftsman for locomotive works in Richmond and in 1884 assistant to Prof. Robert H. Thurston in the mechanical laboratory at Stevens Institute.

In October, 1884, Mr. Maury went to Texas as engineer for the Grand Belt Copper Company, of New York, a connection he retained until the summer of the following year. He then became principal assistant engineer on location and construction for the Ft. Worth and New Orleans Railway. From March to November, 1886, he was engaged in making land surveys for the Southern Pacific Railway Company in western Texas.

From Texas Mr. Maury went to Colombia, S.A., where his father, General Dabney H. Maury, was stationed as Envoy Extraordinary and Minister Plenipotentiary of the United States to Colombia. He served as private secretary to his father until March, 1887, when he became general engineer for Green & Garcia, mine agents in Colombia. He remained in their employ until May, 1890, serving part of the time as general manager of the Tolima, Organoz, Socorro, and other gold and silver mines, erecting machinery and building dams and ditches for the Silencio, Tetuan, and Colon mines, and making surveys, plans, and estimates for other mines in Colombia.

During the remainder of that year Mr. Maury traveled in Great Britain and the United States. He returned to Colombia as general manager for the Saldana Syndicate, Ltd., of Liverpool, England, and until the winter of 1892 had charge of all of its interests there, designing and constructing dams and ditches and directing the operation of mines. He was also general manager for the Anape Syndicate, Ltd.

After his return to the United States in 1892 Mr. Maury took postgraduate work at Stevens Institute through the winter. He then became engineer and superintendent for the Peoria (Ill.) Water Company and later continued in the same capacities with the reorganized Peoria Water Works Company, remaining with the company until August, 1912. He designed and constructed a number of new pumping plants, developed improvements in operation, and designed sewer systems for suburban districts.

During the latter part of this period he had also conducted a private practice as a consulting engineer, and in August, 1912, he opened his own office in Chicago. He was located there until the United States entered the World War in 1917, and again from July, 1919, until his retirement in 1927, during the last four years as senior partner in the firm of Maury and Gordon. His advice on water supplies was sought by municipalities in many parts of the country.

In May, 1917, Mr. Maury put aside his private practice to serve as advisory engineer on water supply for the Construction Division of the United States Army. He was in charge of the design of water systems for all projects of the Division in the United States and possessions. He was also borrowed by the Marine Corps for its water supplies at Paris Island and Quantico, and by the Navy for supplies at Pearl Harbor and other points in Hawaii. He was specially assigned by the War Industries Board to develop water supplies for the army, navy, shipping board, and housing corporation in the Hampton Roads district. He was given the rank of commanding major in the Engineers Reserve Corps in 1917 and of lieutenant-colonel in the Quartermaster Corps in 1918. He was honorably discharged in May, 1919.

In 1920 Mr. Maury won the James Laurie Prize of the American Society of Civil Engineers for a paper on "Water Supplies for the Cantonments, Camps, and Other Activities Built by the Construction Division of the Army." He contributed other papers to the technical press and to the societies to which he belonged. He held several patents on pumping machinery and wells.

Mr. Maury became a member of the A.S.M.E. in 1890. He was past-president of the American Water Works Association, Illinois

Society of Engineers, and Illinois Water Supply Association. He was also a member of the American Society of Civil Engineers, American Institute of Consulting Engineers, Western Society of Engineers, and New England Water Works Association, as well as of Kappa Alpha (Southern) and Tau Beta Pi, honorary engineering fraternity, and a number of clubs.

Mr. Maury married Mary McCaw, of Richmond, in 1893, and is survived by her and their son, Dabney Herndon Maury, Jr.

RICHARD JUSTIN McCARTY (1851–1934)

Richard Justin McCarty was born on March 12, 1851, at Clarksburg, W. Va., the son of Joseph and Ann (McCally) McCarty. He attended Soulé University, Chapel Hill, Texas, from 1862 to 1869 and then studied for two years at the University of Virginia, being graduated in pure mathematics in 1871. Subsequently he took courses in applied mathematics and civil engineering there, completing his work in 1875.

Following a short period as foreman for the erection of a rolling mill at Rosedale, Kan., he was employed by the Kansas Rolling Mill Company in various capacities until 1879. He then worked in the engineering, accounting, and operating departments of steam railroads until 1888, when he became chief engineer of the Metropolitan Street Railway Company at Kansas City, Mo. He held this position until 1895, having charge of designing and constructing extensions to the cable lines and power plants and the maintenance and operation of all of the company's property. After he left the regular service of the company in 1895 he was recalled to make changes in another of its lines and was also employed in 1895 and 1896 by the Kansas City Stock Yards Company to design a pumping and lighting plant and to handle construction work.

In 1897 Mr. McCarty became auditor for the Kansas City, Pittsburg & Gulf R.R., which later became the Kansas City Southern Railway. In 1903 he resigned to devote two years to scientific study, then returned to his former position. Later he was made vice-president of the company and chairman of its valuation committee. He retired permanently in 1918 and spent his remaining years in scientific and philosophical study and writings. His work on "Valuation of Railroad Property" was published in 1915; "Elements of Plane Trigonometry, 1920; Wisdom and Purpose, 1922; Work and Play: An Autobiography, 1925; "Essays in Poetry," written jointly with his wife, 1930; and Vital Evolution, 1933.

He died in Kansas City of heart disease on June 16, 1934. He is survived by his widow, the former Miss Mary Louise Allen, whom he married in 1877, and by three sons, Allen, Richard J., and Charles E. McCarty.

Mr. McCarty became a member of the A.S.M.E. in 1901 and also belonged to the American Society of Civil Engineers, Sons of the American Revolution, Royal Societies Club, London, and the Zeta Psi fraternity.

JOHN McGEORGE (1852–1933)

John McGeorge, honorary member of the Cleveland Engineering Society, was instantly killed on the evening of February 27, 1933, when struck by an automobile while walking near his home in Cleveland. Mr. McGeorge had been a member of the A.S.M.E. since 1891.

He was born in Manchester, England, on May 2, 1852. Leaving school when about fourteen years of age, he served a seven-year apprenticeship with Emmerson Murgatroyd & Co., Stockport, England, working in both the shops and drawing office. He also studied evenings at the Mechanic's Institution of Stockport and later, while employed in Manchester, took evening courses at the Owens College there.

After completing his apprenticeship, Mr. McGeorge worked successively as draftsman with Galloway & Sons, engineer with the Boiler Insurance Company, and draftsman and manager of Deakin Parker & Co., all of Manchester. He was connected with the Deakin company for about seven years and during this period invented a drum or shaft governor. Later he engaged in drafting for companies in Nottingham, Grantham, and Guilford, England.

In 1884 Mr. McGeorge came to the United States. During his early years here he constructed special machinery for the Bellaire Stamping Company, Bellaire, Ohio, including machinery of his own design for making the Mason fruit jar cap. Subsequently he was employed by the Pittsburgh Iron & Steel Engineering Co., Pittsburgh, Pa., as chief draftsman.

In 1892 he became associated with Samuel T. Wellman, of the Wellman-Seaver Engineering Company (now the Wellman Engineering Company), and served as chief engineer of the company from 1896 to 1903. With Mr. Wellman he developed the rolling open-hearth furnace, the open-hearth charging machine, and other equipment which meant much to the development of the steel industry. Since 1903 his work had been largely in the consulting field. He also invented an electric factory truck in wide use as a labor-saving device in the handling of materials.

Mr. McGeorge was elected to membership in the Cleveland Engineering Society in 1896 and honorary membership was conferred upon him in 1931. He was also a life member of the Society of Automotive Engineers.

DANIEL GEORGE McMILLAN (1871–1934)

Daniel George McMillan, engineer for the Jersey Central Power & Light Co., South Amboy and Sayreville, N. J., died in Elizabeth, N. J., on May 30, 1934. He is survived by his widow, Eleanor T. (Christie) McMillan, whom he married in 1907, and by a daughter, Mildred Eleanor.

Mr. McMillan was born at St. Louis de Gonzague, Quebec, Canada, on May 14, 1871, the son of Neil and Flora (Menish) McMillan. He secured his early education in Montreal schools, served an apprenticeship at the Royal Electric Company there, and spent three years in the mechanical and electrical laboratories of McGill University. For five years he served as chief engineer of the Canadian Singer Factory at St. Johns, Quebec, then came to the United States as assistant chief engineer of the Singer Manufacturing Company at Elizabethport, N. J. He remained with this company for nearly ten years, being its chief engineer the latter part of the time. Subsequently he was superintendent of power for the Willys Corporation, Elizabeth, and maintenance engineer of the Elizabeth General Hospital, prior to his connection with the Jersey Central Power & Light Co.

Mr. McMillan became an associate-member of the A.S.M.E. in 1917. He was very active in the masonic fraternity, in which he had held a number of important posts, and was a member of Everymans Bible Class at the Third Presbyterian Church in Elizabeth.

HIRAM LEES MELLOR (1865–1933)

Hiram Lees Mellor, owner of the Lawrence Pump & Engine Co., Lawrence, Mass., a member of the A.S.M.E. since 1908, died on January 5, 1933. He was born at Sandwich, N. H., on December 2, 1865, but moved with his parents to Lawrence at an early age and was educated in the public schools there. He served an apprenticeship as a machinist and draftsman with S. S. & W. O. Webber, Lawrence, manufacturers of textile machinery, printing presses, shop tools and jigs, and attended night school, thus fitting himself for a position as draftsman with the Lawrence Machine Company. He spent four years in that work, then became superintendent of the company, which manufactured centrifugal pumping machinery, steam engines, and related equipment. About 1904, he started in business for himself, founding the Lawrence Pump & Engine Co., which he continued to manage until his death.

He had served as treasurer and deacon of the United Congregational Church in Lawrence. He was married, and is survived by his widow and a daughter, Mrs. J. L. Dean, whose husband now manages the business.

EDGAR HAMILTON MERRICK (1886–1934)

Edgar Hamilton Merrick, whose death occurred in Cleveland, Ohio, on January 21, 1934, was born at Gananoque, Ontario, Canada, on May 4, 1886, son of Dr. Edgar H. and Sara E. (Carpenter) Merrick. He was graduated from Sibley College, Cornell University, in 1908, with an M.E. degree, and during the next six years was machinery salesman for Hill, Clarke & Co., Chicago, Ill. He then became secretary and sales manager for the Perkins Windmill & Engine Co., Mishawaka, Ind., where he remained for three years.

From 1917 to 1927 Mr. Merrick was connected with Manning, Maxwell & Moore, Inc., New York, N. Y., as district manager of their Cincinnati office for seven years and of the Cleveland office for three years. He engaged in machinery business for himself during the next year, then became sales engineer for Dravo-Doyle Company, of Pittsburgh, Pa., handling the products of the Shepard-Niles Crane & Hoist Corp. Since 1931 he had been in business for himself as sales engineer, in Cleveland.

Mr. Merrick became an associate of the A.S.M.E. in 1932, and was a 32d degree Mason. He is survived by his widow, Florence C. (Earle) Merrick, whom he married in 1917, and by two children, Frances Chapin and Richard Henry Merrick.

VLADIMIR VICTOR MESSER (1877–1932)

Vladimir Victor Messer, who died in 1932, on or about May 2, was born in St. Petersburg, Russia, on December 2, 1877. He attended

the naval academy of the Imperial Russian Navy and was commissioned a lieutenant in 1896. His first work in the United States was as chief draftsman for the Los Angeles Gas & Electric Co., in 1906. The following year he became consulting engineer for the Sweetland Filter Press Company and Brubaker Bros., in San Dimas, Calif., and subsequently served the Commercial Gas Engine Company, of Los Angeles, in connection with irrigation equipment. In 1912 he engaged in the design of the steel structure for the Canadian Pacific Railway terminal at Vancouver, as an employee of Coughlan & Sons, of that city. He then returned to Los Angeles, where he became structural engineer for Fitzhugh & Fitzhugh, architects. He subsequently held a similar position with Lescher & Kibbey, architects, in Phoenix, Ariz.

About the year 1915 Mr. Messer went to New York, where he was associated with Percival R. Moses and Frederick Pope as consulting engineer. During the World War, in 1918-1919, he was chief engineer for the Newport Chemical Works and Newport Hydro-Carbon Company, Milwaukee, Wis., and from then until 1924 again associated with Moses and Pope. At that time he formed the V. V. Messer Manufacturing Co., located first in Long Island City, and later in New York.

Much of his time during the latter part of his life was spent in work on inventions and on special missions to other countries, including the building of a steel plant and railroad in Russia, and zinc plant in South America, and in connection with the cork industry in Europe. Other special connections were with the Goodyear Tire & Rubber Co., in Akron, Ohio, the National Analine Company, for which he built an indigo plant in Buffalo, N. Y., and the Miller Rubber Company, Inc., New York.

Mr. Messer became a member of the A.S.M.E. in 1916 and belonged to the Chemists' Club, New York. He is survived by his widow, Edithe Maxham Messer, whom he married in 1917. Their only son, Paul, died in October, 1933.

HAROLD R. MILLER (1906–1934)

Harold R. Miller was born at Norwalk, Ohio, on July 3, 1906. He secured his early education there and was graduated from the Ohio State University in 1928 with a B.S. degree in mechanical engineering. He immediately entered the employ of the Philip Carey Manufacturing Company, at Lockland, Ohio, and at the time of his death on March 31, 1934, was assistant superintendent of power.

Mr. Miller became a junior member of the A.S.M.E. in 1933 and belonged to the Theta Xi and Tau Beta Pi fraternities. He is survived by his widow, Mary (Ross) Miller, whom he married in 1926, and by a daughter, Marjorie Anne Miller.

JAMES MILNE (1865–1934)

James Milne, chief electrical and mechanical engineer in the Department of Works of the City of Toronto, Ontario, Canada, in charge of water supply, for about twenty years, died in that city on May 21, 1934.

Mr. Milne was born on January 29, 1865, at Woodside, Aberdeen, Scotland, the son of William and Jessie (Hird) Milne. He secured his technical training at Robert Gordon's College, Aberdeen, and as an apprentice with C. Davidson & Sons and Abernethy & Co., Aberdeen. He then went to Montreal, Canada, where he worked for a time in a machine shop and later secured employment with the Edison General Electric Company. He spent three years there and during the next six years was superintendent of the Incandescent Electric Light Company at Toronto. For two years he taught machine construction and drawing, applied mechanics, and steam engineering at the Toronto Technical School, then spent eight years as general manager and chief engineer of the Underfeed Stoker Company, Toronto, at the same time carrying on a consulting engineering practice. Early in February, 1906, he became general superintendent of the British Columbia Electric Railway Company, Vancouver, operating street railways, light, and power in Vancouver, Victoria, and New Westminister, B.C. From 1910 to 1913 he was assistant manager of the Windsor Salt Works, Windsor, Ontario, and engaged in consulting work. He began his long connection with the City of Toronto in 1913.

Mr. Milne became a member of the A.S.M.E. in 1907. He also belonged to the American Institute of Electrical Engineers, Engineering Institute of Canada, and the Association of Professional Engineers of Ontario, and was a member of the Engineers and Parkdale Canoe Clubs in Toronto and of the masonic fraternity. He was a contributor to technical publications and a member of the Toronto Symphony Orchestra, in which he played the contra-bassoon.

Mr. Milne had been twice married. His first wife died in 1899 and his second in 1929. He is survived by a son, James C. R. Milne, and by a married daughter.

GUY KÖCHLING MITCHELL (1878–1934)

Guy Kochling Mitchell, formerly president and proprietor of the Standard Electric Machinery Company and partner in the Standard Appraisal Company, both of Baltimore, Md., died of pneumonia at his home in that city on January 15, 1934.

Mr. Mitchell was born in Baltimore on July 5, 1878. He attended the Baltimore Polytechnic Institute and in 1899 began work for the United Electric Light & Power Co. as draftsman for the department handling equipment and operation. He spent six years in that position, then in 1902, after a few months at Embreeville, Tenn., installing an electric plant and transmission line for the Embree Iron Company, he returned to Baltimore to do estimating and layout work in the distribution department of the United Electric Light & Power Co.

In 1906 Mr. Mitchell became manager of the electrical department of Crook Horner Company, Baltimore. When this company dissolved the following year he purchased the electrical and elevator departments and established the Standard Electric & Elevator Co. operating it as a manufacturing and contracting concern. The name of the company was changed to the Standard Electric Machinery Company in 1921.

During the early days of the company it specialized in replacing steam drives by electric-motor drives, and under the direction of Mr. Mitchell installations varying from 50 hp to 1000 hp were made in plants in Baltimore and vicinity. At the same time he carried on the development of electric elevators, especially the single-phase, and a new line of dumbwaiters, hoists, and cranes. During the World War he devised an automatic system for reconnecting and rerating motors and generators of all makes and types.

Mr. Mitchell became an associate of the A.S.M.E. in 1913 and a member six years later. He was also a member of the American Institute of Electrical Engineers. He is survived by his widow, Katherine V. Mitchell.

ROBERT LEVIS MITCHELL, JR. (1911–1934)

Robert Levis Mitchell, Jr., son of Doctor and Mrs. Robert L. Mitchell, of Baltimore, Md., died at Perth Amboy, N. J., on December 28, 1934. He had been a member of the engineering staff of the National Lead Company at Perth Amboy since early in July.

Mr. Mitchell was born in Baltimore on September 21, 1911. He attended the Friends School there and secured his degree in mechanical engineering from Johns Hopkins University with the class of 1934. He was a student member of the A.S.M.E. at the university and became a junior member of the Society upon graduation. He was also a member of the university amateur theatrical group, the Barnstormers, and of Alpha Tau Omega fraternity.

Surviving Mr. Mitchell, in addition to his parents, are a sister, Miss Nancy Mitchell, and a brother, William.

LESTER A. MORELAND (1874–1934)

Lester A. Moreland, former production engineer for the Worthington Pump & Machinery Corp., Harrison, N. J., died on March 21, 1934, after an illness of more than a year. Mr. Moreland was born at Skaneateles, N. Y., on December 11, 1874, the son of Lewis P. and Harriet (Daniels) Moreland. After leaving public school he began to learn the machinist's trade with the Straight Line Engine Company, of Syracuse, N. Y., but soon decided that he would prefer toolmaking. He therefore transferred to the E. E. Stearns Co., Syracuse, and there and in other shops learned the trade.

In 1898 he entered the employ of the Oliver Typewriter Company, at Woodstock, Ill., as a toolmaker, and soon was placed in charge of of the department. As the company had no drafting or designing department, he made what drawings were required. After six years with the company, he became foreman of the tool designing, experimental, and toolmaking departments of the Illinois Sewing Machine Company, at Rockford. Later he was made assistant superintendent in full charge of all departments, including the foundry and patternmaking.

In 1908 Mr. Moreland went to Providence, R. I., taking charge of the machine department of the American Locomotive Automobile Company, and later of its toolroom and grinding department. The following year he became tool supervisor of the Warner Gear Company, Muncie, Ind., with which he was connected until 1915. One of the special machines which he designed for the company was an automatic machine for inserting corks into clutch plates for automobile clutches.

After leaving the Warner company, Mr. Moreland spent a year with the Remington Arms Company, at Eddystone, Pa., as assistant superintendent of the tool department, and two years with the British Munitions Company, of Montreal, Canada, as master mechanic in the fuse loading and assembling plant.

In 1918, when the World War was nearly over, Mr. Moreland went to Trenton, N. J., to become chief engineer and designer of the John E. Thropp's Sons Co. Among the designs made for the company by him were a special machine for engraving non-skid designs in tire molds, a fabric-spooling machine for taking the fabric from the bias cutter, a special banding machine, and a collapsible core and chuck. He had been with the company about ten years when he became production engineer for the Worthington Pump & Machinery Corp.

Mr. Moreland became a member of the A.S.M.E. in 1923, and belonged to the Engineers Club in Trenton and to the masonic fraternity. He is survived by his widow, Emma J. (Chappel) Morelan i, whom he married in 1899, and by a son, Lester D. Moreland.

GEORGE WILLIAM MORETON (1860–1934)

George William Moreton, who died in Wilmington, Del., on March 2, 1934, after a year's illness, was English by birth. The son of John and Annie (Smith) Moreton, he was born on July 23, 1860, at Minshull Vernon, Cheshire, England. He secured his early education at public schools in Crewe and Birmingham and later was a science and art student at the Crewe Mechanics Institute, and winner of a Whitworth Scholarship in 1885.

Mr. Moreton began work as an office boy for the London and Northwestern Railway in Birmingham at the age of fourteen, and three years later was transferred to its shops at Crewe as an apprentice. He completed his training in 1881 and continued to work for the company as machinist and draftsman until he came to the United States.

Mr. Moreton's first employment in this country was with the Pond Machine Tool Company, Plainfield, N. J., with which he was connected as draftsman from 1888 to 1892. He then engaged in similar work for the Betts Machine Company, of Wilmington, of which he became general superintendent in 1898, and later served also as secretary and vice-president. When the company was sold, during the World War, becoming the Betts Shops of E. I. duPont de Nemours & Co., Mr. Moreton was retained as superintendent and consulting engineer for several years. Since then he had been associated with the Consolidated Machine Tool Corporation of Rochester, N. Y., as consulting engineer and manager of the Hilles & Jones plant in Wilmington.

Mr. Moreton became a member of the A.S.M.E. in 1909. He also belonged to the Wilmington Country and Wilmington Whist Clubs and the Whitworth Society of England. He was a director of the Artisans Saving Fund, Wilmington, and a member of Trinity Church there. He is survived by his widow, Hilda W. (Brotherhood) Moreton, whom he married in 1906, and by two children, John B. and Winnifred Moreton.

THOMAS MORRIN (1853–1934)

Thomas Morrin, son of John and Mary Morrin, was born at Waterloo, N. Y., on August 6, 1853, and died at his home in San Francisco, Calif., on August 1, 1934. He attended public school in Waterloo and at the age of fifteen began an apprenticeship at the Island Works in Seneca Falls, N. Y., where steam fire engines were manufactured. After the completion of his apprenticeship in 1871 he worked for fifteen years as a machinist, being employed in Bay City, Mich., and San Francisco and Marysville, Calif.

In 1886 Mr. Morrin became master mechanic for the Carson & Tahoe Lumber & Co., at Glenbrook, Nev., where he had full charge of railroad, steamboat, and sawmill machinery. Two years later he accepted a similar position with the Western Beet Sugar Company in Watsonville, Calif., where he remained until July, 1890. During the next two years he was foreman in charge of the construction of a machine shop, then became master mechanic and chief engineer for the D. O. Mills properties in and near San Francisco, a position which he held until 1908.

Mr. Morrin also practiced independently as a consulting mechanical engineer from 1904 until 1928, when he practically retired, though he continued to act as supervising engineer for the Phelan estate, San Francisco, until the date of his death.

Mr. Morrin became a member of the A.S.M.E. in 1897 and belonged to the Engineers Club in San Francisco. He was especially interested in fine cabinet work in mahogany and walnut, and took walking trips into the Sierra Nevada Mountains. He is survived by a daughter, Miss Mary Irene Morrin. His wife, Irene (Hoyt) Morrin, died in 1916.

VICTOR EMANUEL MUNCY (1860–1934)

Victor Emanuel Muncy, whose death occurred at Ashland, Ky., on October 26, 1934, was born at Louisa, Ky., on December 1, 1860, the son of Samuel K. and Teresa (Carter) Muncy. After teaching at the Academy of the State (Agricultural and Mechanical) College of Kentucky for a time, he became interested in engineering. He received a B.S. degree from the college in 1891 and secured a position there as teacher in elementary mathematics and physics. He continued in that position until 1905, except during 1900–1901, when he served as business agent for the college.

He joined the faculty of the Ohio Mechanics Institute in 1905 as instructor in applied electricity and physics. He was given an M.S. degree by the State College of Kentucky in 1907, and during the scholastic year 1907–1908, on leave of absence from Ohio Mechanics Institute, he took a course in electricity and power plant engineering at the State University of Kentucy which brought him a B.M.E. degree in 1908. He then returned to his duties at Ohio Mechanics Institute, where in 1911 he was appointed dean of the School of Mechanics and Electricity, later becoming head of the Department of Physics and Electricity. He resigned in 1930 after a severe illness. The State University of Kentucky conferred an M.E. degree upon him in 1913.

Professor Muncy became a member of the A.S.M.E. in 1914. He also belonged to the American Institute of Electrical Engineers, the Illuminating Engineering Society, the Royal Society of Arts, American Association for the Advancement of Science, the Engineers Club of Cincinnati, and Tau Beta Pi, honorary engineering fraternity.

Professor Muncy's first wife, Emma (Garred) Muncy, died in 1893, two years after their marriage. He was separated by divorce in 1913 from Mary O. (Hodges), whom he married in 1908.

HENRY HOTCHKISS MURRAY (1871–1934)

Henry Hotchkiss Murray, mechanical engineer and manager for the Mechanical Improvements Corporation, Camden, N. J., died at the Burlington County Hospital, Mount Holly, N. J., on February 28, 1934. Mr. Murray was born at Viola, Kent County, Del., on March 16, 1871, the son of George Henry and Olive I. (Purinton) Murray. He prepared for college at the Hillhouse High School, New Haven, Conn., and was graduated from the Sheffield Scientific School of Yale University with a Ph.B. degree in 1893. The following year he did post-graduate work there in mechanical engineering and was an assistant instructor in shop visiting.

From 1894 to 1906 Mr. Murray was draftsman for McIntosh, Seymour & Co., Auburn, N. Y., with the exception of the first six months of 1896, when he served as acting professor of mechanical and electrical engineering at Delaware College, Newark, Del. From 1906 to 1930 he was connected with the Victor Talking Machine Company, Camden, serving in the capacities of designer, chief draftsman, mechanical engineer, chief engineer, consulting engineer, and manager of the field technical service. He had been with the Mechanical Improvements Corporation since 1930.

Mr. Murray held many patents pertaining to the improvement of the talking machine and a number for camera cases for underwater photography. He was very active in the community of Riverton, N. J., where he made his home. From 1915 to 1923 he was a member of the borough council; from 1916 to 1923, chairman of the Memorial Park Committee; from 1917 to 1934, director of the Cinnaminson Building and Loan Association; from 1926 to 1932, director of the Cinnaminson Bank & Trust Co.; and in 1932–1933, member of the Riverton Board of Education. He served as chairman of the committee on the location of the Philadelphia-Camden bridge of the Camden Chamber of Commerce in 1921, and during the World War was active in Riverton in connection with the sale of liberty bonds and other war work. At that time he was in charge of airplane parts, gun stocks, etc., manufactured by the Victor Talking Machine Company.

Mr. Murray became a junior member of the A.S.M.E. in 1899 and a member in 1905. He also belonged to The Franklin Institute, Yale Engineering Society, Union League of Philadelphia, Society of Colonial Wars, Riverton Country Club, and Yale Club, New York. He married Miss Georgiana Groot in 1898 and is survived by her and their daughter, Cornelia Groot Murray.

ALFRED NATHAN (1866–1933)

Alfred Nathan, president of the Nathan Manufacturing Company, New York, N. Y., died at the Presbyterian Hospital in that city on May 22, 1933, following an operation. He was a native of New York, where he was born on November 21, 1866, the son of Max and Rosalie Nathan.

Following his graduation from Stevens Institute of Technology with an M.E. degree in 1890 he became assistant mechanical engineer for The Geo. F. Blake Manufacturing Co., a position which he held until 1897. He had been associated with the Nathan Manufacturing Company since then, as assistant secretary until 1903, and vice-

president from that time until he became president of the company in 1909.

Mr. Nathan had been a junior member of the A.S.M.E. since 1891. He belonged to the Beta Theta Pi and Sigma Alpha Epsilon fraternities, and to a number of clubs in New York and vicinity, including the Uptown and Criterion clubs, and the Deal and Hollywood golf clubs. He is survived by his widow, Mabel E. (Lauer) Nathan, whom he married in 1892, and by a son, Alfred Nathan, Jr.

HAROLD VAN HOUTEN NEEFUS (1883–1934)

Harold Van Houten Neefus, for many years associated with Francisco and Jacobus, engineers and architects, New York, N. Y., died in Greenwich, Conn., on August 23, 1934, of pneumonia.

Mr. Neefus was born in Newark, N. J., on August 21, 1883, the son of Henry Freeman and Olive (Van Houten) Neefus. After being graduated from the Stevens Institute of Technology with an M.E. degree in 1904, he was employed for three years as a draftsman by the Public Service Corporation of New Jersey. During the next two years he engaged in experimental work, including drafting and shop work, for the Blevney Machine Company, Newark. In 1909 he took a position as assistant to the secretary and general manager of the Foos Gas Engine Company, with which he remained until 1911. He then went to Buffalo to take charge of manufacturing and sales for the Bogart Gas Power Company. In 1914 he became mechanical engineer for the Northern Division, including six plants, of The Texas Company, New York.

During the World War, from 1916 to 1918, Mr. Neefus was engaged in the production of munitions at the Canada Car & Foundry Co. Subsequently he served for two years as special engineer for the City of Chicago in connection with the electrification of the Illinois Central Railroad and the development of the Union Station. He became connected with Francisco and Jacobus in sales and promotion work in 1920 and later was put in charge of the Chicago office and mid-west territory. At the time of his death he was serving as manager for the Eastern District, New Jersey Department, of the Home Owners Loan Corporation, with headquarters at Newark.

Mr. Neefus became a member of the A.S.M.E. in 1915 and belonged to the Delta Tau Delta fraternity. His wife, Grace (Berger) Neefus, died the year following their marriage in 1910. He is survived by a son, Van Houten Neefus.

VICTOR ROBERT NELSON (1898–1934)

Victor Robert Nelson, whose death occurred on October 3, 1934, was born in Cleveland, Ohio, on June 3, 1898, the son of Niels and Annie (Madsen) Nelson. During the summer after his graduation from the Central High School in Cleveland he was employed by the Linde Air Products Company, and he spent subsequent vacations, while attending the Case School of Applied Science, working in various shops for practical experience. He was a member of the Reserve Officers Training Corps at the School in 1917–1918.

In the summer of 1920, followng his graduation with a B.S. degree in mechanical engineering, Mr. Nelson was employed by Van Dorn & Dutton Co., Cleveland, in connection with production routing and time records. In the fall he secured a position in the U.S. Ordnance Engineer's Office in Cleveland, working under the supervision of the resident engineer on the design and specifications for an artillery tractor and other equipment. After he had been there about a year the Cleveland office was discontinued and he was transferred to the Rock Island Arsenal, where he continued in similar work until March, 1922.

He then returned to the Van Dorn & Dutton Co., which in 1928 became a division of Gears & Forgings, Inc. His early work for the company was in the sales and estimating departments. He then became production supervisor and at the time of the merger was put in charge of the organization of a department combining and coordinating the work of the order and production departments, and certain phases of the work of the engineering department. He continued to serve as production engineer for the company until his death, increasing his knowledge in this field by a course in industrial management through the LaSalle Extension University.

Mr. Nelson became an associate-member of the A.S.M.E. in 1931. He had served as a member of the local Committee on Apprenticeship of the National Metal Trades Association, the Committee on Standards of the Cleveland Engineering Society, the Production Standards Committee (as chairman) of the Associated Industries of Cleveland, and the Production Executive Committee of the Cleveland Chamber of Commerce. He belonged to the masonic fraternity.

Mr. Nelson married Miss Ruth Ellen Heininger in 1926 and is survived by her and by two daughters, Margaret Ellen and Karen Elizabeth Nelson.

FRED NOLDE (1874–1934)

Fred Nolde, secretary and treasurer of the Refrigerating Machinery Association, Philadelphia, Pa., died at his home in that city on December 19, 1934. He was born at Norristown, Pa., on January 16, 1874, the son of Henry and Caroline Nolde. He attended the Central High School in Philadelphia and then the Drexel Institute there, from which he was graduated with a B.A. degree in 1891.

Following his graduation Mr. Nolde took a position as draftsman for the Pennsylvania Iron Works Company in Philadelphia. He remained with this company until 1903, being advanced to the position of chief draftsman and sales engineer, and engaging in the design, construction, operation, and sales of cable railroad machinery, steam engines, hydraulic machinery, ice making and refrigerating machinery, and gasoline engines. During the next year he was connected with James Beggs & Co., selling power machinery in New York, and after that held a similar position with the Allis-Chalmers Manufacturing Company, in the Philadelphia district.

From 1905 to 1927 Mr. Nolde was associated with the De La Vergne Machine Company, as sales engineer, chief engineer, and manager in New York until 1926, when he became consulting engineer to the company, with headquarters in Philadelphia. After about two years in that position he became eastern sales agent for the Vilter Manufacturing Company, of Philadelphia, a position which he held until he took the office of secretary and treasurer of the Refrigerating Machinery Association in October, 1927, first on a part-time basis and latterly as a full-time occupation.

Mr. Nolde became a junior member of the A.S.M.E. in 1901. He resigned in 1910 and was reinstated in 1918 as a full member. He was also a member of the American Society of Refrigerating Engineers and belonged to the masonic fraternity and to a number of clubs, including the Engineers' and Bankers in New York. He married Miss Hedwig P. Haenchen in 1913 and is survived by her and their son, Fred Nolde, Jr.

ARVID NORDIN (1881–1933)

Arvid Nordin, whose death occurred on July 19, 1933, had been associated with the M. H. Treadwell Co., New York, N. Y., for nearly twenty years.

Mr. Nordin was born on July 30, 1881, at Westkinde, Sweden, and was educated in that country. After being graduated from the college at Venersborg he studied mechanical engineering for three years at the Polytechnic Institute at Gothenburg. During his college vacations he worked as an apprentice machinist and boilermaker at the Eriksbergs Mechanical Works, Gothenburg, and Nydqvist & Holm Locomotive Works, Trollhattan.

Mr. Nordin came to the United States in 1901 and during the next four years worked as draftsman and designer-checker for the Niles-Bement-Pond Company, Philadelphia, Pa., Westinghouse Electric & Manufacturing Co., Pittsburgh, Pa., Carnegie Steel Company, Sharon, Pa., Allis-Chalmers Company, Milwaukee, Wis., Illinois Steel Company, South Chicago, and Sargent & Lundy, Chicago, Ill. From 1905 to 1912 he was connected with the Tennessee Copper Company, Copperhill, Tenn., in the positions of designer-checker, chief draftsman, and mechanical engineer. From then until he took up his work with the Treadwell organization he was engineer for the Link-Belt Company, Chicago.

During his association with the M. H. Treadwell Company, Mr. Nordin devoted a large measure of his ability and energy to the development of the various items of hydraulic equipment which they manufacture. He was the inventor of many improvements in the design and details of spillway and intake gates, hoists and accessory equipment, and held many valuable patents on these improvements. As contracting engineer for the company, he enjoyed an unusually wide acquaintance among hydraulic engineers and in the hydroelectric power industry in general. In recognition of his ability and accumulated experience with respect to hydraulic equipment, his advice and opinions were in constant demand.

Mr. Nordin became a member of the A.S.M.E. in 1913. He is survived by his widow, Ruth L. Nordin, of Allegan, Mich., and by a son, John Arvid Nordin.

EDWARD WILLIAM O'BRIEN (1883–1934)

Edward William O'Brien, who died at St. Joseph's Hospital in Providence, R. I., on August 4, 1934, was born in that city on November 29, 1883. His parents were Edward and Mary (Lindsay) O'Brien. Mr. O'Brien attended the Technical High School in Providence and was graduated from the evening course at the Rhode Island School of Design in 1903. Later he took special courses at Franklin Union, Boston, and the Boston Y.M.C.A. in applied mechanics, hydraulics, and other subjects.

From 1903 to 1907 Mr. O'Brien was employed by Knight C. Richmond, engineer and architect of Providence, as a draftsman and designer, working on power plants and industrial buildings. He spent the next two years in Fitchburg, Mass., at the D. M. Dillon Steam Boiler Works, engaged in special work for the New England Boiler Manufacturers Association on boiler design standardization, and compiling a catalog for the company.

During the years 1910–1917, with the exception of about a year, he was associated with Charles H. Fish, consulting engineer of Boston, working part of the time in the office on the design of industrial buildings, and making appraisals and reports, and part of the time in the field, supervising construction. In 1913–1914 he was engaged by the General Electric Company at Lynn to design and serve as inspector during the construction of a reinforced-concrete storehouse.

The Harry M. Hope Engineering Co., Boston, employed Mr. O'Brien from 1919 to 1921, keeping him in the field the greater part of the time. He spent about eight months as general inspector during the construction of a large power plant in Connecticut, and more than a year in St. Louis, Mo., in connection with the construction and equipment of a power house and three eight-story reinforced-concrete buildings for the United Drug Company.

He was next connected with the American Printing Company, Fall River, Mass., as assistant to the plant engineer. His most important work for this company, with which he remained until 1930, was the supervision of the design, construction, and equipment of a large cotton mill in Tennessee, including the mill itself, and a storehouse, power plant, and pumping station, as well as some two hundred dwellings for mill operatives, with water and sewer systems.

Since 1930 Mr. O'Brien had been connected with the Public Buildings Department of the City of Providence, being second deputy to the inspector of public buildings, in charge of zoning, at the time of his death.

Mr. O'Brien became a member of the A.S.M.E. in 1927. He is survived by his widow, Gertrude (Curran) O'Brien, whom he married in 1926, and by two children, Margaret J. and Robert E. O'Brien.

SPENCER OTIS (1858–1933)

Spencer Otis, whose death occurred on June 10, 1933, was born in Orange, N. J., on February 26, 1858, the son of Daniel Carmichael and Clarissa Otis. He entered Amherst College in 1876 but was obliged to leave because of illness. The following year he secured work at a brick and terra cotta factory in Louisville, Ky., and in 1877 he began an apprenticeship with the Union Pacific Railroad at its Omaha, Neb., shops. Upon the completion of his training he worked for that road for some years, advancing to the position of master mechanic.

In 1888 he became general manager of the Kansas City Switch & Frog Co., and two years later president of the Phoenix Foundry Company. He engaged in consulting work, beginning in 1891, and five years later organized the Spencer Otis Company, of Chicago, manufacturers and agents for railway supplies. He served as president of this company until its sale some twelve or fifteen years later. For a number of years, beginning in 1892, he was also president of the National Dump Car Company, Chicago, which in 1904 was combined with the Rodger Ballast Car Company, with Mr. Otis as vice-president. He held many patents pertaining to railway cars and equipment.

About 1902 Mr. Otis became interested in large-scale farming, and much of the latter part of his life was devoted to it, especially to the development of pastures in the Middle West. His chief engineering connection in recent years was with the National Boiler Washing Company, of which he became president in 1919, and the Locomotive Terminal Improvement Company, which he formed in 1925 to manufacture plants for the former company, and to develop and build plants for locomotive terminals. At the time of his death he had retired and was residing in Waco, Texas, with a married daughter.

Mr. Otis became a member of the A.S.M.E. in 1890 and also belonged to the Western Railway Club, the Union League Club, Chicago, and Barrington Hills Country Club.

He was twice married, his first wife, Eleanor G. Beard, dying in 1885 and his second, Julia Melchers, in 1902. He is survived by one son, Spencer Otis, Jr., of Chicago, and by five daughters.

GEORGE BAILEY PAGE (1887–1934)

George Bailey Page, Philadelphia district manager for The Terry Steam Turbine Company, of Hartford, Conn., died at his office from a hemorrhage on September 10, 1934. His widow, Helen (Ferguson) Page, whom he married in 1919, and two children, George F. and Jane Helen Page, survive him.

Mr. Page was born at Williamsport, Pa., on April 27, 1887, the son of Earnest A. and Sarah (Bailey) Page. He attended the Dickinson Seminary in Williamsport and was graduated from Cornell University with a mechanical engineering degree in 1911. He then served an apprenticeship at the DeLaval Steam Turbine Company, Trenton, N. J., and worked for the company in different capacities until early in 1916. During the next five years he was district engineer for the Rush Machinery Company, Pittsburgh, Pa., holding the honorary title of vice-president. In 1921-1922 he was Pittsburgh district sales engineer for the Underfeed Stoker Company of America and then held a similar position with the Sanford Riley Stoker Company for nearly two years.

Between then and 1926 Mr. Page was a member of the firm of Geo. B. Page & Co., in Pittsburgh, leaving there to become associated with B. F. Sturtevant Co., New York. He had been with The Terry Steam Turbine Company since January 1, 1932. He was well versed in both sales and installation work in his field.

Mr. Page became an associate-member of the A.S.M.E. in 1924, and had belonged to the Engineering Society of Western Pennsylvania and the Association of Iron and Steel Electrical Engineers, and to Alpha Chi Rho fraternity.

GEORGE EDWARD PERKINS (1877–1934)

George Edward Perkins, who died at the Brooklyn Hospital on May 4, 1934, was born in Newburyport, Mass., on November 23, 1877, the son of George Collyer and Sarah (Hinckley) Perkins. He attended high school in Amesbury, Mass., for three years, and then found work in the boiler and dynamo rooms of the electric light company there. From June, 1900, to November, 1902, he secured varied experience as operating engineer and electrician in resort hotels in New England and Florida. He then became operating engineer in charge of the steam plant of W. W. Cross & Co., Inc., Brockton, Mass., with which he remained until 1909, and subsequently held a similar position with the T. D. Barry Co., also in Brockton.

Mr. Perkins entered the employ of the Fidelity & Casualty Co. of New York, in November, 1911, as a boiler inspector. About a year later he was transferred to the home office of the company as assistant to the chief boiler inspector. He remained with the company until the end of January, 1920, his work in connection with the inspectors and the insured requiring a knowledge of the design, construction, and operation of steam boilers and engines. Since then he had been assistant engineer, in the Engineering Department, of the Royal Indemnity Company, New York, his duties being similar to those of his previous position, but involving more responsibility.

Mr. Perkins became a member of the A.S.M.E. in 1925, and was active in the masonic fraternity and Odd Fellows, holding several offices. He is survived by his widow, Alice L. (Duston) Perkins, whom he married in 1904, and by a daughter, Helen M. Perkins.

GEORGE SIMEON PERKINS (1868–1933)

George Simeon Perkins, who had been engaged in contracting and superintending construction in and about San Francisco, Calif., for some years, died suddenly on June 21, 1933, at his home in Oakland, Calif. He had been in failing health for two years.

Mr. Perkins was born at Bridgeport, Conn., on August 14, 1868, the son of George B. and Maryetta (Blood) Perkins. After completing his high school course in that city he attended the Stevens Institute of Technology, Hoboken, N. J., securing a degree in mechanical engineering in 1891. During the next six years he worked for the Dow Typesetting & Composing Co., New York, the Philadelphia Traction Company, and the East Jersey Water Company, in connection with the installation of pumping engines at Little Falls, N. J. Subsequently he was employed by the Ingersoll-Sargeant Company, on central station air plants, and by several portland cement plants no longer in existence, including the Pacific, Hecla, and Midland.

Mr. Perkins became a member of the A.S.M.E. in 1926. He is survived by his widow, Adela B. Gayer, and by three children, Daniel Carter, George Stephen, and Mary Gayer Perkins.

JOHN McCLARY PERKINS (1878–1934)

John McClary Perkins, treasurer of the Wittenmeier Machinery Co. of N. Y., New York, N. Y., died in the New York Hospital on August 10, 1934, of pneumonia.

Mr. Perkins was born in Washington, D. C., on September 4, 1878, the son of John McClary and Lucy (Flagg) Perkins. He attended high school at Arlington, Mass., and was graduated from the Massachusetts Institute of Technology in 1901. During the next three years he worked in the steel foundries of the Everett, Mass., branch of the General Electric Company, becoming a foreman molder. He

then took a position as foundry superintendent at the Saco-Lowell Shops, where he installed a complete foundry accounting and cost system and put the foundry on a piece-work basis. He left there in 1909 to build, equip, and put into operation a foundry for the Chalmers Motor Company.

From 1911 to 1916 he was connected with Turner & Seymour, Torrington, Conn., first as foundry manager, and for the last three years as sales manager. He then became works manager of the Gilbert & Barker Manufacturing Co., a subsidiary of the Standard Oil Company, and put into successful operation there the conference committee plan later adopted by all branches of the Standard Oil. In 1919 he went to the Kewanee Works of the Walworth Manufacturing Company, where he settled a strike and formed a conference committee. He became manager of the McNab & Harlin Manufacturing Co., Paterson, N. J., in 1921, and remained there until about 1923, when he became treasurer of the Lapham-Perkins Engineering Company, of New York. He had been treasurer of the Wittenmeier Machinery Company since 1926.

Mr. Perkins became a member of the A.S.M.E. in 1923, and was a former president of the Refrigeration Association of New York. He also belonged to the masonic fraternity, Elks, and New York Rotary Club. He is survived by his widow, Floye (Dinwiddie) Perkins, whom he married in 1906, and by a son, Wilkes D. Perkins.

ARTHUR FRENCH POOLE (1872–1934)

Arthur French Poole, who had been granted many patents for his inventions in connection with electric clocks and adding machines, died at his home in Ithaca, N. Y., on April 26, 1934, after a short illness.

Mr. Poole was born in Cumberland, Md., on August 21, 1872, son of Arthur A. and Virginia (French) Poole. He received his early education there. Later the family moved to Washington, Pa., where he learned the watchmaker's trade under his father, then entered Washington and Jefferson College, with the class of 1891, and studied there for three years. Having become interested in the newly founded Leland Stanford Jr. University, he went there in 1894, taking an A.B. degree in astronomy in 1896. At Stanford he made use of his watchmaking training to work his way through college. He also spent considerable time at Lick Observatory.

Mr. Poole returned to Pennsylvania after his graduation and went to work as a draftsman for John Brashear, noted maker of telescope lenses and scientific instruments, at Alleghany. He left in 1897 to work on a clock system of his own invention and in 1899 formed the Poole Clock Company, Wheeling, W. Va., to manufacture the clock. The company was dissolved in 1902, because of business conditions. His interest turning to electrical work, he joined the Mountain State Electric Company, of Wheeling, to do development work in connection with automatic telephones, and party line systems. Many of his early patents reflect his work here.

In 1908 Mr. Poole went to Chicago, Ill., where for several years he engaged in special development and research work. He worked for Jackson and Jackson on a workmen's time register, for the Holtzer Cabot Company, of Boston, on a frequency meter, and independently on a speedometer. In 1911 he took charge of the patent and development department of the Wahl Adding Machine Company there, and some of his most brilliant work was done in the development of adding machine attachments for typewriters. In 1918 the company acquired patents on automatic pencils, which enabled it to develop and market the Eversharp pencil, and Mr. Poole's inventive genius assisted materially in this work. He was made a director and vice-president of the company in 1920, and two years later, when the Remington Accounting Machine Corporation, a subsidiary of the Remington Typewriter Company, was formed to take over the Wahl adding machine business, he went to New York as vice-president and general manager of the new organization. He remained active as a director of the Wahl company, however, until his death.

Perhaps due to his early training, he was always deeply interested in clocks, especially electric clocks and electric clock systems. His first patent, granted in 1899, was for an electric clock. He was a pioneer in the development of the synchronous motor clock, and methods of frequency control for them, and many of the earliest patents in this field were granted to him. In 1924 he formed the Poole Manufacturing Company for the purpose of making a battery clock of his invention. He established a factory at Westport, Conn., and manufactured these clocks there until 1926, when the business was affiliated with the Morse Chain Company, of Ithaca, N. Y., and moved to Ithaca. His work in inventing and designing this clock led The Franklin Institute to award him a Certificate of Merit in 1933.

Mr. Poole retired from active business in 1931, but continued in development work. At the time of his death he had many patents pending in the patent office. Since his first patent was granted in 1899, he had received more than one hundred, chiefly in the adding machine and electric clock fields.

Like many scientists, Mr. Poole was a lover of music. He had a large collection of symphonic scores, played the 'cello and piano, and while in Chicago was a member of a string quartet.

Mr. Poole became a member of the A.S.M.E. in 1921 and also belonged to The Franklin Institute.

Surviving Mr. Poole are his widow, Maryline (Barnard) Poole, whom he married in 1904; two daughters, Mrs. Martin D. Hardin, Jr., of New York, N. Y., and Miss Elizabeth Poole, of Ithaca; and three sons, Frank and John Poole of Ithaca, and Arthur B. Poole, of Bristol, Conn.

WILLIAM BANCROFT POTTER (1863–1934)

William Bancroft Potter, for many years engineer for the railway department of the General Electric Company, Schenectady, N. Y., died at his home in that city on January 15, 1934. Mr. Potter was one of the best known electric traction engineers in the United States. His career went back prior to 1890, when electric street cars were still struggling to overcome technical difficulties and public prejudice. His contributions to the electric traction art were substantial and long continuing. Many of them were covered by the 130 patents which had been issued in his name.

Mr. Potter was born on February 19, 1863, at Thomaston, Conn., the son of Horace and Charlotte (Pierce) Potter. He gave early evidence of his mechanical aptitude and during the latter years of his school life spent his vacations working in the Seth Thomas clock factory. After completing the Thomaston high-school course he served an apprenticeship as a machinist with Sawtell and Judd, in Hartford, Conn. He continued with that company for two years after the completion of his apprenticeship, securing further training in machine shop and steam engineering work. While repairing stationary engines at the plant of the Hartford Electric Light Company he became interested in electrical apparatus. He foresaw that the development of the electric dynamo would have a marked influence upon the future of the steam engine, and this trend in his thinking led him to study dynamos and electric generating stations. In the summer of 1887 he entered the employ of the Thomson-Houston Electric Company, Lynn, Mass. After a period of shop training he was sent into the field to adjust trouble in electric light plants which the company had installed, and served for a time as superintendent of the electric light company at Raleigh, N. C.

In the fall of 1889, having seen his first electric street car, he returned to Lynn and became a shop student in electric traction work. This was again supplemented by practical experience in the field, particularly on the West End Street Railway Company's system in Boston, and others of less importance.

Later, returning to the Lynn plant, he aided in the development of the Thomson-Houston single-reduction motor for street cars, and when Walter H. Knight was appointed engineer of the railway department he became Mr. Knight's principal assistant. He was active in working out railway circuit breakers, fuse blocks, lightning arresters, and switches. The most serious problem in electric railway work at that period was the matter of an efficient controller for electric cars. Knight and Potter both worked on this, and ultimately they solved the problem by the invention of the series-parallel controller, which became the basic method in use all over the country from that time forward. Mr. Potter's part in the development of the controller led to his being placed in charge of all control work for street railways.

In 1894, when the Thomson-Houston Electric Company became part of the General Electric Company, Mr. Potter was transferred to Schenectady, and in 1895 he was appointed engineer of the railway department, succeeding Mr. Knight. He continued in this position until his retirement in 1930. In that long interval he witnessed and aided materially the tremendous expansion of electric traction in the street railway and interurban field, and also participated in the earliest installations of electrical equipment upon the lines of steam railroads.

The major projects in which he was associated were the electrification of the Manhattan Elevated Railway of New York, the electrification of the Grand Central Terminal, and the Paris and Orleans railroad in France. Other projects with which he was prominently identified included the West Jersey and Seashore, Detroit tunnel, Great Northern Railroad, Southern Pacific, Butte, Anaconda and Pacific and Milwaukee, Chicago, St. Paul and Pacific railroads.

A suggestion made by Mr. Potter in the spring of 1896 resulted in the establishment of the old General Electric test railroad, or test track, along the berm bank of the Erie canal, stretching outward from the local General Electric plant about a mile and a half. There all tests of electric railway equipment were conducted until 1919, when the berm bank track was discontinued.

On this track were tested early types of gas-electric rail cars, some of which later went into commercial service on eastern railroad lines. Mr. Potter participated in many of these test trips and had an active part in directing the development of the propulsion equipment for these cars.

Possibly his most valuable work within the General Electric Company during latter years had been his organization and development of a great engineering staff for electric railway and electric railroad work. His supervision of the department of which he was the head was practically an unbroken stretch of harmonious relations.

Mr. Potter became a member of the A.S.M.E. in 1897. He also belonged to the American Society of Civil Engineers, American Institute of Electrical Engineers, and Society of Naval Architects and Marine Engineers. He served as a member of the A.I.E.E. traction and transportation committee during 1916–1917, 1919–1921, and 1923–1924; its transportation committee, 1925–1932; and its education committee the year before his death. He had contributed many articles to the technical societies.

Mr. Potter had been interested for many years in community life and the development of Schenectady. He particularly followed the fortunes of the Schenectady Civic Players. He was a man of various hobbies, which gave him a means on many occasions of delighting his friends. He was a consistent radio enthusiast from the early days of the art, and had done independent research and development work on a type of radio receiver.

Mr. Potter's club memberships included the Engineers', Transportation, and Railroad, New York; Mohawk, Mohawk Golf, and Edison, Schenectady; and Griswold, Erie. He was twice married, his first wife being Loretta Harward, of Raleigh, N. C., whom he married in 1890, and his second, who survives him, Rose Hubbard, formerly of Sandusky, Ohio, whom he married in 1912. A daughter, Dorothy (Potter) Bird, also survives him.

THOMAS PROSSER (1854–1934)

Thomas Prosser, senior member of the firm of Thomas Prosser & Son, metal dealers, New York, N. Y., died on December 23, 1934, at his home in Garden City, L. I., N. Y., after a long illness. A daughter, Mrs. John Good, and a son, Thomas H. Prosser, both of Garden City, survive him, as do three sisters and four brothers.

Mr. Prosser, who was the eldest of eleven children, was born in Brooklyn, N. Y., on August 24, 1854. He attended the Lafayette and Brooklyn Polytechnic Institutes and at the age of twenty-one became a member of the firm, which was established by his grandfather. He made frequent trips abroad in connection with business for the Krupp Steel Works, of Essen, Germany, for which the firm became American representative in 1848, and also traveled extensively in the United States.

Mr. Prosser became a member of the A.S.M.E. in 1893 and also belonged to the Railroad and Engineers Clubs and the Chamber of Commerce of New York.

FREDERICK GEORGE PROUTT (1870–1934)

Frederick George Proutt, consulting engineering and chairman of the City Board of Water Commissioners of Memphis, Tenn., died in that city on May 27, 1934, after an illness of six months. Mr. Proutt was born at Bowmanville, Ont., Canada, on November 27, 1870, the son of Mark James and Martha (Burke) Proutt. His mother died at his birth. He secured his early education in Canadian public schools and at the age of seventeen entered the employ of the Canadian Bell Telephone Company. He worked there until 1890, when he took a position as superintendent of the Bowmanville Electric Light Company.

In 1892 Mr. Proutt came to the United States and for two years studied electrical engineering at the works of the General Electric Company at Lynn, Mass. Upon completion of the course in 1894 he became chief electrician and assistant to the general manager of the Malden Electric Company, Malden, Mass. He left New England in 1897, accepting the position of chief electrician of the Memphis Consolidated Gas & Electric Co., of which he later became general superintendent. During the nine years he spent with this company he designed plans for and supervised the installation of the first extensive underground conduit system for distribution of electricity in the city.

In 1906–1907 Mr. Proutt was general manager for the Electric Railway Light & Power Co. at Jackson, Miss., for which he designed and installed electric power and gas plants. He returned to Memphis at the beginning of 1908 and opened an office for consulting engineering practice, specializing in the design and management of public utilities. He designed a number of plants in Arkansas, Mississippi, and Tennessee, including light and heat plants for the University of Mississippi, Light and Power for the Brownsville Cotton Oil & Ice Co., water works and sewage disposal systems for the city of Brownsville, and other public utility plants at Friar Point, Laurel, and Cleveland, Miss., and at Blytheville, Osceola, and Luxora, Ark., as well as private installations in Memphis and vicinity.

In May, 1917, during the World War, Mr. Proutt entered the First Officers Training Camp at Chickamauga Park, Ga. He was commissioned a captain of engineers but subsequently discharged because of defective eyesight. He was then appointed consulting engineer for the War Finance Corporation at Washington, D. C., and devoted two years to Government work in this civil capacity, part of the time being spent in Washington and the remainder in Memphis. His work included a survey of Tennessee industries for the Naval Consulting Board.

Mr. Proutt became chairman of the Memphis City Board of Water Commissioners in 1920, and held that office until his death. His able representation of the city in 1920 in the appraisal of the plants of the Memphis Consolidated Gas & Electric Co., which were subsequently acquired by the Memphis Power & Light Co., led also to his selection in 1921 as consulting engineer for the State Railroad and Public Utilities Commission of Tennessee; this connection also continued throughout the remainder of his life.

Mr. Proutt had also served as president of the Consumers Water Company, at Blytheville, and as treasurer of the Home Light & Ice Co., at Cleveland. At the time of his death he was president of the Peoples Finance & Thrift Co., at Memphis, and a trustee of the William R. Moore School of Technology, and for five years he was a trustee of the Memphis and Shelby County Tubercular Hospital.

In 1914 Mr Proutt aided in organizing and was the first president of the Engineers' Club of Memphis. To all club activities he was generous with his time and resources, the Technical Education Fund, which since his death has been given his name, being his chief interest. He served as chairman of this fund from the time of its inception.

He was also a charter member of the Memphis Section of the American Institute of Electrical Engineers. He became a member of the A.S.M.E. in 1915. He was a vestryman at St. Luke's Episcopal Church in Memphis and had attained the highest degrees in Masonry.

Surviving Mr. Proutt are his widow, the former Miss Laura J. Yarnold, of Whitby, Ontario, Canada, whom he married in 1895, and a daughter, Miss Jean Proutt. A younger daughter, Marjorie, died in 1925.

MARK ANTHONY REPLOGLE (1861–1934)

Mark Anthony Replogle, president of the Replogle Heater Company, Akron, Ohio, died at his home in that city on May 25, 1934, after a year of poor health. He was born at Martinsburg, Blair County, Pa., on September 8, 1861, son of Samuel B. and Margaret A. (Hanawalt) Replogle. His father was the inventor of an automatic buffer and coupling widely used on railroads. His childhood was spent in Mifflin County, Pennsylvania, where he attended the public schools. Subsequently he taught in the schools there for a time, then went to Iowa, where, after a period on a farm, he worked in machine shops in Hampton and Ackley.

In 1885 Mr. Replogle entered the Iowa State Normal School at Cedar Falls, where he took a three-year mechanical course, spending his vacations as representative of the Akron, Ohio, firm of Aultman Miller & Co. in the harvest fields around Cedar Falls. During the next two years he again taught school in Pennsylvania, then became associated with H. E. Olbrich and H. H. Clay, of Cedar Falls, in the manufacture and sale of water-wheel governors. In 1895 the manufacturing rights were purchased by the Selle Gear Company, of Akron, and the Replogle Governor Works was organized, with Mr. Replogle as chief engineer. The Selle Gear Company was later absorbed by the Webster, Camp & Lane Co., for which he became hydraulic engineer in 1899. In 1906 he organized the Lombard-Replogle Engineering Company, specializing in water-wheel governors. The Replogle Heater Company was formed in 1925.

Mr. Replogle's interest in water wheels went back to his childhood, when he made wheels which he tried out in neighborhood streams. From 1889 on he devoted himself to design in this and related fields. He held patents in the United States and other countries for his original inventions, which include a discharge gate for turbine wheels, an electrical governor, a mechanical speed governor, a sliding toggle, mechanical movements, and a smokeless home heater. He was associated with the design and construction of a number of water-power plants, including one at Sault Ste. Marie, Mich., while he was with the Webster, Camp & Lane Co., which was the largest erected in the United States up to that time. He furnished the governors and turned on the water that started the first turbines of the Niagara Falls Paper Company.

In 1894 he published a treatise entitled, "Electricity and Water-Power and Their Inter-relations," republished by the Electrical Re-

view Publishing Company, New York, in 1896, and his paper on "Speed Regulation in Water-Power Plants," prepared at the request of The Franklin Institute, was one of the earliest works in this country on that subject. Other papers by him have appeared from time to time in the technical press in this and other countries.

Mr. Replogle became a member of the A.S.M.E. in 1898. He was a 32d degree Mason. He is survived by a son, George B. Replogle, and by two daughters, Mrs. Edith (Replogle) Harley and Mrs. Wilhelmina (Replogle) Groff, all by his first wife, Emma H. (Steeley) Replogle. His second wife, Carrie (Pardee) Replogle, died in December, 1933.

MYRON B. REYNOLDS (1880–1934)

Myron B. Reynolds, city engineer of Chicago, Ill., died at the Edward Hines Hospital in that city on January 27, 1934, of cancer of the throat. He had been in the service of the city, in various capacities, since 1907, although inactive because of his illness for some time prior to his death.

Mr. Reynolds was born at Pana, Ill., on December 12, 1880. He entered college at Rose Polytechnic Institute in 1900 and spent two years there. He then worked for a year as draftsman on elevated railway rolling stock and structures in Chicago and a year in St. Paul, part of the time on bridge design for the Great Northern Railway and the remainder as draftsman in the Public Works Department of St. Paul. He reentered college as a junior at Armour Institute in 1904 and was graduated two years later.

Immediately following his graduation Mr. Reynolds entered the employ of the City of Chicago. During the next three years he worked as engineer in the Bureau of Engineering, in connection with tunnel construction, and as office assistant to the assistant city engineer. He then spent two years as superintendent of concrete bridge construction for a contracting engineer in Chicago. He returned to the employ of the city in 1911 in the position of assistant engineer of the Bureau of Engineering. After two years he was made engineer of water-works design and held that position until 1923, when he became assistant city engineer. In 1917 he was granted leave of absence for military duty and served as a major in the Corps of Engineers for about fifteen months, being stationed at several different camps in the United States.

In 1927, after the death of John Ericson, under whom he had been serving as assistant city engineer, Mr. Reynolds was called upon to fill the position of acting city engineer for several months and in 1931 he was appointed city engineer. Many of his recommendations have been adopted in modernizing the Chicago water-works system, particularly in connection with metering and filtration projects. He was senior author, with Arthur E. Gorman, city filtration engineer, of a paper on "Chicago's Water Pollution Problem, Past, Present, and Future," which brought him the award, just a few days before his death, of the medal of the Illinois Society of Engineers for the best paper published by one of its members in 1933.

Mr. Reynolds became a member of the A.S.M.E. in 1924. He also belonged to the American Water Works Association and was commander of a post of professional engineers of the American Legion in Chicago. He is survived by his widow, Irene Reynolds, and by a son, Myron, Jr.

PALMER CHAMBERLAINE RICKETTS (1856–1934)

Palmer Chamberlaine Ricketts, president and director of the Rensselaer Polytechnic Institute, which he had served as instructor to president during sixty successive years, and honorary member of the A.S.M.E., died at the Johns Hopkins Hospital, Baltimore, Md., on December 10, 1934.

From an institution of less than two hundred students he had seen Rensselaer grow to seventeen hundred students and from two buildings to twenty or more. For most of this growth he was largely responsible, owing to his scholarship, foresight, and administrative ability. Of the present buildings used by the Institute, only three were erected before his presidency. At present there are twelve distinct courses offered by the Institute, of which only one was offered at the time he undertook the direction of the Institute. This expansion has been the result of his conception of the field of endeavor of a true polytechnic institute.

Palmer Ricketts, the son of Palmer C. and Eliza (Getty) Ricketts, was born at Elkton, Cecil County, Maryland, on January 17, 1856. His early boyhood was spent in Maryland, but in 1865 after the death of his father the family moved to Princeton, N. J., and here he was prepared for college by Mr. John Howard O'Brien, a tutor in Latin of Princeton College, and entered the Rensselaer Polytechnic Institute in September, 1871, at the early age of fifteen.

His high scholastic record was remarkable and was gained while he participated in the student activities of that day. In 1875, at the age of nineteen, he received his degree of Civil Engineer with twenty-three other young men.

In 1874, during the student days of Palmer Ricketts, the Institute celebrated the Fiftieth Anniversary of its founding and from the student body of less than 200 members, eleven men received the degree of Civil Engineer in that year. The C.E. degree was the only degree conferred by the Institute at that time.

On account of his high scholarship Palmer Ricketts was offered an instructorship in mathematics and astronomy, which so appealed to him that he accepted this rather than entering at once into the practice of engineering in the activities of that day, although he carried on practical work in connection with his teaching, as assistant engineer of the Troy and Boston Railroad in 1876.

In 1882 he was made an assistant professor of mathematics and astronomy, and in 1884 he was appointed the William Howard Hart Professor of Rational and Technical Mechanics, which had previously been held by the late William H. Burr. The success of his teaching in structures and hydraulics was so outstanding that he was a consultant in bridge engineering of the Rome, Watertown, and Ogdensburg Railroad from 1887 to 1891, the engineer of the Public Improvement Commission of Troy from 1891 to 1892, the River Commission of Corning from 1897 to 1898, and the designer and supervisor of erection of a number of bridges and hydraulic structures.

His work at the Institute prepared him as an expert in patent cases and he presented testimony in important litigations between the years 1886 to 1897.

In 1892, after the resignation of Director D. M. Green, Palmer Ricketts, at the age of thirty-six, became the director of the Institute under the presidency of John Hudson Peck, a lawyer of the City of Troy, N. Y. The separation of the directorship from the presidency caused much difficulty in the management and development of the Institute, owing to the lack of understanding of the educational needs of the Institute by the presiding officer of the Board, so that the early days of Director Ricketts were filled with trips from the "Hill" to the city with requests and arguments. Fortunately, in 1901 the two offices were combined and Director Ricketts became president and director. Although president for the last thirty years he was always affectionately called "the Director," a title which his loyal friends used, and, we believe, he liked.

On November 12, 1902, Director Ricketts married Miss Vjera Conine Renshaw, of Baltimore, Md., and this wedding was marked by demonstrations of affection and admiration for the Director by the faculty and student body. This affection and admiration for him has been extended by the faculty and students to his wife, who entered into and shared all of his plans and activities during the full term of his presidency.

In 1904 the burning of the main building was the beginning of a new Institute, the monument to the ability, wisdom, and perseverance of Director Ricketts. Such a catastrophe as the fire is often a blessing in disguise. It proved so in this case. With the major part of the plant destroyed, an offer was made to transfer the Institute to a large university with the retention of the name of the Rensselaer Polytechnic Institute, but President Ricketts with his faculty determined to remain at Troy and build again on the foundations established three-quarters of a century before.

After a conference with the late Capt. Robert W. Hunt, Director Ricketts went to Andrew Carnegie and persuaded him to give $125,000 for a new building. Then money was raised to purchase the Warren House and grounds on Eighth Street and money was given by Mr. J. J. Albright for part of the cost of the William Weightman Walker Laboratory, named in memory of a graduate of the class of 1886.

Director Ricketts then persuaded Mrs. Russell Sage to give a sum of one million dollars to found a course in mechanical engineering as a memorial to her husband. This was in the year 1907 and at this time the Institute, under the guidance of the Director, inaugurated the courses in mechanical engineering and electrical engineering.

From here on the years have brought to the Institute gifts for buildings and endowment from alumni, friends, and citizens of Troy and an enlargement of its field of education. A recital of this progress would show the regard and trust which these donors have had in the man who indicated the needs of the institution which he had loved, served, and directed for more than a generation.

Following the introduction of courses in mechanical and in electrical engineering, the course in chemical engineering, and, subsequent to 1922, courses, in arts, science, and business administration, in physics, in chemistry, in biology, in architecture, in metallurgical engineering, in industrial engineering, and in aeronautical engineering have been added. A new building which will house the aeronautical, industrial, and metallurgical departments, will be called the Ricketts Building, in his honor.

In all of this development Director Ricketts was guided by the

thought of service. His theory of admissions and his desire to increase the work offered by the Institute was inspired by his desire to give to those who wanted an education in some field of technology a chance to prove their worth. He always thought that offering a chance to those who might make good was more important than the insistence upon formal admission examinations.

In the administration of the Institute, he was ever the champion of those who did not receive the "fair deal." Although believing in student activities and student life, he was not willing to have hazing or freshman rules interfere with the free life of every member of the student body. His stand against hazing came only when this form of student life went beyond bounds of decency, fair play, and even morality. He was ever willing to remain firm to his convictions, even under adverse criticism from students or alumni. His ability to handle student discipline was remarkable and effective. In its administration he had his fixed conviction, but his great sense of humor was a wonderful aid in this work.

He was interested in the possibility of aid, financial and scholastic, for the students needing such. To him personally many owe their graduation, for without his aid it would have been impossible to continue.

Director Ricketts stood for the highest scholarship from students and faculty, and never did he deviate from the motto of the Institute, "Knowledge and Thoroughness," in his administration of Institute educational policies. He insisted on the traditions of daily recitations, and topic work and even in the "scholastic amusements," as Amos Eaton called the work in the laboratories, the work had to be tested by final examination.

In 1924 the Institute celebrated the Centennial of its founding and Director Ricketts was most happy in the recognition which came to the Institute from governments, prominent engineers, and educational institutions of the whole world through the greetings of those in attendance at these extensive ceremonies.

Director Ricketts was active in civic affairs as shown by the positions held at the time of his death. He was a trustee and vice-president of the Troy Public Library, a trustee of Dudley Observatory of Albany, N. Y., of the Albany Academy, of the Albany Medical College, and the New York State College for Teachers. He was a director of the Samaritan Hospital of Troy and vice-president of the Rensselaer County Tuberculosis and Public Health Association. He was also a Director of the National City Bank of Troy.

In 1905 Stevens Institute of Technology conferred upon Director Ricketts the degree of Doctor of Engineering and in six years later New York University conferred the degree of Doctor of Laws upon him.

Director Ricketts was a member of the American Society of Civil Engineers for many years, a director in 1899–1901, and a vice-president in 1916–1917. His connection with The American Society of Mechanical Engineers extended over forty-four years, and in 1932 he was elected to Honorary Membership. Following this election by our Society he was also elected an honorary member of the American Society of Civil Engineers. He was a commander of the Order of the Crown of Italy and a Commander of the Legion of Honor (France). He was a fellow of the American Association for the Advancement of Science and a member of the American Philosophical Society. He was also a member of the American Institute of Mining and Metallurgical Engineers, the Institution of Civil Engineers of Great Britain, and Sigma Xi.

Director Ricketts has written two histories of the Rensselaer Polytechnic Institute and a number of papers have been contributed by him to the State Commission on Railroads and on Education, to the technical and daily press, and to the Proceedings of technical societies. In all of these he was a clear and forceful writer, free from all sham and uncertain expressions.

Not only was Director Ricketts a man of great foresight, administrative ability, and perseverance but he was a most helpful leader under whom to work. He would listen carefully to your plans and suggestions and then give you the authority to carry out plans which he approved. He never withheld praise for good work and in many cases where adverse criticism might have been offered by others he would take the responsibility himself and assume any blame attached to the transaction. His faculty and his trustees were always ready to follow his lead after a decision had been reached by discussion. His force of character, his human interests, and his devotion to Rensselaer remain as a cherished memory and guiding influence for our work in the future.

As was written of Wren in St. Paul's so of Ricketts at Rensselaer we may write in clear letters: "If you ask for my monument look about you."—ARTHUR M. GREENE, JR.[1]

[1] Dean, School of Engineering, Princeton University, Princeton, N. J. Past Vice-President, A.S.M.E.

WILLIAM ROBINSON (1876–1934)

William Robinson, master mechanic for the Eberhard Faber Pencil Company, Brooklyn, N. Y., died in that city on December 31, 1934, after an illness of several months. He is survived by his widow, Elizabeth (Thomson) Robinson, whom he married in 1906, and by two daughters, Mrs. Helen (Robinson) Fairchild and Miss Dorothy T. Robinson.

Mr. Robinson was born in Calderbank, Scotland, on March 3, 1876, son of Andrew and Margaret (Watson) Robinson. He was educated in the United States, attending grammar school and evening high school in Brooklyn, and taking a mechanical engineering course through the Alexander Hamilton Institute. He then served an apprenticeship as a machinist with Ball & Jewell, Brooklyn, shortly afterward (in 1898) becoming a naturalized citizen of the United States.

After working as a machinist for R. Hoe & Co., the Progressive Iron Works, Chelsea Fibre Mills, and a few small shops, he entered the employ of the Eberhard Faber Pencil Company in 1907. He was a machinist for the company for about three years and foreman for two and a half years prior to becoming master mechanic. He did much to develop the products of the company, and held patents on several inventions of his own, including a mechanical pencil and a pencil lengthener.

Mr. Robinson became an associate-member of the A.S.M.E. in 1915, was president of the Bayview Park Association, Port Washington, L. I., at the time of his death, and belonged to the masonic fraternity.

VERNON ROYLE (1846–1934)

Vernon Royle, president and treasurer since 1885 of John Royle & Sons, machinery manufacturers of Paterson, N. J., died of pneumonia at his home in that city on December 17, 1934. Four distinct lines of industry bear the impression of his inventive and manufacturing ability—photo-engraving, textile and fire-hose weaving, rubber goods, and electrical insulation.

Mr. Royle was born in Paterson on June 9, 1846, the eldest son of John Royle, Sr., of English ancestry, who founded the Royle machinery business in Paterson in 1855. His mother was Agnes Houston Royle, a native of Scotland. His early education was acquired in the "pay schools" of Paterson, public schools not having been established there until about 1858.

He served an apprenticeship in patternmaking with Wm. G. & J. Watson, machinists of Paterson, from 1864 to 1868. He then secured a position in the engravers' joining business of Heber Wells, later Vanderburg & Wells, in New York, N. Y. This contact with the boxwood engraving trade and with the early experiments in photo-engraving led to his later improvements in machinery for that industry.

In 1877 Mr. Royle decided to join the Paterson machine business. He became president when his father retired eight years later and under his guidance and subsisting almost wholly upon his own inventions, the Royle machine shop of the seventies grew to a modern manufacturing plant doing a business that was international in its scope, and the leader in each of its numerous lines. It remained a partnership until 1898, when it was incorporated under the same name of John Royle & Sons. Mr. Royle continued active in the management of the business until his death.

In photo-engraving and related processes, Vernon Royle's machinery for routing, lining, beveling, trimming, and blocking plates for the printing press has materially furthered the development of the world's illustrative arts during the past fifty years. Substantially all commercial weaving of figured textile goods is done today through the medium of jacquard pattern cards made on Royle card-cutting machines. Woven fire hose and gasoline service station hose are productions of Royle circular looms.

In the rubber industry, automobile tire treads and inner tubes are made in vast quantities on Royle tubing machines. The same is true of miscellaneous tubing, garden hose, pencil tips, rubber heels, and hundreds of other articles in soft and hard rubber and celluloid. Royle machinery for applying rubber insulation upon electric wire and cable is likewise the standard process of manufacture.

Mr. Royle was keenly interested in his community. He was secretary of the Paterson Board of Education from 1872 to 1889 and for several terms was a member of the board. He had been a director of the Hamilton Trust Company of Paterson for 25 years, was a director of the Cedar Lawn Cemetery Association, and a member of the local Taxpayers Association. He was a former member of the Passaic Valley Sewage Commission.

Mr. Royle became a member of the A.S.M.E. in 1907 and also belonged to the New Jersey Historical Society, the masonic fraternity, and the Hamilton Club, of Paterson.

He was married in 1872 to Miss Jeannie Malcolm, who died in 1908. He is survived by a son, Vernon E. Royle, now president of the company, and by three grandchildren and two great grandchildren.

GEORGE NICHOLAS SAEGMULLER (1847–1934)

George Nicholas Saegmuller, formerly a member of the firm of Bausch & Lomb Optical Co., Rochester, N. Y., died at his home in Clarendon, Va., on February 12, 1934. He was born just 87 years before, on February 12, 1847, at Neustadt-an-der-Aisch, Bavaria, the son of J. L. and Babette (Bertholdt) Saegmuller.

After four years' training at the polytechnic school at Nuremberg, Mr. Saegmuller went to England, where he was employed as draftsman for four years, 1865–1869, by Cooke & Sons, York, manufacturers of astronomical instruments. The following year he served in the German Army as a one-year volunteer and from 1870 until 1905 was a partner in the firm of Fauth & Co., Washington, D. C., manufacturers of astronomical and engineering instruments. This firm combined with the Bausch & Lomb Optical Co. in 1905 and Mr. Saegmuller held the office of vice-president of the latter until he retired from business in 1925.

In Who's Who in Engineering for 1931 will be found the following statement regarding Mr. Saegmuller's achievements: "Among engineers (he was) best known as the inventor of the solar attachment by means of which the true meridian is found by a single observation of the sun and which is largely used in the surveys of public lands. In astronomical circles he is known as the inventor of the Star Dials which make circles on equatorially mounted telescopes unnecessary and by means of which a star may be found without computing the hour angle; also for accurate graduations produced on automatic dividing engine. For the last thirty years his most important work was in connection with the developments of fire control instruments for the American navy. He, with the then Captain Samson, originated for our navy the first telescopic gunsights, boresights, and in fact all fire control instruments used in our navy and most important of all the development of our large rangefinders which are found in every turret of our battleships."

Mr. Saegmuller became a member of the A.S.M.E. in 1911. He also belonged to The Franklin Institute, the American Association for the Advancement of Science, and several clubs.

Mr. Saegmuller married Maria J. Vandenbergh, in Washington, D. C., in 1874, and is survived by her and by their three sons, J. L., Fred B., and George M. Saegmuller.

EDWIN JOEL SANDERSON (1877–1934)

Edwin Joel Sanderson, manager of the A. C. Ramsey Co., an insurance firm of Terrell, Texas, since 1934, die in Dallas, Texas, on December 27, 1934. He was born at New Vienna, Ohio, on February 18, 1877, the son of Francis Wyatt and Frances B. (West) Sanderson. After a year at the Ohio State University he entered the employ of James Leffel and Company, Springfield, Ohio, manufacturers of water wheel turbines. He remained with this company until 1931, working as draftsman for five years, the latter part of the time in charge of the department, then eight years in the engineering department, four years as sales engineer, twelve as sales manager, and the remainder of the time as general manager of the turbine department. He was manager of the Clark Screw Machine Company, Springfield, for a short time before going to Texas.

Mr. Sanderson became a member of the A.S.M.E. in 1930. He had been secretary-treasurer of the Terrell Building and Loan Association since 1932, had served as a director of the Rotary Club in both Springfield and Terrell and was chairman of the club's Crippled Children's Committee. He was a 33d degree Mason and had been a director of the Chamber of Commerce in Springfield and Terrell. He is survived by his widow, Carrie D. (Van Loan) Sanderson, whom he married in 1932.

NORMAN ROBERT SEIDLE (1877–1934)

Norman Robert Seidle, whose death occurred in Chicago, Ill., on May 14, 1934, was born in Lebanon, Pa., on January 25, 1877, the son of Christian and Jane (Mull) Seidle. He studied at Franklin and Marshall College for two years and at Swarthmore College for one year, then entered the employ of the Standard Boiler Works at Lebanon. With the exception of about a year (1900–1901) spent with the North Penn Iron Company, Philadelphia, he was connected with the Standard Boiler Works until 1904, rising to the position of superintendent and assistant manager, in charge of steel-plate construction.

From 1904 to 1919 Mr. Seidle was manager of the Plate Construction Department of Joseph T. Ryerson & Son, Chicago. He had charge of the design and manufacture of boiler specialties, and of steel pipe lines for hydroelectric developments and water supply, as well as of general plate construction and erection and pressed steel work.

After leaving the Ryerson company Mr. Seidle spent three years as general manager of James G. Heggie & Sons Co., Joliet, Ill.; about a year in the same capacity with the General Boiler Company, Waukegan, Ill.; a similar period as manager of the boiler department of the Harrisburg (Pa.) Manufacturing & Boiler Co.; seven years as treasurer and general manager of the McAleenan Bros. Co., and vice-president of its successor, the McAleenan Corporation, Pittsburgh, Pa.; and two years as vice-president and general manager of the Youngstown Boiler & Tank Co. In December, 1933, he became executive director of the National Steel Tank Association and secretary-treasurer of the Code Authority of the metal tank industry, the position he held at the time of his death.

During the World War Mr. Seidle was a civilian member of the Procurement Division of the United States Army, and a "Minute Man." He became an associate of the A.S.M.E. in 1917, was a past-secretary of the Joliet Rotary Club, and belonged to the Delta Tau Delta fraternity and the Odd Fellows. He was deeply interested in religion and for many years had served as a vestryman in the Episcopal Church.

Mr. Seidle is survived by two sons, N. Robert and Charles A. Seidle. His wife, Florence (Wedekind) Seidle, whom he married in 1905, died in 1926.

GEORGE HOTCHKISS SMITH (1851–1934)

George Hotchkiss Smith, whose death occurred in Providence, R. I., on June 7, 1934, had been a member of the A.S.M.E. since 1881. The fifty-year medal of the Society was presented to him in 1931.

Mr. Smith was born in New Britain, Conn., on December 22, 1851. He supplemented his public schooling with study at Cooper Union, New York, and served an apprenticeship in the machine shop of Smith & Garvin, at Bricksburg (now Lakewood), N. Y. In 1878 he went to Providence, to work as a draftsman for the Brown & Sharpe Manufacturing Co. He was made chief draftsman the following year, and remained in that position until 1885, when he entered business with Elmer A. Beaman under the firm name of the Beaman & Smith Co. He retired from business about the year 1915 because of ill health.

Mr. Smith was a past-president of the Providence Engineering Society and a member of the masonic fraternity. He is survived by a son, Walter J. B. Smith, of Providence. His wife, Louise J. (Luther) Smith, whom he married in 1882, died in 1916.

NATHANIEL AUSTIN SMITHWICK (1864–1934)

Nathaniel Austin Smithwick died on July 6, 1934, at his summer home, Waites Landing, Falmouth Foreside, near Portland, Maine. He had made his home in Maine since his retirement in 1912.

Mr. Smithwick was born at Damariscotta, Me., on March 25, 1864, the son of Captain Frank and Caroline (Austin) Smithwick, and as a boy he sailed with his father to many ports. He attended Lincoln Academy, Newcastle, Me., and Phillips Exeter Academy, Exeter, N. H., spent six months as an apprentice machinist with Barrett Bros., Boston, and was graduated from Worcester Polytechnic Institute, with a B.S. degree, in 1886.

After his graduation Mr. Smithwick spent a year as machinist at the Thomson-Houston Electric Company, at Lynn, Mass., and two years as draftsman for Erastus Woodward, mechanical engineer of Boston. The remainder of his engineering work was done for the Goulds Manufacturing Company, of Seneca Falls, N. Y. He was draftsman for five years, manager of the designing and experimental department for eleven years, and after that chief engineer of the company. He was largely instrumental in introducing triplex power pumps into mining, oil refining, water works, and other fields. He took part in a series of efficiency tests of motor-driven triplex pumps during his early days with the company, and later designed and supervised the installation, at Austin, Texas, of the first electrically operated water works pumping plant in the United States. In 1910 he went to South Africa to further the use of electric power pumps in mining operations. He held patents for governor valves for automatic pumps and for an improvement in vertical suction pumps.

Mr. Smithwick became a member of the A.S.M.E. in 1916 and was always keenly interested in scientific and engineering developments. Yachting and yacht designing were naturally of special interest to him, in view of his early trips with his father.

Surviving Mr. Smithwick are his widow, Mabel (Kenney) Smithwick, whom he married in 1901, and their only son, Austin K. Smithwick.

THOMAS WADE STONE (1877–1933)

Thomas Wade Stone, vice-president and general manager of The Western Gas Construction Company, Ft. Wayne, Ind., died on September 28, 1933, at the Methodist Hospital in that city, a few hours after suffering a stroke of apoplexy.

Mr. Stone was born on October 4, 1877, at New Corydon, Ind., a son of Dr. Michael and Mary (Elzey) Stone. The family moved to New Bremen, Ohio, when he was a small child and he attended public schools there and was graduated from the New Bremen High School in 1894. He then taught school for two years at Kettlersville, Ohio, a small town near New Bremen, and for one year at New Bremen. He attended Armour Institute at Chicago for a year and then entered Ohio State University at Columbus, from which he was graduated in 1902 with a degree in mechanical engineering. He won honors in mathematics and was elected to membership in Sigma Xi, honorary scientific fraternity.

Following his graduation from the university Mr. Stone went to Fort Wayne to become draftsman for The Western Gas Construction Company. He was advanced to the position of chief draftsman the following year, became chief engineer in 1916, and was made vice-president of the firm in 1928. In 1931 he also became general manager of the plant. Patent office records dating back to 1914 show the result of Mr. Stone's inventive ability in the gas manufacturing industry. The inventions credited to him include various mechanisms for use in the manufacture of gas, purifying devices, and other apparatus for the industry.

Mr. Stone became a junior member of the A.S.M.E. in 1903 and a member in 1916. He also belonged to the American, Canadian, and Indiana Gas Associations and to a number of clubs in Ft. Wayne, in many of whose civic activities he was actively interested. He belonged to several of the higher orders in the masonic fraternity. During the World War he aided in the manufacture of phenol at the plant of The Western Gas Construction Company for use in making explosives. He participated in numerous drives for the sale of Liberty Loan bonds, raising money for the Red Cross, and other war activities.

Mr. Stone was married to Miss Dorothy M. Greiwe, of New Bremen, in 1905, and is survived by her and by two sisters.

EDWIN STRUCKMANN (1872–1934)

Edwin Struckmann, since 1928 connected with the Lone Star Portland Cement Company of Kansas, died in Kansas City, Mo., on March 15, 1934. He was born at Aalborg, Denmark, on April 24, 1872, the son of a Danish sea captain. He served a four-year apprenticeship at the Nielsen & Winther Tool & Machinery Co., Copenhagen, and worked for some months as a mechanic at Kofoed & Hauberg's Machine Co. in that city. He also passed examinations for engineering service in the Danish Mercantile Marine and was a reserve assistant engineer in the Danish Royal Navy for about seven months.

His desire to become a navigating officer, however, was not to be fulfilled. On the return from a trip before the mast to South America his eyesight proved defective. He turned to engineering with the hope of becoming a ship's engineer, but after his graduation in 1896 from the Technical Institute in Copenhagen, he became interested in brick plants, and entered the employ of F. L. Smidth & Co., of Copenhagen. He was connected with this company for ten years, working in various capacities from draftsman to engineer in charge of construction and operation of brick and cement plants. One of his assignments was the construction of a brick plant in the northern part of Sweden, where the region was so desolate that a railroad and town had to be built before work on the plant itself could be started. Later he was sent to Russia to reconstruct and operate a brick plant and was there during the Russo-Japanese War, suffering many of the hardships of the times. A daughter, born to Mr. and Mrs. Struckmann in Sweden, died while they were in Russia. His final assignment with the company was the construction of a plant for the Canadian Portland Cement Company at Port Colborne, Ontario, Canada.

Since 1907 Mr. Struckmann had been connected with a number of portland cement companies in the United States. For something over three years he was superintendent of the Kansas City Portland Cement Company's plant and from then until the fall of 1911 held a similar position with the Continental Portland Cement Company of St. Louis, Mo. He then went to Des Moines, Iowa, where he was superintendent of the Iowa Portland Cement Company's plant until 1920 and then was connected with the Pyramid Portland Cement Company, first as vice-president and general manager, and from 1922 to 1925 as president and general manager.

From 1925 to 1929 he was employed by the Knickerbocker Portland Cement Company, Hudson, N. Y., first as superintendent, then as general superintendent. In 1929 he became general superintendent of the Western Division of the Lone Star Cement Company of Kansas, at Kansas City, Mo. At the time of his death he was stationed at Bonner Springs, Kan.

Mr. Struckmann became a member of the A.S.M.E. in 1913, and belonged also to the American Society of Danish Engineers. He is survived by his widow, Marie V. (Olsen) Struckmann, whom he married in 1900, and by a son, Holger Struckmann, as well as by a sister, Mrs. Holden Knudsen, of Copenhagen, Denmark.

CHARLES ANTHONY SUPIOT (1906–1933)

Charles Anthony Supiot, mechanical engineer for Hires, Castner & Harris, Inc., Philadelphia, Pa., died of pneumonia on May 21, 1933.

Mt. Supiot was born at Westtown, Pa., on October 6, 1906, the son of Charles Aime and Cecilia Supiot. He was graduated from the University of Pennsylvania in 1929 with a B.S. degree in mechanical engineering. He had been connected with Hires, Castner & Harris, Inc., since his graduation, beginning as a draftsman and subsequently becoming mechanical engineer for the company.

Mr. Supiot was a member of the A.S.M.E. Student Branch at the University of Pennsylvania and became a junior member of the Society upon graduation. He is survived by his mother; his father died in November, 1933.

CARROLL D. THOMAS (1863–1934)

Carroll D. Thomas, for nearly fifteen years chief boiler inspector for the State of Oregon, died at St. Vincent's Hospital in Portland, Ore., on December 24, 1934. He was born on November 13, 1863, at Hollansburg, Ohio, where he spent his early life. He attended the Central Normal College at Danville, Ind., for two years, and taught school and was principal of public schools in Ohio and Indiana for a number of years. He went to Oregon in 1884 and taught school in that state the following two years. He joined the gold rush to Alaska during 1887 and became operating engineer for the Treadwell Gold Mining Company, of Juneau. He returned to the States in 1888, engaging in mining operations in Colorado. In 1890 he went to Unionville, Mont., where he worked for a year on erection for the McCann Gold Mining Company, and from then through 1893 as designing, erecting, and operating engineer for the Whitlatch Union Gold Mining Company. For ten years beginning in 1894 he was engaged in erection work in Colorado mines, part of the time in the Cripple Creek district and from 1898 on as chief operating engineer of the Portland Gold Mining Company at Victor, Colo.

Mr. Thomas entered the power field in 1905 as operating engineer for the Pacific Power & Light Co. at Astoria, Ore. Two years later he became boiler inspector for the Hartford (Conn.) Steam Boiler Inspection and Insurance Company, in the Portland, Oregon, district. He continued in this position until he became state boiler inspector in 1921.

Mr. Thomas became an associate-member of the A.S.M.E. in 1925, and was a member of the Conference Committee to the Boiler Code Committee of the Society. He had served as chairman of the National Board of Boiler and Pressure Vessel Inspectors and as technical adviser to the Industrial Accident Commission of the State of Oregon.

Surviving Mr. Thomas are his widow, Mrs. Beatrice Thomas, of Salem, and a son, Carl F. Thomas, of Portland, as well as three brothers and two grandchildren.

OSKAR VON MILLER (1855–1934)

Oskar von Miller, pioneer in electrical generation and distribution in Germany, founder of the world-famous Deutsches Museum, Munich, and honorary member of the A.S.M.E., died in Munich on April 9, 1934. His long and honorable career was closely identified in Germany with the growth of the electrical industry which has wrought far-reaching changes in industrial and domestic life and in western culture. He labored with vision, intelligence, and energy, keenly conscious of these changes and astute enough to realize the necessity of impressing upon the youth of Germany the significance of the powerful technological influences that determine the environment in which their lives are lived.

Oskar von Miller was born at Munich, May 7, 1855, the tenth son in a family of fourteen children. His grandfather had been director in the Academy of Art in Munich, and his father, Ferdinand von Miller, the head of a bronze foundry, was an artizan of considerable ability and won government awards for his statues. His mother, Anna von Pösl, the daughter of a family of high social and governmental standing, whose marriage with Ferdinand von Miller was

contrary to the wishes of her parents, found time, in spite of the large family, to keep the books for the foundry.

The children were strictly brought up and encouraged in self-support at an early age. Oskar von Miller attended the Technische Hochschule at Munich, and, after having been graduated from it at the head of his class, entered the civil service, holding several transportation posts during the next few years. Among his early engineering tasks was the building of a bridge over the River Main in the winter of 1879 when the weather was so cold that no one else could be found to do the work.

But von Miller's major engineering interest, that of the electrical industry, began in 1881 when he asked for and received a furlough and journeyed to Paris to see the First Electrical Exposition. Here he became intensely interested in electricity and its applications with the result that he organized an electrical exhibit in Munich in 1882, at which the French engineer, Deprez, successfully transmitted direct current from Miesbach to the Glaspalast in Munich, a distance of 57 km.

Following the successful Munich exhibit, von Miller was sent abroad to France, England, and America to study the technology of the infant electrical industries. It was on this journey that he met Edison for the first time, and while in Vienna, after his return home, he was invited by Emil Rathenau to join in the introduction of Mr. Edison's electric lighting plants in Germany. He refused this unexpected and flattering offer because of his desire to spend his talents and energy in the service of the Bavarian state. He envisioned the development of the water-power resources of Bavaria, but his superior considered the plans premature. Perhaps it was the spirit of the times, combined with his own enthusiasm and the experiences of his travels that inspired young von Miller in the vision he was to live to see a reality many years later. The young German empire, politically powerful after the crushing defeats of Austria and France, and guided by the forceful Bismark, was emerging from an agricultural into an industrial nation of first rank, rich in resources of materials and human energy, and possessed of the scientific spirit which provides the basis for technological growth. Progress and technological development were in the air.

In Berlin, Emil Rathenau had formed the German Edison Company, now known as the A.E.G., and in 1883 von Miller joined him as a director of the company. By 1884 they had opened the first central station in Berlin. Here the boilers were set above the engine room where Edison bipolar dynamos were driven by belt, three to every engine. For the next five years they were busy developing electrical power plants throughout Germany.

Yielding to his desire to return to his native Munich, von Miller left the A.E.G. in 1889. Life was not easy, but the director of the Portland Cement Works at Lauffen sought him out with a proposition to supply the city of Heilbronn with power from Lauffen. This he accomplished, completing the work just prior to the electrical exposition at Frankfurt, in 1891, of which he became the president.

While power had been transmitted at the Munich exposition, electrical generation was there the major interest. Electrical transmission over considerable distances appealed to von Miller and the idea of transmitting electricity from his Lauffen plant to Frankfurt seemed worth trying. Consultation with Charles E. L. Brown convinced him that an alternating current could be so transmitted, as indeed it was, at 25,000 volts over a three-phase system 178 km in length. Of the 234 horsepower at Lauffen, 181 reached Frankfurt, a loss of only 22.6 per cent. In the same year, at Kassel, von Miller installed the first alternating-direct-current system, in which electricity was transmitted as alternating current and converted to direct current for use.

Following the Frankfurt exhibition, von Miller was firmly established as an electrical engineer and his genius was providing electric lighting and power plants throughout Germany. Space will not permit even a list of these projects. His interests spread to railway electrification and to the use of electricity in the chemical industry and for cooking and domestic appliances. In 1911 there were initiated the plans for the comprehensive hydroelectric power development of Bavaria, totaling 600,000 kva and comprising the famous 168,000-hp project at Walchensee, opened in 1924, with its 1000 km, 100,000-volt transmission system, and a yearly output of 180 million kilowatthours. Thus came to fruition the dream of his young manhood. In 1930, an extensive plan for the electrification of all of Germany engaged his attention.

But important as these engineering achievements of von Miller proved to be, he is best known throughout Germany and the world at large for the Deutsches Museum in Munich. His interest in the museum idea is said to have originated in a visit to Kensington Museum in 1878 when he saw the famous "Puffing Billy," built by William Hedley in 1813, and Stephenson's "Rocket." Lying fallow in his mind for a quarter of a century, the idea of a museum for his native city in which laymen and young people could see the industrial foundations on which our present civilization is based was presented by him to a group of government representatives, fellow citizens, scholars, and technologists in 1903, and he became the founder, president, and director of the institution. To this project he gave the best of his energy and enthusiasm and drove it through to an amazingly popular success in spite of tremendous difficulties.

When it outgrew its original quarters a few years after its opening, the city of Munich provided a commanding site for new buildings on a beautifully located island in the River Isar. Here, in 1925, after the long delay of the War, the present museum was opened to the public. Thousands of visitors to Munich pass through its 400 separate rooms and halls and from a city of 700,000, more than a million pass every year along the nine miles of its exhibits. It has provided inspiration for the founding of similar museums in this country. Space will not permit an estimate of what this great contribution means to the world's understanding of the conditions under which men live and how technology is constantly undergoing development.

Mrs. von Miller, whose death in the fall of 1933 broke a family group unusual in its solidarity, was Marie Seitz, the daughter of Franz Seitz, a professor at the University of Munich. Of her marriage to Dr. von Miller in 1884 seven children were born, three sons and four daughters, two of whom died at an early age. The family was accustomed to meet for a day or an evening together every two weeks, and each year gathered for a religious service at the little church in Neuhausen where Dr. and Mrs. von Miller were married.

Von Miller possessed to a rare degree human qualities that endeared him to every one. His tireless energy permitted him to accomplish great deeds and his infectious enthusiasm carried others along with him in the pursuit of his objectives. Breadth of vision provided these objectives in heroic measure, and a keen sense of his obligation to his country and its culture led him to give his services to such projects of social significance as the electrical exhibitions of his early manhood and the museum and the electrical development of Bavaria which occupied his later years. When the great von Miller saw a need, he did not stop until he had satisfied it, true to his family motto, "If I rest, I rust."

JOSEPH ADDISON WADDELL, JR. (1877–1934)

Joseph Addison Waddell, Jr., western district manager of the Spencer Heater Company, a subsidiary of the Cord Corporation, with offices in Chicago, Ill., died suddenly of coronary thrombosis on April 28, 1934, while in St. Louis, Mo.

The son of Legh Richmond Waddell and nephew of Senator Joseph Addison Waddell, of Virginia, he was born at Staunton, Va., on November 5, 1877. He received a B.S. degree in mechanical engineering in 1900 and M.E. degree two years later from Virginia Polytechnic Institute. While working for his Master's degree he taught mathematics and experimental engineering at the Institute, and during the next year was employed in the erecting and layout department of the Deane Steam Pump Company, Holyoke, Mass.

Mr. Waddell first became associated with the Spencer Heater Company, then located in Scranton, Pa., in 1903 as engineer in charge of sales and mechanical engineering. Two years later he was made general superintendent and in 1913 works manager, with entire charge of production. He held this post until 1917, when he was released to serve in the Production Division of the Emergency Fleet Corporation, United States Shipping Board. He had charge of the Boiler Section and was responsible for the allocation of material to the various manufacturing companies throughout the United States which were building boilers for the Corporation. After the armistice he adjusted contracts and claims arising from cancelations of orders, remaining with the Corporation until the end of 1919.

During the next four years Mr. Waddell was connected with Morris and Company, of Chicago, as manager of its Phosphate Mining Department at Bartow, Fla. He directed the construction of a hydraulic plant, including the power plant, washing and separating plants, and drying and storage plants, repair shop, and other buildings, and installed the machinery and other equipment. After the completion of the plant he directed the operation of the mine and the production of pebble phosphate rock until the company was purchased by Armour and Company, Chicago. A model of the Bartow phosphate mine has been placed in the Smithsonian Institution in Washington, D. C.

From then until 1927 he was not engaged in engineering work, and in 1924 he resigned his membership in the A.S.M.E., which he had held since 1913. He applied for reinstatement in 1930.

When Mr. Waddell again took up engineering duties in 1927 it was with the Spencer Heater Company, located at Williamsport, Pa., in the capacity of chief engineer. He held patents on Spencer heaters dating back to as early as 1910 and after his return to the company

developed the present line of products and was granted patents in both the United States and Canada on magazine stoking boilers for heating purposes. Since 1933 he had been stationed at Chicago as western district manager, but had also continued as chief engineer of the company.

Surviving Mr. Waddell are his widow; a daughter, Martha; and a son, Joseph Addison Waddell, 3rd, also with the Spencer Heater Company.

VINCENT L. WALTERS (1868–1934)

Vincent L. Walters, who became an associate-member of the A.S.M.E. in 1920, died on April 30, 1934. He was born at Bilston, England, on February 6, 1868, and was educated in that country. His father was master mechanic in a large steel mill and the son trained for erecting and mill work. He had not worked long in England, however, when his brother, in the United States, advised him to come to this country. He wished for a position as draftsman, but there were so many applicants for such work in New York that for a number of years he found erecting and mill work offered better pay.

Later, however, he obtained work in which he was more interested as designer and experimentalist for the Ideal Cash Register Company, Bound Brook, N. J. He was connected with this company until 1901, designing, among other things, a spring winding machine and special dies, and having charge of the tool and gage room.

From 1901 to 1912 Mr. Walters was employed by the Weston Electrical Instrument Company, Newark, N. J. He designed intricate mechanisms for a variety of instruments and machines and for three years was in charge of the tool department of the company.

After a few months in 1912 and 1913 as experimentalist and model maker for Sloan and Chase, Newark, Mr. Walters went to Orange, N. J., for the manufacture of the Monroe calculating machine, on the experimental stages of which he had been working for some time. He designed all the tools necessary for its manufacture and was assistant superintendent of the Monroe Calculating Machine Company for four years.

Mr. Walters next spent several months with the Mehl Machine Tool & Die Co., Roselle, N. J., then became superintendent of A. Rimelspacher & Co., designing a special thread rolling machine and directing the manufacture of machinery and tools. In the summer of 1917 his aid was solicited by Joseph Gough, of Newark, and during the following winter he worked on the perfection of a universal joint gage for a Government assignment. Subsequently he became foreman for Jackson Waddell, Newark, where he remained until the latter part of 1919. He then became general foreman for the Pierce Accounting Machine Company, Inc., New York, for whom he carried on experimental as well as manufacturing work until 1924.

FRANK ROSE WHEELER (1878–1934)

Frank Rose Wheeler, a specialist in condensing equipment, died of a cerebral hemorrhage at his home in Chicago, Ill., on March 1, 1934.

Mr. Wheeler was born at Wheeler, N. Y., on April 1, 1878, a son of Don D. and Mary (Rose) Wheeler. He was graduated from high school in Tacoma, Wash., and subsequently was a special student at Leland Stanford Jr. University in 1898 and 1899 and from 1901 to 1903. During these years he also worked as a draftsman for the City of Tacoma and the Northern Pacific Railway, and following his graduation, for C. C. Moore & Co., of Los Angeles and San Francisco, and as engineer and vice-president of the Tracy Engineering Company, Los Angeles, working upon the design of power plants.

In 1904 Mr. Wheeler became Pacific Coast manager for the C. H. Wheeler Mfg. Co., of Philadelphia, in charge of the sale of condensing apparatus. He took over the Chicago district in 1916 and remained with the company until 1929, when he became manager of the Condenser Heater Department of the Elliott Company, Jeannette, Pa. He spent three years in this position, and during the remainder of his life was connected with the Utilities Power & Light Co. in Chicago.

Mr. Wheeler became a member of the A.S.M.E. in 1909 and also belonged to the Western Society of Engineers, the Beta Theta Pi fraternity, and to several clubs in Chicago and San Francisco. He was a contributor to the technical press.

Mr. Wheeler is survived by his widow, Blanche (Harper) Wheeler, whom he married in Pittsburgh in 1912.

GEORGE E. WHIPPLE (1890–1934)

George E. Whipple, solicitor for United Drydocks, Inc., New York, N. Y., died of a heart attack at his home in Teaneck, N. J., on May 3, 1934. He was born in Brooklyn, N. Y., on January 3, 1890, son of George E. and Nellie T. (Doody) Whipple. He attended public schools in Brooklyn and studied art in New York. The most of his engineering experience was with Theo. A. Crane's Sons Co., of Brooklyn, with which he became associated in 1917. From then until 1928 he was located in the New York office of the company, as draftsman and designer, and assistant executive. He was also assistant superintendent of the shipyard, supervising all repairs on boilers, engines, and hulls. He became solicitor for ship repairs for the company in 1929 and the following year took the position of solicitor with United Drydocks, Inc. He was a licensed ship engineer, first class.

Mr. Whipple became an associate-member of the A.S.M.E. in 1927. He was a 32d degree Mason and belonged to the Sons of the American Revolution, Odd Fellows, and Rosicrucians. He was a deputy warden of the New Jersey Fish and Game Commission. In addition painting in oils and sketching in pen and ink, he was interested in photography and in floral horticulture.

Mr. Whipple is survived by his widow, Marie B. (Arden) Whipple, whom he married in 1920.

WILLIAM HIGH WILLISTON (1879–1934)

William High Williston was born on October 10, 1879, at Somerville, Mass., where he secured his grammar and high-school education. He was graduated from the Massachusetts Institute of Technology in 1902 with a B.S. degree, and was employed continuously from December of that year until his death on June 7, 1934, by Manning, Maxwell & Moore, Inc. He spent his early years with the company in drafting and designing at the Hancock Inspirator Company and Hayden & Derby Manufacturing Co., rising to the position of chief designer. He became mechanical assistant to the vice-president of the parent company in 1913 and was made assistant works manager of the Boston plant three years later. Subsequently he was promoted to the position of works manager of that plant, then railroad sales manager. He was appointed vice-president in charge of railroad sales in 1927, and at the time of his death was director and vice-president in charge of railroad sales of the subsidiary company, Consolidated Ashcroft Hancock Co., Inc., as well as works manager of the Boston plant.

Mr. Williston became a member of the A.S.M.E. in 1925. He was an enthusiastic philatelist. He is survived by his widow, a son and a daughter, and his father, Belvin T. Williston.

WALTER WOOD (1849–1934)

Walter Wood, of R. D. Wood & Co., Philadelphia, Pa., manufacturers of cast-iron water and gas pipe, died on April 20, 1934, in Washington, D. C., while there on a business trip. He was born in Philadelphia on December 6, 1849, a son of Julianna (Randolph) Wood and of Richard Davis Wood, who was a partner in the firm of R. D. Wood & Co., and one of the organizers of the Pennsylvania Railroad.

Mr. Wood was graduated from Haverford College in 1867 with the degree of Bachelor of Arts and took post-graduate work at Harvard University, securing his A.B. degree there in 1868. He then began work in the office of his father, becoming managing partner when his father died in 1869. He was also president of the Florence (N. J.) Pipe Foundry & Machine Co., owner of The Millville (N. J.) Daily Republican, and treasurer of the Cumberland County Gas Company, the Millville Electric Light Company, the Millville Water Company, and the High Pressure Supply Company.

Mr. Wood also interested himself in civic affairs. He became a member of the Committee of One Hundred (Philadelphia) in 1880, and served for four years with this group, which investigated and attempted to improve local governmental conditions. From 1887 to 1895 he served as a Civil Service examiner and was a trustee of Haverford College. In recent years he had been an active proponent of the plan to build a ship canal across New Jersey, linking the Delaware River at Bordentown with Raritan Bay. He advocated the project before the House Rivers and Harbors Committee a few weeks prior to his death.

Mr. Wood became an associate of the A.S.M.E. in 1880 and a member ten years later. He was one of the organizers and charter members of the American Foundrymen's Association and a member of the American Institute of Mining and Metallurgical Engineers, American Society for Testing Materials, American Waterworks Association, and of a number of clubs in Philadelphia, New York, Washington, D. C., and Boston. He was a director of the Philadelphia Bourse and of the Burlington City Loan & Trust Co. He was unmarried and is survived by six nieces, and by two nephews, Richard and Grahame Wood, all of Philadelphia.

EDMUND WILHELM ZEH (1867–1934)

Edmund Wilhelm Zeh, president of the Zeh & Hahnemann Co., Newark, N. J., manufacturers of presses, dies, and automatic machinery for working sheet metals, died on March 17, 1934.

Mr. Zeh was a native of Germany, having been born at Frankfort-on-Main on September 12, 1867, the son of Carl Wilhelm and Catharina (Emmel) Zeh. At the age of 16 he entered the shops of Collet & Engelhard, at Offenbach-on-Main and after two years there spent four more in securing drafting-room practice with the company. He then entered the technical high school at Darmstadt, from which he was graduated in 1891 with an M.E. degree. He returned to the employ of Collet & Engelhard as a constructor and continued in that work until 1893.

Mr. Zeh came to the United States in 1893 to see the World's Fair at Chicago and remained to work as a designer for the Niagara Machine & Tool Works, in Buffalo, N. Y. He was made superintendent of the works the following year, and held that position until 1904, when he helped to found the Zeh & Hahnemann Co. He held patents on percussion power presses, details for double crank presses, double action presses, stacking devices, guards, button machinery, and can body machinery.

Mr. Zeh became a member of the A.S.M.E. in 1915. He was president of the Newark Technical Society and a member of the Verein deutscher Ingenieure. He is survived by his widow, Anna M. (Mantz) Zeh, whom he married in 1889, and by one son, now president of the Zeh & Hahnemann Co.

New Pioneers on a New Frontier

By RALPH E. FLANDERS

THE greatest fact in American history has been the existence of the frontier.

For centuries the centers of industry, commerce, and settled agriculture lay in the East, expanding decade by decade in a westward progress that was uninterrupted and successful. The border line of that movement was held by the pioneers. Before them lay the unknown regions which the imagination pictured as teeming with wealth of forest, mine, and soil. Behind them came the settlers, who found and developed the underlying realities of the pioneer's dream.

This physical, geographical frontier for many generations served our nation in three important ways; it gave unlimited opportunity to youth, it furnished a seemingly boundless field for the profitable investment of capital, and it generated a favorable psychology throughout the whole structure of American society.

The opportunity for youth was a visible actuality at so recent a date as to be remembered by many in this gathering tonight. In the eastern farming regions the process was almost automatic. With the large families of a generation or two ago it was obviously impossible for all to gain a good living on the restricted home acres. The boys in due time moved outward, some to the cities (themselves growing with the growing commerce to and from the frontier) and others directly to the virgin soil and forest of the newly opened lands, where they could find the opportunity and the room to make new lives for themselves on a more ample scale.

But so widespreading and rich was the western domain that the expanding population of the eastern seaboard was insufficient to occupy and develop its resources. Their numbers were swelled by the millions from the crowded countries of Europe who descried the opportunities from afar, swarmed into the transatlantic shipping, and crowded the immigrant trains into our virgin territory. The numbers of these immigrants were numbered by the millions and tens of millions. Our own population growth did not suffice. There was room for all.

Money was needed as well as men. There were farms to be equipped, mines to be opened, roads and railroads to be built, cities to be erected. For generations the savings of the settled East poured across the Alleghanies, across the Mississippi, across the Continental Divide, and found profitable investment in these new and rich territories. Fortunes were lost, but more fortunes were made. There was never a word of "overproduction" or "overinvestment." The thought was so ridiculous that the words were unneeded and uninvented.

As with men, so with money. The savings of the East were inadequate to the needs and opportunities of the West. In consequence, millions of dollars came pouring out of the coffers of Europe to finance the settlement of western America, and the expansion of eastern commerce and industry which western development demanded. The millions grew into billions before the demand was satisfied and the stream slacked its flow.

All of this produced a national psychology of a fortunate sort. We were convinced that the future held more for us than the present and the past. We were willing to risk time and money in productive enterprise. The future, we were sure, would not betray us—nor did it. Even as our physical surrounding made our psychology, so our psychology made our future. The process was natural, healthful, and fortunate beyond all accounting.

But—the frontier is gone!

No doubt we will continue, now and then, to find new oil fields. New areas of fertile soil will be irrigated and added to our inheritance of arable land. New mineral deposits will be found and exploited. All this will go on continuously for many years, yet the total effect will be small. It will not constitute the outstanding, controlling fact of our nation's history, as it did for nearly three hundred years. Sometime in the period since the turn of the century—not on any given day or in any given year—the physical frontier in the grand sense disappeared and disappeared forever.

This was the greatest event of our times. If we are looking for some effective cause for the evils which have been afflicting us, why look further? We build up our false or inadequate theories of "overproduction" when we have never had a decent general standard of living in this country; of "technological unemployment" when on technology alone can we found our hopes for the higher standards of the future; of "overinvestment" when an adequate provision of goods and services to the mass of our fellow citizens requires larger and more efficient productive facilities than we have ever dreamed of. All of these explanations and many more are shallow and inadequate.

The outstanding historical event of our generation is the disappearance of the frontier, and the consequent disappearance of the old, trusted, and tried opportunities for youthful opportunity and the profitable investment of capital; and with these gone there is beginning to go that favorable, constructive type of national psychology which has energized our progress hitherto.

What shall we do in the face of an emergency so fundamental?

Two courses are open to us. We can readjust our social, political, and industrial institutions to a future of limited opportunities for men and for money, with a national outlook keyed down to safety as our objective, instead of the old purposeful advance toward a better future. The alternative is that we find an equivalent for the lost frontier—an equivalent which will as effectively open new opportunities for men and for capital, and make it possible for us to retain our constructive national psychology.

For the time being, we seem to be making the first and poorer choice. In some directions deliberately and in others by indirection we are slowing down our production of goods and services. In place of a confident advance toward business risk and personal adventure, we are all playing safe—business man, worker, and farmer. We are at this moment organizing a new world of restricted production, restricted human enjoyment, and restricted opportunity for the coming generation. We have chosen to play the lesser part.

We need not do this and we must not do it. For the effective equivalent of the old physical frontier lies ready at our hands for our occupation, development, and enjoyment. That frontier lies so close at hand that it escapes our notice. Its separate features are so familiar to us that we have missed its significance as a whole. For the new frontier is not a distant physical region, it is an ever-present social possibility. This new social frontier is *a greatly raised standard of living for the mass of our fellow citizens.*

At first sight this proposal for a new frontier may seem trite and inadequate. But let us examine it before passing hasty

Eighth Henry Robinson Towne Lecture on Engineering and Economics, delivered as the 1935 Presidential Address at the Annual Meeting, New York, N. Y., December 2–6, 1935, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

judgment. Let us consider first and principally its material characteristics. Of what are they composed?

A higher material standard of living does not mean higher wages, higher salaries, or higher dividends. It does not mean higher prices for goods or services—least of all does it mean restriction of output. It does mean more and more goods and services at lower and lower prices relative to incomes.

Let us first consider whether a higher standard of living, defined in these terms, is physically possible. Next, let us see whether, if attained, it can take the place of the lost frontier in furnishing opportunity for youth and for capital, and in providing a favorable national psychology. Finally, if these inquiries lead to favorable conclusions, let us see what it is that prevents our occupation of this new frontier, so that we may remove the hindrances and proceed with our new social advance.

There can surely be no question as to the physical possibility of a rising standard of living. We have the material resources required. The very abundance of our coal fields, oil wells, and fertile soil have embarrassed our clumsy institutions until we have imagined abundance to be a curse instead of a blessing. For the materials we need and do not have there are ample stores of native products for exchange in the markets of the world.

We are favored as well in the character of our population. Drawn from a diversity of races, they bring to our land every useful type of acquired skill and native ability that could be asked for; and their energies are heightened by climates that are for the most part particularly favorable for effective work of hand or mind.

Finally, years of experience have produced in this country a body of business and technical experience directly adapted to the production and distribution on a large scale, at low cost, and with minimum human effort, of a rich variety of desirable goods and services.

The rising standard of living is physically possible.

Quite obviously, when we consider the matter, this new social frontier of the higher standard of living offers the same advantages as did the old physical frontier if we can but enter into and occupy it.

We seek more and better goods and services at less relative cost. This can only be effected to the desired degree by both expansion and refinement of our productive machinery and processes. The expansion of industry will call for more and more workers. The needed expansion and improvement of production will call for more and more investment. Only by this expansion of operations and revival of investment can we simultaneously produce more and better goods and services, distribute them more widely, do so at a less relative cost, and employ more men in the process at a number of working hours per week which tends to decrease rather than increase. All other programs fall short of this complete solution.

Our progress toward a higher standard will thus definitely provide the opportunities for men and for money that were furnished by the old frontier; and as this fact becomes obvious, it is plain that our old psychology of firmly based optimism will revive, and our newly injected defeatism will wither and disappear—a consummation devoutly to be wished for.

If this new social frontier is physically attainable, and offers a continuation of the services which were rendered to us for so many generations by the old frontiers, we must be in earnest in our determination to discover and surmount the obstacles which deter us from entering into it.

We have made good progress toward an ever-rising standard of living in the past, but in recent years our forward movement has been checked, and we have even been forced backward from our goal. The causes of our trouble have not been single, but many. But, of the many, two are of such overshadowing importance that it is folly to disturb ourselves about the minor difficulties until we have found means of surmounting these major ones. In fact, we cannot even see the other problems clearly until these two have been solved. Thus attacked, the whole problem will more readily yield to solution.

The first obstacle is a false idea, and it is the more dangerous from being held by a great majority of the population of the country. Business, labor, and agriculture account for almost the whole body of persons engaged in providing a high standard of living and all three of these groups are imbued with this false idea and strive to make it effective. That false idea is that the interests of each separate group are best served by control or restriction of output and by maintenance or raising of prices.

Industry has long been fascinated by the possibility of understandings between competitors which lead directly or indirectly to price and production control. So evidently profitable does this appear that the movement toward agreement and combination has been almost irresistible. As early as 1890 Congress recognized the rapid growth of the movement and passed the Sherman anti-trust act forbidding "conspiracies in restraint of trade." But in spite of that legislation and of the succeeding Clayton act and the establishment of the Federal Trade Commission, business has, openly or secretly, consciously or unconsciously, moved in that direction. Some industries have, indeed, been so "successful" in coming to agreements that they have encouraged outside competition and quite evidently defeated their purposes.

Labor-union policy has been identical with business policy. But since the commodity dealt in is labor and skill, the fallacy is expressed in somewhat different terms. Labor-union policy seeks "shorter hours and higher wages" without any expressed or discernible limit. And some unions, like some businesses, have been so "successful" in this policy that their members are idle for months and years when other workers are profitably employed.

Agriculture has long looked with envy on the "success" of business and labor in carrying out this false idea and at last it too has its chance, under the AAA, to limit production and raise prices; and it too is meeting with the "success" of lost foreign markets, stimulated foreign competition, and actual importation of products which our farmers are well able to supply.

When business, labor, and agriculture hold the same beliefs, be they true or false, we must not be too surprised if the administration hastens to embody those beliefs in the law of the land. This was done, and as a result we had AAA and NRA. But legislation cannot purge a fallacy of its folly. These two institutions together lead to a universal condition of less goods at higher prices. But our goal of a higher standard of living requires more and more goods at relatively less prices. The governmental policy is surely false. It leads away from our goal. There is no magic algebra which can prove the truth of the equation, AAA + NRA = Prosperity. It does not equal prosperity. It equals a lowered scale of living for the people of this country, and no other answer to this equation can be found.

This first obstacle, then, is in the nature of a drag or brake or a heavy load to be carried. The second has more the nature of a recurring catastrophe which, when it occurs, not merely retards our advance but stops it completely. It not merely stops it, but throws us backward and destroys the very mechanism of progress, so that we must spend weary months and years in repairing it before we can regain our lost ground and resume our advance.

This second obstacle is the periodic onslaught of speculative frenzy to which our social organization is subjected.

We should clearly understand what we mean by "speculative." In the sense in which we are using the word it has no connection with business enterprise or business risk. A man may risk his time and all the funds at his command in the development of a new machine or a new product, or simply in an attractive business opportunity of the conventional sort. The outcome may be doubtful and may be called "speculative." But the proceeding is essentially healthy if pursued with judgment and in the light of experience. On the willingness of the business community to engage in such risks are based our hopes for expanding employment and a rising living standard. Speculation is quite another thing and is most unhealthy when carried out on a large scale. It will best be understood if we describe the conditions under which it flourishes.

Periodically business men become discouraged with the slow and meager profits of normal business, which is the business of producing and distributing goods and services. Normal business profits are small. If on the one hand we admire the returns from certain well-managed or especially fortunate organizations, on the other we observe the thousands of businesses which struggle along for years without profit, finally sinking into bankruptcy with losses which run to hundreds of millions in the aggregate. Between the two extremes lies the general average of business success which, with infinite work and worry, returns to its owners little more than the normal interest on the capital invested.

From time to time the business world, discouraged with this meager return, looks about and discovers lying ready at hand a marvelous mechanism which promises to work to a most attractive end. Instead of finding in his hands at the end of the year only the small profits of this year's business, this mechanism promises that the business man can hold in his hands to use or spend and enjoy *now*, not only the profits of this year but next year's profits as well—the profits of five years ahead—the imagined profits of future generations. This mechanism, ready at hand for such delectable use, is the speculative market for securities, real estate, and commodities, with the financial mechanism to which it is geared. The endeavor to realize far future profits by the use of this mechanism is "speculation" in the sense in which we are using the term.

When the professional speculators are joined by thousands of business men, and finally by the general public in the operation of this mechanism, it does seem to work. For many months or for a term of years we do find new, spendable wealth in our hands—new millions, new billions. Apparently we can reach far into the future, seize its profits and enjoy them now.

But it is in appearance only. There is no mechanism which will reach into the future and seize the profits of years not yet born. The reality is ugly and sordid. If there are new billions of "wealth," those billions came directly from bank borrowing by purchasers of the securities, real estate, or commodities, to finance their purchases above cash margins which were comparatively narrow. Bank-credit money, from its very nature, is generated by the process of borrowing and disappears when the debt is paid. In consequence, for every billion of new wealth there is somewhere a billion of new indebtedness, and if that billion of indebtedness becomes due and must be paid, then somewhere a billion of "wealth" must disappear.

That volume of indebtedness—that source of fallacious wealth—is an incredibly flimsy and fantastic structure when we reach the end of a protracted speculative boom. It finally becomes evident to every one that the future profits on which present prices are based can never be realized. When that does become evident prices fall and debts become due. And then, for long months and years every cent of savings, every mite that can be spared from the bare expenses of existence, must be devoted to the liquidation of that indebtedness. These sums are lost to purchasing power, and these months are months of destruction and defeat. The damage must be painfully repaired before we can again resume our progress toward the new social frontier, the raised standard of living.

These two obstacles, the false idea and the destructive calamity, are not light matters. We have struggled with them for generations, and they have grown stronger with the years. What hope is there that we will ever control or overcome them?

I am glad to stand before you tonight and to say that to me the prospect for sanity and intelligence in these matters looks brighter than at any time in the past. We have done much thinking. Experience has brought to us bitter lessons. Some of them we have learned.

We have, for instance, one example before our eyes of an industry which has never for a moment worshipped the false gods of production control and raised prices. The automotive industry has always been willing to submit to severe competition, and in consequence it has year by year built more and more and better and better cars and sold them for lower and lower prices. In further consequence it has made the greatest increase in employment and payroll dollars and is the most prosperous of any of our great industries. It has made the greatest contribution to industrial recovery. Other industries are taking notice and considering their ways.

Furthermore, there is a growing realization that if industries agree on price and production instead of competing, they open the door to government regulation. Indeed under those conditions, government control becomes an inescapable duty. On the other hand, for an industry which submits to the hazards of competition, and governs its prices and output thereby, governmental control is an unwarranted impertinence and a social calamity. Viewed in this light, our antitrust legislation is the strongest protection available to business. These things are becoming clear, and if there is any drift of business opinion it is away from the fallacious search for safety and toward intelligent courage.

Industry must lead the way. We cannot expect labor or agriculture to do so. The prosperity which will come to industry as a whole in so doing will so directly increase the demand for labor and for agricultural products that the artificial methods hitherto applied by these two groups will be clearly seen as the hopeless proceedings which in reality they are.

As to the control of speculative frenzy, we can point to much more definite items of achievement. Beginning with the Glass-Steagall act of the last months of President Hoover's administration, and ending with certain useful elements of the banking act passed last summer, we have provisions which by no means insure us against a recurrence of this calamity, but which do provide us with tools which, if wisely used, will greatly diminish the severity of any future attack.

Hitherto it has not been possible to restrain the expansion of speculative credit without throttling the flow of credit for normal business in the process. Now, for the first time, we can restrain the evil while supporting the good. We need have no repetition of the period from 1926 to 1929 with its disastrous consequences. We can, if we will, prepare a future freed of the worst follies of the past, in which we can move steadily and purposefully toward our social objective of a raised standard of living for our people as a whole.

It must be clear to all that engineers have a particular interest and responsibility in these matters. We cannot sit idly by and see the choice made for us.

If, faced with the disappearance of the physical frontier, we cravenly resign ourselves to accepting that fact as final, and key our national policy and our national hopes down to that dismal

decision, there will be little future for the engineer. There will be fewer of us, and our services will be of a subordinate order.

If, on the contrary, we make the more courageous decision to replace the lost physical frontier with the new social frontier of the raised standard of living, then the engineer will come into his own.

For the raised standard of living demands more goods and services, of better quality and at lower cost. This is the service which the engineer is qualified to render. To this was he born; for this was he educated; this is his life work. In a society dedicated to this end he will find profitable employment, satisfying recognition, and useful essential service of the general good. With the scientist, the inventor, and the broadly visioned business executive he will pioneer in the founding of a new order as far surpassing our present one as that does the barbarism of earlier ages.

We are faced with these alternatives—to retreat or to advance. Is there any doubt as to which the American people should choose? Nay, rather, is there any doubt as to which they *will* choose?

Annual Report of the Council

DURING the past year Society activities were on a substantially better basis than in 1933–1934. Rigorous economy has been observed and it is believed real progress has been made. For the first time in three years the Society income at the end of the first six-months' period was greater than estimated and it was possible to make some increase in appropriations at that time. The financial report for the year will show a modest addition to surplus and a reduction in the debt.

Information About Members

The improved financial status of the Society enabled the Council and its Executive Committee to give more thought to the interests of the individual members. As a first step, a professional-data form was circulated during the spring, on which members were asked to record their experience and special qualifications. The analysis of these forms is about 60 per cent complete at the close of the fiscal year. Approximately 7000 members returned data and the information will be valuable in formulating programs for publications and activities to meet the general interests of the members. We have up-to-date records of 7000 members that will enable us to give aid to those employers seeking men with unusual experience and qualifications. We also have an accurate record of 860 consulting engineers, showing their detailed specialties, from which to answer inquiries for men qualified to handle specific problems. About 750 members have volunteered for service on committees.

Improving the Profession

The enhancement of the status of the engineer is the stated purpose of the Engineer's Council for Professional Development in which the A.S.M.E. is participating. The Engineers' Council has made splendid progress in its program of accrediting engineering schools and, as the fiscal year draws to a close, plans are under way to examine some twenty schools in the New England and Middle Atlantic areas. These two areas were chosen for the first trial of accrediting and the development of the scheme will depend upon its success in this experimental area. The Engineers' Council has also promulgated two programs in which the Society is called upon to participate actively through its sections.

(1) The guidance of young men planning to enter engineering as a career.

(2) Stimulation of a self-development program for young men who have been graduated from engineering schools and are preparing themselves to become full-fledged engineers and for those young men who have not had the advantage of a formal education.

Plans for both of these programs have been prepared and communicated to the Sections. The successful execution of these plans provides a direct problem for each Section.

Registration

During the past year the Council has given a great deal of consideration to the movement looking to the establishment of registration laws for engineers throughout the United States. As the year closes, thirty-five states have such laws.

In June the Council adopted an important policy in this matter as follows:

(1) The A.S.M.E. will present the broad aspects of registration to its members in those states not having registration and stimulate its consideration by them.

(2) The A.S.M.E. will not publicly urge registration in those states where the movement has not taken definite shape.

(3) In those states where a registration movement has been initiated which has the support of representative members, the A.S.M.E., through its members in those states, will offer to support the movement by helping to organize it further, by assisting to formulate a proper legislative bill, by soliciting the support of other engineering societies and outstanding members, by advising appropriate strategy, and by other suitable and proper means.

(4) In those states where registration laws have been enacted, the A.S.M.E., through its members, will encourage (a) amendment of the registration laws for the purpose of improving and making them more uniform, and (b) stricter enforcement of those laws.

At the close of the year Council was giving consideration to the steps necessary to carry out this policy.

American Engineering Council

The American Engineering Council has completed a good year. Its report appears in detail on another page and is well worth painstaking study. The American Engineering Council has made substantial progress in relating itself to government agencies on engineering matters and has initiated a series of contacts looking to the placement of engineers in government services. It has been instrumental in initiating a special census of engineers, with particular reference to educational background, occupation, income, and present status of employment. Over 50,000 records of individuals are in the hands of the Bureau of Labor Statistics of the U. S. Department of Labor and it is expected that the report will be available about the end of the calendar year.

Junior Activity

One of the important problems pressing for early solution is the assimilation into the Society activities of the large number of graduates of engineering schools. The program of post-graduate training planned by the E.C.P.D. previously mentioned offers an excellent opportunity for the Society to take an important position of leadership. During the past year a special committee on junior participation was appointed, which has made some valuable suggestions for junior activity. Many sections have adopted active programs for junior participation, but there is still a great opportunity for future developments in this program.

Changes in Membership Grades

An important change in the membership structure was initiated during the year. As a result of discussions in the E.C.P.D. and in the Committee on Policies and Budget, a revised plan of membership grades was advanced and, after acceptance by the members in meeting at Cincinnati in June, 1935, was submitted to letter ballot. The plan abolishes the present Associate-Member grade, makes some changes in the requirements for a new grade of Member, and adds the Student Member, and the Fellow, the latter being the engineer of distinction.

General Activities

The meetings of the Society during 1934–1935 were generally satisfactory. The plan of having annually a Calvin W. Rice Memorial Lecture was initiated at the Cincinnati meeting by Dr. Adolph Meyer, of Zurich, Switzerland.

The increase in income from advertising enabled the Council to provide more money for publications during the latter part of the fiscal year. The *Journal of Applied Mechanics* was issued with some assistance in financing from universities, companies,

CHANGES IN MEMBERSHIP, OCTOBER 1, 1934, TO SEPTEMBER 30, 1935

	Membership		
	Oct. 1, 1935	Oct. 1, 1934	Net Changes
Honorary Members	16	17	−1
Life Members	67	67	0
Members	6375	6548	−173
Associates	268	293	−25
Associate-Members	2604	2658	−54
Juniors (10)	1448	1497	−49
Juniors (20)	3239	3147	+92
	14,017	14,227	−210

and individuals. The publication problem is, however, a major one and at the close of the fiscal year is being given intensive study by the Publication Committee, the Professional Divisions, the Advisory Board on Technology, and the Council.

With appropriations less than customary two years ago, the operation of Sections was carried on with reasonable satisfaction. Three hundred and one meetings were reported. A scale of measurement of Section operation has been developed and put into use. By this it is hoped that the work of a Section during any period can be more accurately evaluated. Also it aids the Section officers to gage the results of their administration.

In addition to cooperating in the preparation of programs for sessions at annual and semi-annual meetings, the Professional Divisions held five successful national meetings during the year.

This year marked the completion of the installation of the new plan of student branch operation. The number of members in student branches reached a total of 3250. Ten student meetings were held with splendid success.

The Committee on Awards has completed a new scheme for administering the honors and awards for the Society, by which a Board of Honor and a Medal Committee will be established. Revisions of the By Laws are under consideration by the Council at the close of this fiscal year.

The technical committee work of the Society was carried on with unexpected activity in view of the condition of the times. Nineteen of the twenty-four research committees showed substantial progress. Ten standards were completed and presented to the American Standards Association for approval. One new Power Test Code and one revised code were published and two new sections and one revised section of one of the codes were completed and approved by the Council.

During the year progress was made in improving contact between the members of the Council and the members of the Society at large. In addition, the President and Secretary visited 48 Sections and 34 Student Branches.

The financial report indicates that the Society has operated well within its income, and has reduced its indebtedness materially.

Advisory Boards

This year saw the initiation of three advisory boards, formed to coordinate the functioning of certain related committees: The Advisory Board on Technology is concerned with meetings, divisions, research, and publications; the Advisory Board on Standards and Codes is concerned with the boiler code, standardization, power test codes, and safety; the Advisory Board on Professional Status is concerned with membership, registration, and the E.C.P.D. These boards made up of representatives of committees with a chairman designated from the Council and set up on an experimental basis for two years, have started to function and have made substantial progress.

Reports of Committees

The complete reports of the standing and special committees follow. They are worthy of painstaking study.

The Parker Case

Shortly before the opening of the fiscal year, Mr. John C. Parker brought action in the Supreme Court looking to an investigation of Society activities, particularly in connection with the Engineering Index and the Boiler Code. The investigation was started in April and continued intermittently through the rest of the year. It is expected that the report of the investigation will be completed before the Annual Meeting. Upon its completion, the Council will render a complete report to the membership.

C. E. Davies, *Secretary*

Reports of Standing and Special Committees

FINANCE

For the second consecutive year since the effects of the depression in the fall of 1931 began to be reflected in its financial affairs, the Society has lived within its income.

(*A*) Yearly Operating Results based upon inclusion of initiation fees:

	1931–32	1932–33	1933–34	1934–35
Total Income.....	$576,590.14	$409,729.73	$395,642.53	$383,830.05
Total Expense and Charges.....	644,588.52	441,281.86	354,936.56	362,905.06
Net Income or Deficit for the Year.	$ 67,998.38 (deficit)	$ 31,552.13 (deficit)	$ 40,705.97 (net income)	$20,924.99 (net income)

(*B*) Yearly Operating Results based upon exclusion of initiation fees:

	1931–32	1932–33	1933–34	1934–35
Total Income	$560,301.81	$396,934.29	$380,287.93	$368,029.82
Total Expense and Charges.....	644,588.52	441,281.86	354,936.56	$362,905.06
Net Income or Deficit for the Year.	$ 84,286.71 (deficit)	$ 44,347.57 (deficit)	$ 25,351.37 (net income)	$ 5,124.76 (net income)

The Finance Committee considers this accomplishment an encouraging indication that the financial condition of the Society is improving. The actual total income during the past year is 6 per cent greater than the budgeted estimate. The situation with respect to dues is considerably better than it was a year ago. For the past two years there has been a slow, but steady increase in the revenue received from advertising and sale of publications. The earnings from investments have continued to hold at an average of approximately 4 per cent. The financial position of the Society, as reflected by its balance sheet, is increasingly liquid. Questionable assets have been written down to amounts believed to be conservative; the current liabilities have been reduced. If these improvements may be considered as indicative, it would seem that a critical period in the history of the Society has been successfully passed.

Statements

In accordance with the practice of recent years, this annual report of the Finance Committee, for the fiscal year ended September 30, 1935, includes detailed comparative statements of the Society's operations for the past two fiscal years. A brief explanation of the statements may assist the membership and committees in a clearer understanding of what the Finance Committee has set forth.

The summary of expanses given in the income and expense statement in Exhibit A is supported by detailed statements, viz.: direct appropriations to Standing Committees of Council in Schedule 1; printing and distribution expenses of publications in Schedule 2; and the itemized expenses of operating the office of the Society in Schedule 3. Additional schedules are included for those members who prefer to have the expenses shown differently, as follows: the departmental expenses of the office are shown in Schedule 4, with the explanation of the activities carried on by each department; in Schedule 5 is given the total cost of the many activities of the Society, obtained by adding to the direct appropriation for each activity its proportionate share of the office expense; finally, the total cost of Society activities is summarized into major groups of services in Schedule 6. The accompanying chart of income and expenditures per member is based upon the total income, including initiation fees, as given in the first column of Exhibit A and upon total expenses and charges as given in the first column of Schedule 6.

The amount collected from initiation fees was not used for operating expenses, but was put directly into surplus as shown in Exhibit A. The net income for the year shown at the bottom of Exhibit A was, likewise, added to surplus. It represents the difference between all income, except that from initiation fees, and total expenses and charges. These additions to surplus, together with other entries directly affecting surplus, are shown in Exhibit B. The balance in the surplus account on September 30, 1935, is the difference between the total assets and the total liabilities of the Society on that date and is so shown in the balance sheet, Exhibit C, before providing for decline from the purchase price to the present quoted market value of the Society's investments, exclusive of trust-fund investments.

The annual audit of the Society's accounts for the fiscal year ended September 30, 1935, has again been made by Messrs. Haskins & Sells, Certified Public Accountants. As explained in the notation following this report, Exhibits A, B, and C and Schedules 1 and 3 were prepared from the auditor's report, whereas, the statements Schedules 2, 4, 5, and 6 were prepared from the Society's records. The statements from the two sources are in entire agreement.

Financial Management

Evidence of the efforts made by the Council to improve the financial position of the Society is apparent from the following: (*a*) insistence upon strict adherence to the budget, (*b*) write-offs of uncertain assets, (*c*) wipe-off of deferred charges, (*d*) facing the facts about present market values of securities, (*e*) reduction of the bank debt, (*f*) advantageous disposal of marketable securities, (*g*) constant attention to the Society's investments, (*h*) unremitting study of trust-fund and other fund requirements, and (*i*) judicious formulation of future policies.

Budget Adherence

Some of the major budget policies formulated by Council in June, 1934, which have been strictly adhered to are: (*a*) the amount available for budget appropriations for Society expenses not to exceed 95 per cent of the estimated gross income, (*b*) an amount equal to the income received from initiation fees to be appropriated from surplus for the reduction of the bank debt, (*c*) efforts to be made to reduce the bank debt by the advantageous sale of securities as opportunity arose, (*d*) no new activity to be undertaken unless definitely known that the funds required would be available without decreasing appropriations or existing essential activities.

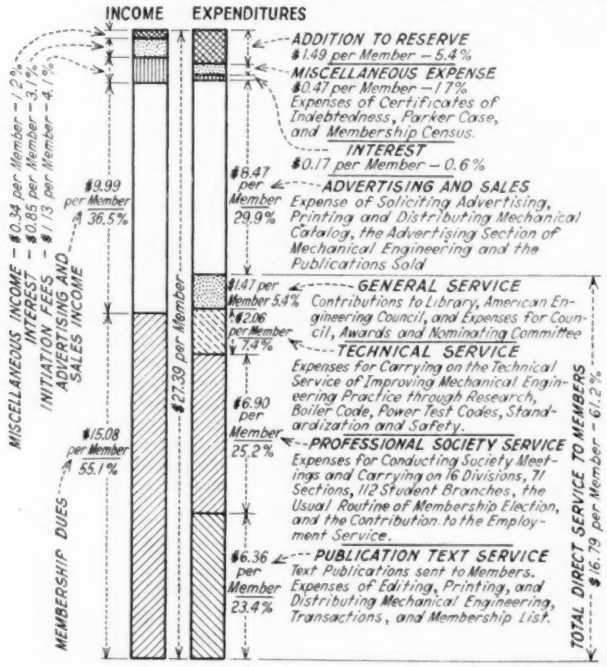
Recent Write-Offs

Upon recommendation of the Finance Committee, after careful consideration, Council has approved many drastic write-offs of uncertain assets and deferred charges during the past four years, in order to present more accurately the Society's condition. An examination of the surplus statements and balance sheets for September 30, 1932, 1933, 1934, and 1935 shows the following major write-offs or creation of reserves:

1932, Dues.....	$ 55,000.00	
Deferred deficits of Engineering Index from Oct. 1, 1927, to Sept. 30, 1931.....	81,740.99	$136,740.99
1933, Dues.....	$164,317.89	
Advertising account.....	20,384.69	
Obsolete and inactive items in inventory.....	78,660.48	$263,363.06
1934, Dues.....	$120,448.65	
Revaluation of Engineering Index inventory and transfer of receivables to Engineering Index, Inc.	34,217.78	
Deferred charge for fiftieth anniversary.....	24,399.66	
Adjustment in publication inventory	10,098.19	$189,164.28
1935, Dues.....		$ 10,000.00

Dues Situation

After a three-year adherence to a lenient dues-payment policy, the Council deemed it necessary in 1934 to begin clarifying the membership status by dropping or suspending, on September 30, 1934, those members who on that date owed dues for two full years or more. Further analysis of the dues accounts in 1935 resulted in the dropping of additional members on June 18, 1935. Although the actual write-offs of the unpaid dues of these members did not take place until the current fiscal year, provision therefore was made out of income in the years shown below:



Year ended September 30, 1932.....	$ 55,000.00
Year ended September 30, 1933.....	164,317.89
Year ended September 30, 1934.....	120,448.65

The sum of these three charges when added to the corresponding expense of $10,000.00 for the present fiscal year, makes the total provision for uncollectible dues for the entire four-year period ended September 30, 1935, $349,766.54.

As the result of the foregoing write-offs and creation of reserves, the amount of dues receivable shown on the balance sheet, Exhibit C, is considered to be collectible in its entirety.

Furthermore, a most favorable dues situation has resulted from the efforts of Council to clarify the membership status. This is

A.S.M.E. INCOME AND EXPENDITURES PER MEMBER, 1934-35

apparent from the fact that, despite a 30-per cent shrinkage in the membership during the past year, the cash collections of dues were improved, as shown:

Year ended September 30, 1934.....$199,868.73
Year ended September 30, 1935..... 201,967.21

Current Condition

On the basis of quoted market values of investments, the current condition of the Society is more liquid than it was a year ago, as shown by the ratio of current assets to current liabilities:

At September 30, 1934.....1.3
At September 30, 1935.....1.9

This corresponds with an increase in the net working capital, or excess of current assets over current liabilities of:

	Current Assets	Current Liabilities	Net Working Capital
At September 30, 1934.....	$154,741.85	$114,562.88	$40,178.97
At September 30, 1935.....	135,289.88	74,771.93	60,517.93

The foregoing ratios and statement of net working capital are computed on the conservative basis used in the Society's balance sheets, and do not take into consideration real estate mortgage bonds and certificates both unpledged and pledged as collateral to bank notes payable having a quoted market value of $71,350.00 at September 30, 1934, and $75,685.00 at September 30, 1935. The reason for the exclusion of these items is their less ready marketability as explained later under the heading "Investments."

Debt Reduction

The demand note held by the bank has been steadily reduced as shown below:

	Amount of Note	Yearly Reductions
September 30, 1933.....	$164,000.00	
September 30, 1934.....	57,500.00	$106,500.00
September 30, 1935.....	17,000.00	40,500.00

The reduction has been accomplished by the application of funds received from three sources:

	1933–34	1934–35
Current income.....	$ 8,897.36	$13,951.93
Sale of securities.....	61,287.42	17,713.29
Sale of certificates of indebtedness to members.....	36,315.22	8,834.78
Total reduction in bank debt.....	$106,500.00	$40,500.00

Sale of Securities

By close observation of the daily market quotations of the issues of railroad and public-utility bonds owned by the Society, the Finance Committee, upon authority of Council, was able to sell certain securities from the Society's portfolio at a profit and thereby to reduce the bank loan. The face value, cost, and net selling price of the securities sold during the past two years are given in the accompanying Table 1.

TABLE 1

	Face Value	Cost	Net Selling Price
(A) Securities sold during 1933–34			
Binghamton Light, Heat and Power Co. 5%, 1946.....	$ 5,000.00	$ 5,000.00	$ 4,931.62
Central Maine Power Co. 5%, Series D, 1955.....	10,000.00	10,100.00	9,974.37
Commonwealth Edison Co. 5%, 1935	5,000.00	5,118.75	5,194.50
Cumberland County Power & Light Co. 4½%, 1959.....	2,000.00	1,890.00	1,877.95
Dallas Power & Light Co. 5%, Series C, 1952.....	5,000.00	5,000.00	5,184.87
Metropolitan Edison Co. 5%, Series C, 1953.....	5,000.00	5,012.50	5,036.12
New York Central and Hudson River Railroad Co. debenture 4%, 1942.	25,000.00	23,062.50	23,943.12
San Diego Consolidated Gas and Electric Co. 5%, Series B, 1947.....	5,000.00	5,075.00	5,144.87
Total during 1933–34.....	$62,000.00	$60,258.75	$61,287.42
(B) Securities sold during 1934–35			
Alabama Power Co. 5%, 1951.....	$ 5,000.00	$ 5,000.00	$ 4,831.90
Cumberland County Power & Light Co. 4½%, 1959.....	3,000.00	2,835.00	2,816.86
Public Service Company of Northern Illinois 5%, 1966.....	5,000.00	4,962.50	5,107.26
Texas Power & Light Co. 5%, 1956...	5,000.00	4,850.00	4,957.27
Total during 1934–35.....	$18,000.00	$17,647.50	$17,713.29

Sale of Certificates of Indebtedness

On March 21, 1934, the Council authorized an aggregate issue of $125,000.00 of four per cent Certificates of Indebtedness, due January 1, 1936, to January 1, 1944, to be sold to the membership of the Society. Between that date and September 30, 1934, certificates amounting to $36,450.00 were purchased by members. In the current year additional certificates amounting to $8,700.00 have been purchased by members, thus bringing the amount issued to $45,150.00 on September 30, 1935. Of this amount $600.00 face value of certificates have been donated to the Society by members and are held in the treasury. Those members who purchased Certificates of Indebtedness are to be commended for their willingness to assist the Society. By their loyal support they have not only enabled the Society to reduce its indebtedness to the bank and to lower the annual interest rate by one per cent from the former level; but, in instances where purchased certificates have been donated to the Society, those members have beneficently opened a new channel of revenue through which the Society's financial condition may now be continuingly strengthened.

Investments

The status of each real-estate mortgage bond and certificate has been analyzed and studied. With the exception of two mortgage bonds with a combined face value of $54,000.00, all mortgage bonds and certificates owned by the Society, whether as investments or as trust-fund securities, are issues of the Lawyers Mortgage Company. Practically all mortgage bonds of the Society are secured by real-estate properties in New York City. The Department of Insurance and the Mortgage Commission of the State of New York have endeavored to rehabilitate the Lawyers' Mortgage Company by supervising its operations during the depression. The quoted market value for real-estate mortgages in New York City is low, inasmuch as investors are not buying that form of security; but the majority of the properties

in which the Society has a participating interest are being well managed. This is evidenced by the average yield on real-estate mortgage bonds and certificates owned by the Society which was:

	Trust-Fund Investments	Other Investments	Average
For Fiscal year: 1933-34	4.46%	3.37%	3.64%
1934-35	4.13%	3.59%	3.75%

Although the average yield is exceptionally good for this class of investment at the present time, the mortgages are still in a "distress market." In most cases the market value of these investments is expected ultimately to return to nearly the original purchase price.

The complete schedule of securities owned by the Society appeared in the annual report of Council for 1932–1933 on page 25 of the Record and Index Section of Transactions for 1933. A schedule of securities as of September 30, 1935, has not been included in this report inasmuch as the only changes are those previously noted under the heading "Sale of Securities."

Respectfully submitted,

WALTER RAUTENSTRAUCH, *Chairman* — WM. H. GESELL
WM. T. CONLON — K. M. IRWIN
W. D. ENNIS — ERIK OBERG, *Treasurer*
ELY C. HUTCHINSON, JAMES H. HERRON — *Council Representatives*

ACCOUNTANTS' CERTIFICATE

The American Society of Mechanical Engineers:

We have made an examination of your accounts for the year ended September 30, 1935. Under the terms of our engagement, the accounts receivable, other than advertising accounts, at September 30, 1935, and collections during the year were not verified by confirmations obtained from the debtors, nor were the quantities of the inventories verified by us.

In accordance with recommendations made by us in previous years, the Society during the year under review has compiled detailed records of dues receivable from members. This compilation shows balances receivable at September 30, 1935, aggregating approximately $21,000.00 in excess of the amount shown by the general records. No effect has been given in the accompanying statements to any part of such excess, and therefore the income of the Society for the year under review is conservatively stated. A study now being made by us in conjunction with the Society's staff indicates that a substantial part of the above-mentioned excess has its origin in actions taken by the Society to continue in membership certain individuals whom it had previously expected to drop from the rolls. A supplemental report will be issued setting forth the extent to which the surplus will be adjusted during the fiscal year beginning October 1, 1935, on account of the foregoing.

In conformity with the practice followed by the Society, there have not been included in its accounts nor in the accompanying statements any accruals of interest receivable or payable other than on outstanding certificates of indebtedness.

In our opinion, subject to the foregoing and to the notations on the accompanying statements, the attached balance sheet and statements of income and expenses and of surplus set forth, respectively, your financial condition at September 30, 1935, and the results of your operations for the year ended that date.

(Signed) HASKINS & SELLS

New York
November 30, 1935

NOTE: The following Exhibits A, B, and C and Schedules 1 and 3 have been prepared from the report of Messrs. Haskins & Sells; Schedules 2, 4, 5, and 6 have been prepared by the Finance Committee from the Society's records.

EXHIBIT A

COMPARATIVE STATEMENT OF INCOME AND EXPENSES

For Two Fiscal Years Ended September 30, 1935

INCOME	1934–35	1933–34
Initiation fees (carried to Surplus)—See Exhibit B	$ 15,800.23	$ 15,354.60
Membership dues (Less provision for dues considered uncollectible at September 30, 1935, $10,000.00; September 30, 1934, $120,448.65)	$201,660.34	$198,731.15

SCHEDULE 6. TOTAL COST OF A.S.M.E. ACTIVITIES

	1934–35	1933–34
General Service—Contributions to Library, American Engineering Council, and expense of Council, Awards, and Nominating Committees	$ 20,628.95	$ 18,904.08
Society Activities—Expenses for Society Meetings, Professional Divisions, Local Sections, Student Branches, Membership Election, and contributions to Employment Service	96,919.78	86,756.11
Technical Service—Expenses of Committees on Boiler Code, Power Test Codes, Research, Safety, and Standardization	28,489.82	32,929.06
Publication Text Service—Expenses of editing, printing, and distributing text section of *Mechanical Engineering*, Transactions, *Journal of Applied Mechanics*, and Membership List	89,332.01	79,442.40[a]
Advertising and Sales—Expenses of soliciting advertising, printing, and distributing Mechanical Catalog, Advertising Section of *Mechanical Engineering*, and publications sold	118,841.11	106,617.49
Engineering-Index—Expenses of editing, printing, soliciting, and distributing Card Service and Annual Volumes		21,235.20
Certificates of Indebtedness—Expenses of soliciting sales, printing certificates, legal service and interest	1,895.18	1,047.64
Cost of Parker Case—Expenses of legal counsel, minutes of hearings, and printing papers on appeal	2,326.37	
Membership Census—Expenses of printing, distributing, and analyzing biographical data sheets of members	2,054.66	
TOTAL	$360,487.88	$346,931.98

[a] No expense of *Journal of Applied Mechanics* nor Membership List in 1933–34.

EXHIBIT B

STATEMENT OF SURPLUS

For Fiscal Year Ended September 30, 1935

BALANCE, OCTOBER 1, 1934, PER SOCIETY ANNUAL REPORT		$222,596.59
CREDITS:		
Initiation Fees	$15,800.23[a]	
Adjustment of Prior Years' Interest—Retirement-Fund Reserve	1,810.46	
Reduction in Capital Investment	557.56	
Adjustment of Prior Year's Inventory	115.76	
Net Income for the Year, per Exhibit A	5,124.76	23,408.77
TOTAL		$246,005.36
CHARGES:		
Write-Off of Loan to Committee on Thermal Properties of Steam	$ 4,000.00	
Assessment by United Engineering Trustees, Inc., for construction of Library stacks in a prior year	2,500.00	
Reduction of Brashear Biography Inventory value	457.92	
Adjustment of Custodian-Fund Interest Applicable to prior year	197.99	7,155.91
BALANCE, SEPTEMBER 30, 1935 (representing excess of income, including initiation fees, over operating expenses and other charges, and subject to provision not having been made for decline of $163,200.64, as of September 30, 1935, in the quoted market value of the Society's investments, exclusive of trust-fund investments)		$238,849.45

[a] It being the practice of the Society to take up initiation fees only as and when collected, the above statement does not include such fees receivable at September 30, 1935, and October 1, 1934.

EXHIBIT C

BALANCE SHEET, SEPTEMBER 30, 1935

ASSETS

CURRENT ASSETS:			
Cash		$ 17,421.80	
Accounts receivable:			
Dues (less reserve for uncollectible items, $32,253.17)	$10,295.34		
Publications and advertising (less reserve for uncollectible items, $4,000.00)	44,840.61		
Miscellaneous	1,232.16	56,368.11	
Inventories:			
Publications for sale	$35,378.54		
Publications in process	8,092.49		
Supplies	4,741.94	48,212.97	
Securities—At cost (quoted market value, $13,287.00)—$23,177.64 deposited as collateral to bank note payable		23,277.64	
TOTAL CURRENT ASSETS			$ 145,280.52
REAL-ESTATE MORTGAGE BONDS AND CERTIFICATES—AT COST (quoted market value, $110,540.00):			
Pledged as collateral to bank note payable		$ 86,000.00	
Pledged as collateral to Certificates of Indebtedness		68,750.00	
Unpledged		109,000.00	
TOTAL REAL-ESTATE MORTGAGE BONDS AND CERTIFICATES			263,750.00
TRUST-FUND ASSETS:			
Corporate stocks and real-estate mortgage certificates (quoted market value, $66,370.52)		$118,127.16	
Cash		2,640.44	
TOTAL TRUST-FUND ASSETS			120,767.60
PROPERTY-FUND INVESTMENTS:			
One-fourth interest in real-estate and other assets of United Engineering Trustees, Inc., exclusive of trust funds		$496,948.48	
Office furniture and fixtures (depreciated value)		23,719.60	
Library books		1.00	
Engineering Index—Title and good-will		1.00	
TOTAL PROPERTY-FUND INVESTMENTS			520,670.08
DEFERRED CHARGES—Society Activities Applicable to Subsequent Years			141.46
TOTAL			$1,050,609.66

LIABILITIES

CURRENT LIABILITIES:			
Note payable—Bank (See securities pledged, contra)		$ 17,000.00	
Accounts payable		21,382.00	
Unfilled commitments—Estimated liabilities relating to "Mechanical Catalog" for 1935–1936, etc.		13,700.20	
Assessment payable—United Engineering Trustees, Inc.		2,000.00	
Custodian funds		16,243.23	
Reserve for prepaid subscriptions		4,000.00	
Accrued interest on certificates of indebtedness		446.50	
TOTAL CURRENT LIABILITIES (exclusive of Certificates of Indebtedness to be redeemed January 1, 1936)			$ 74,771.93
FOUR PER CENT CERTIFICATES OF INDEBTEDNESS, Due January 1, 1936, to January 1, 1944 (10% of the total amount issued to be redeemed January 1, 1936)—See investments pledged, contra:			
Authorized	$125,000.00		
Issued		$ 45,150.00	
Less in treasury		600.00	44,550.00
TRUST-FUND RESERVES:			
Principal		$111,120.02	
Income		9,647.58	120,767.60
PROPERTY FUND RESERVE			520,670.08
RESERVE FOR EMPLOYEES' RETIREMENT ALLOWANCES			15,921.61
DEFERRED CREDIT—DUES RECEIVED IN ADVANCE			35,078.99
SURPLUS (representing excess of income, including initiation fees, over operating expenses and other charges, and subject to provision not having been made for decline of $163,200.64 as of September 30, 1935, in the quoted market value of the Society's investments, exclusive of trust-fund investments), per Exhibit B			238,849.45
TOTAL			$1,050,609.66

NOTATION:

In accordance with the Society's practice, initiation fees receivable are not included in the above statement as they are taken up by the Society as assets only as and when collected.

MEETINGS AND PROGRAM

With each year there are changes in the aspects of the work of the Committee on Meetings and Program and its problems are constantly shifting. Through it all there remain, however, certain fundamental requirements upon which it is periodically necessary to place pressure that the Society as a whole may continue its progress and provide for the service and welfare of the members.

In the year just concluded the Committee's slogan has been "Better meetings and bigger attendance, within the budget." Necessarily the latter presented limitations. Nevertheless, much has been accomplished and reactions to the work of the Committee from the members in general have been encouraging.

For the purpose of developing greater uniformity of action, a suggested policy for the Society with respect to exhibitions held in conjunction with meetings was prepared by the Committee and submitted to the Board of Technology for consideration.

The Annual Meeting which was held December 3 to 7, 1934, was generally satisfactory. Dr. John H. Finley, editor of the *New York Times* delivered the Calvin W. Rice Memorial Lecture, given to commemorate Dr. Rice's contribution to the development of international friendliness in the engineering profession. Because Dr. Rice's services to the Society were outstanding in international relationships in that field. This memorial should be repeated as occasion is offered, as it was when Dr. Adolph Meyer of Switzerland was the lecturer at the Semi-Annual Meeting at Cincinnati.

At the annual banquet the plan of securing as speaker a well-known and outstanding lecturer upon world affairs was extremely well received. To make it possible for members not attending the banquet to listen to the speaker, it was arranged that for a small entrance fee such members would be admitted to the banquet room. The plan worked moderately well, and it is hoped to develop it further.

At the Annual Meeting a small registration fee was charged for nonmembers who were not invited to attend the Meeting. The plan serves to emphasize the value of the Society to the individual member, and it is hoped to develop it further.

The meeting in Cincinnati was eminently successful in every way. Programs for both meetings were published in the publications of the Society and are to be considered as a part of this report by reference.

The revised pamphlet, "Suggestions to Authors" has resulted in increased excellence of presentation of papers. The policy of printing papers in advance of the meetings has been continued with growing popularity.

Council has allotted for all activities conducted under the supervision of the Meetings and Program Committee for the year 1935–1936 the sum of $5700. This amount will be disbursed by the Committee in such manner as to provide the greatest number of meetings. There are now scheduled the 1935 Annual Meeting to be held in December, 1935, the 1936 Semi-Annual Meeting at Dallas, Texas, as well as regional meetings in San Francisco and Niagara Falls also to be held during 1936.

To enable a larger number of members to enjoy the ceremonies and addresses which have been scheduled heretofore on Tuesday evening of Annual Meeting week, known as "President's Night" it has been decided to transfer some of these events this year to the Banquet night on Wednesday. The President's reception and the Presidential Address will be combined with the Banquet and followed by dancing. Tuesday evening will be designated as "Honors Night" at which time the medals and honors will be presented, to be supplemented by one or two addresses or lectures of importance and current interest.

The committee has studied the general programs of the individual Local Sections and has offered to the officers of the Sections suggestions for improving their programs and aid where suitable speakers could not be found locally. The Committee fostered a policy which will insure publication of Local Section papers that meet the standards required of national meeting papers.

Respectfully submitted,

ROBERT I. REES, *Chairman* CLARKE FREEMAN
ELY C. HUTCHINSON R. F. GAGG
HARVEY N. DAVIS D. C. CORY, *Junior Representative*

PUBLICATIONS

At the beginning of the fiscal year the Committee on Publications faced a further decrease in funds below the insufficient amount allotted for publications last year. This forced further curtailment in the services of the committee during the early part of the year, although there was no decrease in the number of papers being presented and recommended for publication. The committee solicited the aid of the Professional Divisions in recommending for publication only papers of outstanding quality and timeliness. The Advisory Board on Technology assisted materially in assenting to a policy for allocating available funds and space among the several technical-paper production agencies of the Society, a plan yet to be worked out in detail, and in urging Council to increase the allotment of funds for publication.

Fortunately an increase in income, both from dues and advertising, enabled the Council to provide more money for publications during the latter part of the fiscal year. Members of the Society expect and are entitled to this direct evidence of an increase in available income. The Committee is continuing to urge the importance of all means for improving the quantity, quality, and timeliness of the technical publications of the Society and for enlarging and improving "Mechanical Engineering."

SUGGESTIONS OF LOCAL SECTIONS DELEGATES

From the Conference of Local Sections Delegates held in connection with the 1934 Annual Meeting the Committee received several suggestions and points of view, all of which were discussed and acted upon.

The confusion existing regarding the name "Record and Index," applied to a publication issued in several sections, only one of which was an index, was cleared up by adopting the name "Society Record" for the sections which are records and "Index" for the final section which is made up of indexes to the Transactions, *Mechanical Engineering*, and miscellaneous publications.

The suggestion that a handbook of codes and standards be distributed free to members was referred to the Advisory Board on Technology.

A suggestion of an assistant editor representing, and resident on, the Pacific Coast was noted but action was withheld for financial reasons.

Comments and suggestions relating to publication policy, requested by the Committee and reported from the individual group conferences were noted and discussed. No serious objections to these policies were registered, but early in 1935 several individuals protested vigorously against the policy of including in *Mechanical Engineering* papers on non-technical subjects, particularly in economic, sociological, and management fields. The Committee attempted to explain its point of view to these critics, and pointed out that in practically every instance the papers on these subjects had been submitted by some official group within the Society, and that the Management Division, whose contributions were objected to on the ground "that they were not engineering," was one of the largest groups in the Society.

For several years the Committee has been alive to criticism of this sort and from time to time has attempted to secure opinions from widely distributed individuals and groups. In the spring of 1935 a "check list" was circulated among selected groups of junior members. One of the objects of this check list was to determine the distribution of reader interest. In all of these attempts to learn what readers want, results have been generally negative. That is, approximately as many do not care for non-technical articles as do. There are very positive statements of preference by some individuals on both sides of this question. It is hoped that the recent census of biographical and professional data will reveal patterns of member interest to guide in selecting material for *Mechanical Engineering*.

TRANSACTIONS

During the fiscal year 1934–1935 the Transactions contained 76 papers, a total of 730 pages; these figures include three issues during 1935 of the *Journal of Applied Mechanics*.

In a memorandum to the Council dated July 2, 1934, it was pointed out that with the proposed budget of $18,000 it would be possible to publish only 64 papers. The Council, in noting the memorandum, expressed the opinion that a minimum of 100 papers per year was desirable and put itself on record as wishing to increase the budget for Transactions as soon as conditions would permit so that this number could be attained. While the figure of 64 papers represented a calendar year, the number 76 actually published in the 12 months of the fiscal year shows how closely that desired number may be realized.

During the summer of 1935 eight papers on hydraulic subjects, whose publication had been postponed because of lack of funds, appeared in the Transactions.

Improvement in the Committee's ability to publish papers resulting from meetings is shown in the record of the Cincinnati meeting. Either in *Mechanical Engineering* or the Transactions 32 of the 38 papers for which manuscripts recommended by the sponsoring groups were received either were published or are shortly to be published.

"Journal of Applied Mechanics"

Under the auspices of the Applied Mechanics Division, a board of editors, headed by John M. Lessells, has been providing material for the section of the Transactions known as the *Journal of Applied Mechanics*. Three issues of the Journal, each of 40 pages, have appeared. The *Journal*, which goes to all members of the Society in good standing, to all subscribers of the Transactions, and to a small list of subscribers to the *Journal* only, has been departmentalized. The departments are: Technical papers; reviews of subject matter within the purview of the Division (to date largely sections of the Division's 1934 Progress Report); design data, a section of material arranged for the immediate use of designers; book reviews; and discussions of papers published in previous issues.

The wealth of available material pressing for publication has proved embarrassing for the editors. At a meeting held in Ann Arbor, Mich., in June, it was decided to limit papers to six pages in order to make possible the publication of a greater number of papers.

Sponsors of the *Journal* are of the opinion that the *Journal* is distributed much more widely than the interest of those who receive it in the subject matter of the papers warrants. They would like to see the circulation reduced to include only those actually desirous of receiving papers of this type. However, a promise was made at the 1933 Annual Meeting to the members of the Society that every member would receive all Transactions papers. This implies that all members shall also receive the *Journal*. The Committee on Publications believes that no change in this policy should be made. In holding this opinion the Committee has in mind not only the 1933 pledge, but the belief that applied mechanics is fundamental to most mechanical-engineering practice. It feels that the wide distribution of all Transactions papers tends to hold the Society's technical interests together, and it recognizes that the great number of younger members, whose careers are still in the formative stage, are better served by "exposure" to a wide range of technical literature than by a too early specialization of interest in what may be, for the individual, a temporary connection with a given field of practice. While the Committee would welcome the voluntary relinquishment of the privilege of receiving the *Journal* by members who have no use for such a publication, it does not wish to be placed in the position of requesting members to give up the *Journal*. Much less would it wish to make every member ask to have the *Journal* sent to him, a request that would not be in keeping with the 1933 pledge.

In order to assist in financing the Journal, its board of editors has solicited funds from interested individuals and organizations. A summary of contributions is as follows:

Universities	$1000.00
Companies	379.00
Individuals	157.00
Total	$1536.00

The Committee has no way of estimating how much money can be collected from these sources during the coming year.

The Committee views the *Journal* as being still in the experimental stage, and withholds its comment on the success of the venture. No criticism of the quality of the technical papers is implied nor intended by this statement, and the Committee wishes to record its deep appreciation of the enthusiasm and services to the Society of the Applied Mechanics Division, the board of editors of the Journal, and John M. Lessells, technical editor of the Journal, on whom the burden of providing the material and soliciting the funds has fallen.

Society Record

Formerly known as the "Record and Index," the present Society Record has been issued from time to time as a supplement to the Transactions. With the February, 1935, issue of Transactions the Society Record contained a complete list of the Society's committee personnel and other reference material as of the administration year that opened in December, 1934. There was thus provided at the earliest practicable moment as complete and up-to-date information on the Society's committees as could be assembled. Heretofore these lists have been of historical interest only as they represented, not the current committee personnel, but that of the previous year.

The scheme of issuing the Society Record in supplements to the Transactions makes it possible to distribute the information contained in the Record as soon as it is available, and also places a more uniform load on the editorial staff. The committee personnel, as already explained, is published as soon as committee appointments have been made; reports of committees are published immediately following the end of the fiscal year and before the Annual Meeting; the indexes to publications appear as soon as the December issues are off the press. Memorial notices of deceased members are issued during the summer.

Membership List

For the first time since 1931 a membership list was published in December, 1934. It was distributed as a supplement to Transactions for December in order to save postage, and the format was consequently changed.

The Committee feels that the effect on the members of the Society of resuming publication of the Membership List was distinctly favorable and valuable. It was therefore with extreme regret that the Committee noted the vote of the Council at its Cincinnati meeting not to publish the Membership List in 1936. It sustains the hope that early resumption of the membership list as a regular annual publication will be ordered by the Council.

"Mechanical Engineering"

Plans for the development and improvement of *Mechanical Engineering* still await increase in Society income from dues and advertising, which will permit additions to an overburdened editorial staff. As already noted, the budget for *Mechanical Engineering* was increased during the summer, permitting the continuance of an average of 67 pages per issue, which otherwise would have been cut materially.

The revenue from advertising this year shows an increase over last year's income. It has been understood that any gain should be applied to the publication, and additional funds were made available for publications as already noted. The Committee's financial statement indicates what has been accomplished.

The Committee has received from several sources queries on the relative proportions of subject matter in *Mechanical Engineering*. This led to an analysis covering about 17 issues which showed the following percentages: Technical papers, 54.3 per cent; professional matter, 14.7 per cent; general, 15.5 per cent; and departmental, 15.5 per cent. It also showed the following distribution as to sources from which the material was derived: Meetings and Program Committee, 29 per cent; Professional Divisions, 26 per cent; Local Sections, 11 per cent; Society Committees, 10 per cent; joint activities with other societies, 2 per cent; miscellaneous contributions and staff articles, including "Engineering Progress," 22 per cent.

Student Branch Bulletin

For eight months during the school year the Student Branch Bulletin, a four-page publication, is distributed with *Mechanical Engineering* to the 3250 members of the Society's 112 student branches.

A hopeful experiment with this publication was inaugurated in September, 1935. A board of editors made up of junior members in the Metropolitan district has taken over the preparation of material for this publication. The following, from the initial issue, explains the objective:

> "The task of editing the 'Student Branch Bulletin' has been taken over by a committee of Junior members of the Society partly to relieve the publications staff, partly to provide an outlet for the energies of younger men, and partly with the hope that the result would be a publication more nearly tuned to the needs and desires of the student engineer."

The Committee wishes to acknowledge its gratitude to this committee and to commend the spirit in which the young men have responded to the opportunity to serve the Society in building up interest among student members.

Mechanical Catalog

The 1935–1936 edition of the Mechanical Catalog marks the twenty-fifth year of reference service to industry. Improved in makeup, the issue for this year has over 10 per cent more pages of product descriptions than the preceding edition and a new index feature with the title, "Manufacturers' List." The "Classified Index" in the volume has some 4000 product headings, carefully checked as to technical nomenclature.

Biennial Report

In 1932, under the chairmanship of W. H. Winterrowd, the Committee on Publications made an extensive study of its functions and problems and presented the results to President Lauer in the form of a comprehensive report. Among other recommendations of this report it was suggested that a similar report be prepared every two years. During the spring of 1935 a new report was prepared and presented to the Council at the Cincinnati meeting. At the suggestion of President Flanders the report was assigned for study and discussion at its October meeting.

Further Study of Publications Policy

Following the presentation of the Biennial Report to the Council the Committee on Publications continued its study of policies at a

meeting on September 6 as a result of more recent developments, among which was a suggestion that the *A.S.M.E. News*, suspended January 1, 1933, be resumed in some form. The Committee's recommendations were presented to the Council at its October meeting.

Conclusions and Recommendations

As is true of all Society committees, the work of the Committee on Publications has been seriously curtailed during the last few years. It wishes to emphasize the following points:

1 Serious curtailment in funds for publication has had a cumulative and adverse effect on Society prestige and on membership morale. Instances have been cited in annual reports of the committee where other agencies have published papers that should be a part of the Society's literature; of committees and divisions that are discouraged and dissatisfied because papers and reports considered by them to be valuable have not been published by the Society, and of groups that have financed their own publications in impermanent form with the result that they are quickly lost to future researchers in these fields. At the base of most publications problems lies lack of funds.

2 Failure to provide adequate and timely publicity on the Society's activities has resulted in growing disinterest in the Society, ignorance and misunderstanding of what is being accomplished, and a consequent weakening of the morale of members, committees, and divisions. An effective house organ or publicity medium is urgently needed. Whether this should be an independent publication, as was the *A.S.M.E. News*, abandoned for reasons of economy a few years ago, or a development of the news function of *Mechanical Engineering* depends on other questions of publication policy. It is the opinion of the Committee on Publications that the Council should, as soon as possible, make provision for an effective and adequate method of giving publicity to the Society's affairs.

3 The Committee is eager to undertake its long deferred plans for developing and improving *Mechanical Engineering*, and earnestly solicits additional funds for this purpose.

4 Assistance to the Committee's continued study of its problems looking to long-time plans for development and improvement of all its publications is solicited.

Respectfully submitted,

S. W. Dudley, *Chairman*
W. F. Ryan, *Vice-Chairman*

LOCAL SECTIONS

The administrative responsibility of the Committee on Local Sections includes matters of finance as well as the correlation and general direction of Local Sections. It acts in a liaison capacity between Sections and Council, Professional Divisions, Research and Standardization Committees, etc., to promote the interest of all. It directs and plans the activities of the Sections and maintains knowledge of these activities by rating, by report, and by personal contact whenever possible.

General Conditions

Considering the industrial conditions of the country the Local Sections may be considered to be in a satisfactory condition, but they have suffered both from lack of sufficient funds and from loss of membership and leaders.

There is a certain unrest difficult to explain, partially due to inadequate financing in maintaining desired and planned activities, with a consequent lag in interest; partially due to lack of intelligent leadership or initiative on the part of the Section Executive Committees. This, fortunately, is not the case in all Sections. Unrest is fostered by lack of knowledge of Society structure, affairs, and purposes. The members of the Committee on Local Sections have tried by personal contact to advise and educate members in these matters.

The attendance of Sections Delegates both at Group Conferences, and at the Group Delegates' Conference has been a matter of extreme concern to the Committee. The attendance has approximated 60 per cent of that necessary, and nonattendance is due simply to inability of members designated as delegates to attend without serious financial loss to them under the present expense allotment. This is a serious matter to those traveling long distances, and a careful survey indicated that, on the average, every dollar supplied by the Society was matched by a dollar from the pocket of the delegate. This has never been expected nor required, and attendance will not be sufficiently large to permit these conferences to function properly or to voice adequately the advice, desires, and suggestions of the membership unless some method is found to finance completely the delegate's trip.

Budget, 1935–1936

The Committee regrets that the estimate of Society income was insufficient to allow the amount it requested and considered the minimum necessary for adequate Section operation. Requests for additional funds are frequent. This is a continuing indication of the insufficiency of funds necessary for constructive operation. Dissatisfaction is expressed as to the disbursement of Society funds and is made the excuse for non-payment of dues.

Group Conferences

Last fall only 53 out of 71 Sections were represented at the Group Conferences. Of these 53, six attended Conferences held in their home cities, therefore only 47 delegates actually traveled to attend. This was the cause of the low expenditure of delegates' mileage, not a commendable saving. Every section is entitled to representation, but that result is secured only when delegates' expenses are fully met.

The superiority and advantages of these Conferences is increasingly evident in better developed agenda, and constructive suggestions to Council. The Committee feels that the work accomplished by these Conferences is most essential.

The Committee approved the following method of electing delegates: "That at each Group Conference Meeting in 1935 two delegates be elected to attend the Delegates' Meeting in New York in December, one delegate to be elected for one year and the other delegate to be elected for two years; and thereafter one delegate shall be elected each year for a term of two years, and be it further provided:

That the Senior Delegate in each Group shall automatically become Chairman of his Group Conference; and it shall be mandatory upon a Local Section to elect such Senior Delegate as its representative to the Group Conference. In such instances the Section will be entitled to another delegate at the Group Conference."

Redistricting Local Sections

At the suggestion of the Committee on Policies and Budget, the Executive Committee of Council requested the Committee on Local Sections to make a study of the principle of redistricting Local Sections along geographical lines perhaps better suited to the purposes and administration of the Society. The Committee made a complete study of the geographical significance, railroad fares, time of travel, and community of Section interest. Careful inquiry was made of Sections' interests and desires, and several tentative groupings were considered and investigated prior to the Sections Delegates' Conference at Cincinnati.

It was decided from this study by the Committee on Local Sections and the Group Delegates that it would be difficult to develop a better arrangement than that of the present seven groups. Any increase in the number of groups would tend to increase expense, correspondence, postage, travel, exchange of information, details of operation, delay in obtaining action or approval. These are a few of the many factors involved.

Student Meetings

The Student Meetings held in 1934–1935 were unqualified successes from the standpoints of interest, college and Section cooperation, attendance, and technical papers. It is apparent that the students appreciate the attendance at these Conferences of members of Council, staff, and standing committees. Fortunately it was possible for President Ralph Flanders to attend and address some of the Conferences. This interest shown by the officers of the Society is most impressive to the student. Such contacts are an inspiration to both students and members, and will bear fruitful results. The Committee wishes it were possible for such contacts to be made a permanent policy.

Schedule and Place of Group Conferences in 1935

Place	Tentative date	Committeeman to attend
Group I, Providence	October 26–27	Ernest Hartford
Group II, New York	November 1–2	Ernest Hartford
Group III, Ithaca	October 26–27	R. E. W. Harrison
Group IV, Chattanooga	October 26–27	W. R. Woolrich
Group V, Columbus	October 27–28	D. B. Prentice
Group VI, St. Louis	November 2–3	D. B. Prentice
Group VII, Spokane	November 8–9	W. L. Dudley

Semi-Annual Meeting in 1936

Upon the invitation of E. W. Burbank, Chairman of the North Texas Section, Council scheduled the 1936 Semi-Annual Meeting at Dallas, Texas, to be held during the third week of June.

Regional Meetings, 1935–1936

The Committee on Local Sections has received an invitation from the Buffalo Section to hold a Regional Meeting at Niagara Falls, now scheduled tentatively for September, 1936; also an invitation from San Francisco to hold a Regional Meeting there in March or April, 1936. This will be accomplished by expanding plans for a western meeting of the Machine Shop Practice Division to include other Divisions.

Manual for the Operation of a Section

The "Manual for the Operation of a Local Section" has been revised and distributed to officers of Local Sections.

"Scale-of-Measurement" Revision

The method of rating and recording the activities of a Local Section as regards its service to the membership, and its service to the Society, which has been in use by the Committee since 1933, has proved extremely useful both to the Sections themselves in evaluating activities and personnel, and to the Committee in guiding and planning the work for any particular Local Section.

The "Scale-of-Measurement" has been revised and simplified. It is believed the change has improved its utility, and that it will be of more positive value.

Junior Program

The Committee has been vitally interested in the useful participation of the Junior Member in the activities of the Local Sections, and concerned for his reception by the members of the profession and the members of the Society. An intelligent solution for the adequate reception and participation of the Junior must be found, and the Committee on Local Sections is interested in planning intelligently toward this end.

President D. B. Prentice of Rose Polytechnic Institute, a member of the Committee on Local Sections, and Chairman of the Committee on Junior Members which cooperates in this work, presented from this committee eight recommendations for stimulating and maintaining the interest and participation of the Juniors in the Society.

Note: Mr. W. W. Macon attended the Annual Meeting in December, 1934, in New York City. He died on January 1, 1935.

Their accomplishment is a planning responsibility of which the Committee is keenly aware. It appreciates both the work and suggestions of the Junior Committee and promises its utmost in cooperation.

Cooperation With Student Branches

The Committee recognizes its obligation to Student Members and Branches through staff contacts such as were made by its secretary, Ernest Hartford in his recent trip. The fine cooperation of the Local Sections whose members have arranged for attendance at Student Branch Meetings, the attendance of students at Local Sections Meetings, and the participation of students in inspection trips arranged by Sections all show the spirit of cooperation. Many Local Sections offer prizes to win the active interest of undergraduates.

Joint Meetings of Local Sections

Sections are encouraged to hold joint meetings with the local engineering organizations and clubs, or sections of other national engineering societies. Through these joint meetings a community of interest is fostered and developed. Much of the investigation and development of the problem of engineering registration has resulted from them.

Employment Service

The Society undertakes to assist members to secure positions, maintaining offices in New York, Chicago, and San Francisco, with the cooperation and help of other National Societies. The Local Sections have cooperated to the fullest in extending the service to engineers and employers.

Cooperation With Other A.S.M.E. Activities

During the last few years the Standing and other Committees of the Society have felt keenly the need and perceived the necessity for cooperation to correlate their efforts and activities, that the greatest good might be obtained from their respective efforts. An effort is being made to realize this aim.

In most cases the Local Sections are the outlet for putting into effect many of the activities of the various Committees in their planned programs and activities.

The work of the Professional Divisions of the Society is invaluable to the Local Sections, as they are equipped to supply planned technical programs to be presented before Local Sections, or before meetings sponsored by Professional Divisions and held with the approval and cooperation of the Local Sections. Such meetings have been successful, but there still remains a large opportunity for the Professional Divisions to submit developed programs of a strictly technical nature which can be utilized in planning for comprehensive Sections programs.

This procedure was suggested to the Professional Divisions by the Advisory Board on Technology on January 12, 1935. Such programs when submitted will be distributed to those Sections within whose sphere of interest the subjects lie.

Inventory and Planning

Local Sections are encouraged to devote some of their meetings to the branches of industry dominant in their locality, and to matters of public interest where the mechanical-engineering profession can make a contribution.

A most effective way in which the members of the Society can attack the problems confronting them is by adopting a program for Section activities in which those well-informed persons available to a Section may analyze the problem, thus providing suitable papers for discussion.

The Committee offers some thirty topics for which qualified speakers are available. These topics are intended to supplement programs of the Divisions and include such general topics as "American Manufacturing Technique in Competition With the World," "Engineering Functions in a War-Time Procurement Program," "The Effect of the Business Cycle on Engineering Activity," "Railroads From the Lay Engineers' Viewpoint," "Competition Between Industries," and many others of a similar trend.

The Committee has, after considerable study, outlined and put into action a planned program for the Local Sections. This planning is an effort to chart the course of the activities related to Local Sections and includes the following items:

Junior program and Section program; Section administration; Group conferences; membership development; Section policies; employment; joint relationships; field offices; cooperation with engineering faculties; representation on A.S.M.E. Council by geographical groups of Sections; services and development program for personnel; work of Engineers Council for Professional Development; cooperation with American Engineering Council; Student Branches; Meetings and Program; Professional Divisions; local engineering societies; registration of engineers; and legislation affecting engineers activities.

This program is to be fully developed in the Group, Annual, and Semi-Annual Meetings by the delegates, and put into effect by them.

The chairmen and executive committees of all Local Sections have had submitted to them a preamble of objectives for Local Section development to be supported by (*a*) The work of inventory; (*b*) Evolving a planning procedure; (*c*) The execution or realization of this plan into a working program.

The planning procedure and the hoped-for execution has been outlined above. The work of inventory is a careful summation of the possibilities inherent in the local Section that can be intelligently utilized, each possibility to be developed by a committee of the Section. This has a multiple purpose. It is to acquaint the members by Committee service of the functions of their Section, and their application to Society and public service. This in itself provides an activity of extreme importance to the members, the Section, and the Society and gives a knowledge of the work upon which the Society is engaged.

Local Sections Papers

The Advisory Board on Technology states that worth-while papers presented at meetings of Local Sections will continue to receive

* In addition to 64 separate Junior activities.

special consideration by the Committee on Publications, and the Editor of "*Mechanical Engineering.*"

Midwest Office

The Committee on Local Sections is glad to express the appreciation of the Sections and Student Branches in the Midwest of the fact that Council has continued the Midwest Office. Many activities and members have found the services of that office of value.

Death of W. W. Macon

Last January Mr. Macon, whose years of effort in behalf of the Society had culminated in his service on the Committee on Local Sections, passed away suddenly and unexpectedly. Your Committee expresses its deepest regret at his loss which it and the Society feel very keenly. All will miss his analytical ability and kindly humor, both given so freely in the service of the Society.

In Conclusion

Your Committee expresses its gratitude to the many sincere and conscientious officers and executive committees of the Local Sections in the many centers of the country for their generous cooperation, and also to the officers, staff, and Council of the Society, together with the Standing Committees for their help in, and their sympathetic understanding of, the many problems with which the membership is confronted.

Respectfully submitted,

William Lyle Dudley, *Chairman* — W. R. Woolrich
R. E. W. Harrison — D. B. Prentice

PROFESSIONAL DIVISIONS

The Professional Divisions have had a successful year during 1934–1935. The outstanding accomplishment was the publication quarterly of the *Journal of Applied Mechanics* and the financial contributions secured by that Division from outside sources to increase the number of technical papers to be published.

During the year five national division meetings were successfully held by the following Divisions: Oil and Gas Power, May, Tulsa; Applied Mechanics, June, Ann Arbor; Graphic Arts, June, Cincinnati; Machine Shop Practice, September, Cleveland; Aeronautic, October, St. Louis. In addition the Textile Division assisted the Greenville, S. C., Section in holding a Southern textile meeting. The programs of these meetings were effectively organized with the close cooperation of the Sections and the Divisions. For the Aeronautic meeting special credit is due to the St. Louis Section for arranging preprints of the meeting papers in pamphlet form.

The Professional Divisions were particularly active during the year in organizing large technical programs for the Semi-Annual and 1935 Annual Meetings. There was a noticeable improvement in cooperative activities between the Divisions, more sessions having been jointly organized. At the 1934 Annual Meeting the Standing Committee successfully arranged the presentation of a joint progress report of the power divisions. This was presented at the close of one of the power sessions by C. F. Hirshfeld, who was assisted in the preparation of his report by the following Divisions: Fuels, Hydraulic, Oil and Gas Power, and Steam Power. It is planned to increase this type of cooperation.

An effort was made by the Divisions during the year to assist the Local Sections in securing speakers for local meetings. The Railroad Division took the lead in this line of endeavor by organizing a special committee whose members were well distributed over the country and by notifying the Sections that these members were available as speakers for local railroad meetings. The Management Division was also active in assisting in coordinating local management meetings, particularly in New York and Boston. The Machine Shop Practice Division encouraged the Sections to hold meetings on the subjects of welding and casting.

Division Activities

Aeronautic Division. The Aeronautic Division held its National Meeting in October at St. Louis, Mo., under the auspices of the St. Louis Section. Over thirty-five papers were presented at the meeting and they were published by the Section in a photo-offset pamphlet, which was sold for $1.50. The Spirit of St. Louis Medal was awarded posthumously at the meeting to Will Rogers for his splendid work in advancing aeronautics.

Other activities consisted of holding a session at both the Semi-Annual and the 1935 Annual Meetings and in assisting several Local Sections in holding local aeronautic meetings. The Division has a special Subcommittee on Industrial Aerodynamics and is actively assisting both the A.S.M.E. Committee on Aircraft Safety and Inspection and the Aviation Committee of the American Engineering Council.

Applied Mechanics Division. The Applied Mechanics Division held its National Meeting on June 18 and 19 at the University of Michigan, Ann Arbor, Mich., under the auspices of the Detroit Section. Thirteen papers were presented at the meeting. The Division is sponsoring or participating in sessions at the 1935 Annual Meeting. It has six special subcommittees: elasticity, strength of materials, plasticity, dynamics, mechanics of liquids and gases, and thermodynamics.

This year saw the publication of the *Journal of Applied Mechanics* as a separate quarterly under the auspices of the Society. The Division secured nearly $2000 in special donations to assist in publishing more technical papers. This, however, does not as yet take care of the quantity of valuable papers that are presented, and the Division

has recommended that the *Journal* be sent only to those members requesting it so as to conserve funds for publication of additional material.

The Division is also undertaking a study of symbols and abbreviations used in applied mechanics, in cooperation with other interested groups, as a preliminary step in the preparation of a list which will be acceptable to a majority and form the basis of a recommended standard.

Fuels Division. The Fuels Division arranged two sessions at the Semi-Annual Meeting and two sessions at the 1935 Annual Meeting. During the year the Special Subcommittee on Fly-Ash and Cinders continued its survey to secure data that industry had accumulated. The Pure Air Committee has continued its activities. The Fuels Division is also cooperating with the A.I.M.E. in the work of the Committee on Fuel Values. This Committee has three special subcommittees on effect of ash on Btu, effect of fusion temperature of ash on fuel value, effect of sulphur with special reference to corrosive effect.

Graphic Arts Division. The Graphic Arts Division is the new name adopted this year for the former Printing Industries Division. The Division held its National Meeting as part of the Semi-Annual Meeting. Ten papers and lectures were presented at the National Meeting, which was held jointly with the Graphic Arts Research Bureau. The Bureau was organized at the Division's National Meeting in Philadelphia in October, 1934. The object of the Bureau is to coordinate, stimulate, and sponsor research in the Graphic Arts field. The Bureau at its Cincinnati meeting voted to request affiliation with the Society. Membership in the Bureau consists of about 400 individual members and three affiliated organizations. The Bureau and the Division are planning a National Meeting to be held in Washington, D. C., in March or April, 1936.

Hydraulic Division. The Hydraulic Division held a session on Hydraulic Turbine developments at the Semi-Annual Meeting in Cincinnati. At the 1935 annual meeting, two sessions will be devoted to the study of Cavitation and have been arranged in cooperation with the Power Division of the A.S.C.E. and the Applied Mechanics Division of the A.S.M.E.

The Division is continuing the activities of the Water Hammer Committee and has secured the cooperation of many prominent engineers in other societies and in various foreign countries. Plans are being completed for a second symposium on Water Hammer in December, 1936.

Iron and Steel Division. The Iron and Steel Division held one session at the Semi-Annual Meeting and two sessions at the 1935 Annual Meeting, one of which was held jointly with the Applied Mechanics Division.

Machine Shop Practice Division. The Machine Shop Practice Division held four sessions and cooperated with the Railroad Division in a fifth at the Semi-Annual Meeting. For the 1935 Annual Meeting two sessions are planned and a joint luncheon with the Job Shop Committee of the Management Division. The Division also cooperated in the Machine-Tool Congress held in Cleveland, Ohio, and jointly with the Cleveland Section, held two evening meetings on September 10 and 11. At the beginning of the year the Lubrication Engineering Subcommittee of the Petroleum Division was transferred to the Machine Shop Practice Division and reorganized. Other subcommittees are: foundry, welding, and machine design. The Division also has liaison connection with the Research Committee on Cutting Metals, Cutting Oils, and Gears. The Foundry Committee together with the Birmingham Local Section and the American Foundrymen's Association held a two-day meeting on February 28, and March 1, 1935. Several Local Sections held meetings on the subjects of welding and casting as a result of the Division's suggestions and cooperation. These meetings were well attended and created considerable interest.

Management Division. The Management Division sponsored three sessions at the Semi-Annual Meeting and is sponsoring four sessions at the Annual Meeting as well as cooperating in a luncheon and one other session. The Division has started work on a Supplement to the Bibliography of Management Literature to cover literature published from January, 1931, to date.

The Management Division assisted the National Management Council in securing papers for the Sixth International Congress for Scientific Management held in London, England, during July, 1935, and on behalf of the National Management Council planned and organized a series of nine joint meetings to be held in the New York Metropolitan area during 1935–1936 in which local sections of ten societies and associations interested in managerial affairs will participate.

During the past year the Waste Elimination Committee has been active in sponsoring sessions at the Semi-Annual and Annual Meeting.

The Job Shop Management Committee is to hold a joint meeting with the Machine Shop Practice Division at the coming Annual Meeting and it has developed considerable interest in Job Shop Management problems by sending out several questionnaires during the year.

The Marketing Committee has undertaken a national survey to determine the present status of marketing research in industry and has also in the course of preparation a Bibliography of Literature on Marketing Research.

The Division has the following subcommittees: Economics, human relations, job shop management, management research, marketing, quality control, time and motion study, waste elimination, and statistics in industry. It has representation in the National Management Council.

Materials Handling Division. The Materials Handling Division was active this year for the first time in several years and sponsored three sessions at the Semi-Annual Meeting in Cincinnati.

Oil and Gas Power Division. The Oil and Gas Power Division held its Eighth National Meeting on May 8 to 11, 1935, in Tulsa, Okla., in cooperation with the Mid-Continent Section. There were presented nine technical papers which were preprinted in the *Oil and Gas Journal* and *Diesel Power*. The division will have a session at the 1935 Annual Meeting.

The special Subcommittee on Oil-Engine Cost will present its seventh yearly report at the 1935 Annual Meeting. This report for the year 1934 covers over one hundred and fifty plants. The report is available in pamphlet form and may be purchased from the Society.

Petroleum Division. The Petroleum Division is holding a session at the 1935 Annual Meeting. The subcommittees were active in the Mid-Continent area and a series of local meetings was held in Tulsa. The Subcommittee on Lubrication Engineering was transferred this year from the Petroleum Division to the Machine Shop Practice Division. The Division is planning a national meeting next year to be held at the time of the Petroleum Exposition in Tulsa, Okla., in May, 1936.

Power Division. The Power Division held two sessions at the Semi-Annual Meeting and has planned three sessions at the 1935 Annual Meeting besides a cooperative session with the Applied Mechanics Division. The Industrial power group has planned to hold, at the 1935 Annual Meeting, its usual Wednesday luncheon conference. Among the special research committees in the power field the Boiler Feedwater and Steam Research committees are planning to hold sessions at the 1935 Annual Meeting.

Process Division. The Process Industries Division continued its active role during its second year. At the Annual Meeting the Subcommittee on Sugar will hold a session, its Subcommittee on Heat Transfer will hold two sessions on radiant heat and cooperate in a third session. The Subcommittee on Drying presented at the Semi-Annual Meeting its recommended practice on Testing Drying Equipment and is sponsoring a session on Dust Separation at the 1935 Annual Meeting. The Air Conditioning Subcommittee held a Metropolitan Section meeting in October. The Heat Transfer Committee has issued in pamphlet form the previous papers presented at its sessions. The Division has developed relations with the American Institute of Chemical Engineers and the American Ceramic Society both of which have appointed liaison representatives.

Railroad Division. The Railroad Division held a joint session with the Machine Shop Practice Division at the Cincinnati Semi-Annual Meeting and has planned to hold at the 1935 Annual Meeting two sessions, including a symposium on Railroad Lubrication. Besides this the Division will hold a joint session with the Applied Mechanics Division. During the year the Division organized in order to assist certain Local Sections that might appropriately hold local railroad meetings.

Textile Division. The Textile Division plans to hold its session at the 1935 Annual Meeting in cooperation with the Graphic Arts and the Management Divisions. There will also be the usual luncheon conference after the Annual Meeting session. The Division assisted the Greenville Section of the Society in holding a meeting there on April 10 during the Southern Textile Exposition. This meeting was to have been held in October, 1934, but was postponed until the spring of 1935.

Wood Industries Division. The Wood Industries Division held a two-session symposium on Wood Housing at the Cincinnati Semi-Annual Meeting. The Division is holding a session at the 1935 Annual Meeting on Modern Timber Construction.

Respectfully submitted,

W. A. Shoudy, *Chairman*

G. B. Pegram — L. K. Sillcox

MEMBERSHIP

The Committee on Membership submits the following statistical report covering the recommendations of the Committee to Council during the fiscal year October 1, 1934, to October 1, 1935:

REPORT

The Committee on Membership held twelve regular monthly meetings during the fiscal year 1934–1935.

The following are the applications considered in the transaction of its work and a summary showing the action taken:

Applications pending October 1, 1934	137
Special cases before Council	57
Applications received during fiscal year 1934–1935	2206
Total applications handled during the year 1934–1935	2400
Recommended for membership	2222
Transfers denied	3
Deferred	4
Withdrawn, incomplete, and canceled	40
Applications pending October 1, 1935	131
Total applications handled during year 1934–1935	2400

The 2222 recommended for membership were divided into the following grades:

Members	104
Transfers to Member	89
Transfers from Student Member to Member	1
Associates	3
Associate-Members	79
Transfers to Associate-Member	107
Transfers from Student Member to Associate-Member	2
Juniors	165
Transfers from Student Associate to Junior	76
Transfers from Student Member to Junior	1596
Total recommended	2222
Transfers	196
Total new members recommended	2026

During the fiscal year 1934–1935 the Committee on Membership made the following recommendations:

Transfers from Student Member to Junior declared void	735
Elections to other grades declared void	28
Total elections declared void	763

During the year closing, the Committee has devoted a portion of several meetings in addition to special meetings to joint discussion with the Secretary and also representatives of other Committees interested in effecting the proposed changes in the Constitution and By-Laws[1] pertaining to Membership, as the Amendments now appear on page 532 of the August, 1935, issue of *Mechanical Engineering*.

Certain changes in the By-Laws have been suggested by the Membership Committee, including the recommendation that the title of the Standing Committee on Membership be changed to the Standing Committee on Admissions.

A canvass of all Local Sections was initiated through a letter of April 5, 1935, from the chairman of the Committee on Membership to the chairmen of the Local Sections, requesting a report from the Executive Committees stating whether or not they wish, in the future, to receive a copy of the professional record of every applicant for membership within their respective territories.

The following response resulted: Thirteen replies were received in which four wish full copy of record, and nine wish only special cases referred to them.

A new reference form for new members and transfers has been adopted.

The committee now has under consideration the policies which will govern the effective administration of its work of passing on applications not only for the proposed grade of Fellow but for all other grades in order to maintain the highest standard obtainable.

Respectfully submitted,

H. A. LARDNER, *Chairman*
R. H. MCLAIN
C. L. DAVIDSON
L. R. FORD
F. C. SPENCER
O. E. GOLDSCHMIDT, *Advisory Member*

CONSTITUTION AND BY-LAWS

For some little time it has been appreciated that there should be somewhat more uniformity in the admission requirements for the several grades in the national engineering societies and recommendations have been made from time to time that our Society and others should add the grade of Fellow to give recognition to the senior engineers who have achieved distinction in the engineering field.

To meet these needs the Committees on Policies and Budget, and Membership, at the request of Council, submitted to the Committee on Constitution and By-Laws a draft of suggested amendments along these lines, which amendments as revised were submitted to the membership in the usual printed ballot form in August, 1935, for vote to be announced at the Annual Meeting in December.

The new articles of the Constitution divide the membership into two groups, the first, including all of the voting members, is to be entitled the "Corporate Membership" which consists of the new grade of Fellows, the Members, and the Junior Members. The second group will also include three grades, namely, Honorary Members, Associates, and Student Members.

The requirements for Fellow are such as to insure that the grade shall have the proper distinction. It is not necessary that one should be able to meet the full requirements if exceptionally qualified because provision has been added that the Council may, by unanimous vote, elect a Fellow who has distinguished scientific attainments. In order to form the nucleus of Fellow a temporary provision permits any past or present member of Council to apply for the grade of Fellow and if properly qualified to become a Fellow automatically. This section was a controversial one but in the form submitted to the membership is thought to be in accord with the wishes of the membership at large. The Associate Members have been advanced to the grade of Member if over thirty years of age and will be automatically advanced upon reaching that age so that in a few years the present grade of Associate Member will be abolished.

The new amendments to the By-Laws which have been reviewed and proposed for approval by the Council include a change in the title and duties of the Standing Committee on Membership and in a rewording of Paragraph 3 of Article B14 providing that the income from initiation fees shall not be used for current expenses but shall be added to the surplus at the close of each fiscal year. This change makes no real alteration in the method of handling funds but does simplify the bookkeeping and will aid the auditors in their annual report.

Respectfully submitted,

H. H. SNELLING, *Chairman*
RICHARD KUTZLEB, JR.
HERBERT B. LEWIS
WM. H. KAVANAUGH
R. D. BRIZZOLARA
G. N. COLE, *Junior Adviser*

RELATIONS WITH COLLEGES

The past year was notable in the history of the Committee because of the fact that it saw the completion of the new plan and of changing from the old system of operating Student Branches to the new. This was accomplished through the introduction of the plan in the early part of the college year when a visit was made by a representative of the Committee to each of the colleges which comprise Groups VI and VII.

Naturally the number of members in Student Branches enrolled under the new plan increased considerably and reached a total membership of 3250. This further development of the plan was sufficient to encourage the presentation at the Semi-Annual Meeting, Cincinnati, of an amendment to the Constitution of the Society providing for the grade of Student Member, and also to suspend the initiation fee of these Student Members who transfer to the grade of Junior within a limited time after graduation. In the 112 colleges a total of 336 meetings were held.

The economic conditions of the country, while improved, have not created a sufficient demand for recent graduate engineers to show any marked increase in the number of Student Members transferred to the grade of Junior upon graduation. Of 1318 Student Members graduated with the class of 1934, 530 completed their transfer to Junior membership by the payment of the initiation fee. The loss of the remaining 800 can be accounted for largely because of the eco-

TABLE 1 COMPARISON OF BRANCH ACTIVITIES BY GROUPS

Group	No. of branches	Avg no. meetings per branch	Avg attendance per meeting
I	15	7	42
II	18	4	41

TABLE 2 GROUP MEETINGS, 1935

GROUP I, NEW ENGLAND STUDENT MEETING, CAMBRIDGE, MASS.

Attendance: 175 Papers presented: 11

Prize	Recipient	Title of Paper	College
First	H. T. Sawyer	Development and Investigation of an Indicator for High-Speed Engines	Rensselaer Poly. Inst.
Second	R. F. Hopkins	Effect of Transverse Slots and Holes on the Torsional Properties of Shafting	Brown University
Third	H. B. Kimball	Problems in Miniature Design	Mass. Inst. of Tech.
Fourth	W. R. Steur	Water Channel Method of Flow Visualization	Worcester Poly. Inst.

GROUP II, EASTERN STUDENT MEETING, NEW YORK, N. Y.

Attendance: 225 Papers presented: 10

First	Benjamin O. Delaney	Engine Indicators	Princeton Univ.
Second	John A. Sauer	A New Apparatus for Testing Materials in Combined Bending and Torsion	Rutgers Univ.
Third	Alan S. Compton	Maintenance Welding	Drexel Inst.
Fourth	John R. Blizard	Air Resistance of Tube Bundles	Poly. Inst. of Brooklyn

GROUP III, ALLEGHENIES STUDENT MEETING, STATE COLLEGE, PA.

Attendance: 175 Papers presented: 10

First	Philip S. Criblet	The Precipitation of Dust From Flue Gases	Johns Hopkins Univ.
Second	R. L. Homsher	Governing Hydraulic Turbines for Best Efficiency	Penn State College
Third	Wm. Leavenworth	The What and Why of a Whirling Arm	Univ. of Akron
Fourth	J. J. Prendergast	Tests on a Streamlined Power Craft	Case School of Applied Science

GROUP IV, SOUTHERN STUDENT MEETING, KNOXVILLE, TENN.

Attendance: 180 Papers presented: 13

First	A. C. Todd	Economic Aspects of Stream Lining for Automobiles	Georgia School of Tech.
Second	H. B. Edwards	Uses of Glass in Mechanical Engineering	Univ. of Virginia
Third	Luke R. Hadnot	A Dryer for the Artificial Dehydration of Forage Crops	Louisiana State University
Fourth	John R. Kilgore	A New Kind of Mirror	Vanderbilt Univ.

GROUP V, MIDWEST STUDENT MEETING, CHICAGO, ILL.

Attendance: 210 Papers presented: 15

First	Edw. J. Wellauer	A Mathematical Determination of the Contact Length of Helical and Herringbone Gearing	Marquette University
Second	Einar W. Jensen	Stresses in an Automobile Engine Crankshaft	Univ. of Iowa
Third	Janus DeHamer	The Development of a Test for Set in Split-Bamboo Fishing Rods	Mich. College of Mining & Tech.
Fourth	Walter Schlagel	Employment Conditions Among Recent Engineering Graduates	Iowa State College

GROUP VI, NORTHERN UNIT STUDENT MEETING, LINCOLN, NEB.

Attendance: 75 Papers presented: 9

First	E. D. Beachler	Diesel Boilers	University of Nebraska
Second	Harold Grasse	Artistic Industrial Design	Univ. of Kansas
Third	H. C. Bates	A Study of Causes of Failures of Tubes in Refinery Cracking Stills	Kansas State Agri. College
Fourth	H. E. Simonson	The Regenerative Vapor Cycle	Univ. of Nebraska

GROUP VI, SOUTHERN UNIT STUDENT MEETING, DALLAS, TEXAS

Attendance: 116 Papers presented: 13

First	Glenn W. King	Combining Motion Study and Machine Design for Efficient Production	Rice Institute
Second	Saviour Perrone	Steam Jet Vacuum Refrigeration	Univ. of Texas
Third	Alex W. Francis	Some Aspects of Increasing Ultimate Recovery of Crude Oil From Natural Reservoirs	Univ. of Oklahoma
Fourth	W. C. Rodgers	Application of Refrigerating Cycle to the Heating and Cooling of Buildings	Texas A. & M. College

GROUP VII, NORTHWEST STUDENT MEETING, SEATTLE, WASH.

Attendance: 110 Papers presented: 10

First	Robt. E. Laughlin	The Diesel Field	Univ. of Washington
Second	James Kratzer	The Photoelectric Cell	Wash. State College
Third	Robert D. Watt	Design of a Universal Air Conditioner	Univ. of Washington
Fourth	Edward Wegman	Air Conditioning at High Altitudes	Montana State College

GROUP VII, CENTRAL UNIT STUDENT MEETING, BOULDER, COLORADO

Attendance: 95 Papers presented: 7

First	Carl L. Ritter	Cooling of Boulder Dam	Colorado State College
Second	Thomas R. Mackay	San Gabriel River Flood Control	University of Utah
Third	Alvin Welton	Brake Equipment on Modern High-Speed Trains	Colorado State College
Fourth	Harry L. Hoffman	Discussion of Flotation	Univ. of Colorado

GROUP VII, SOUTHWESTERN STUDENT MEETING, BERKELEY, CALIF.

Attendance: 106 Papers presented: 17

First	Bradley H. Young	Design of Oleo-Pneumatic Shock Absorbers for Aircraft	California Inst. of Technology
Second	Byron Masterson	Spot Welding in Thin Sheet Structures	University of California
Third	A. L. Buonaccorsi	Seismogram Wave Analysis	Santa Clara Univ.
Fourth	Clyde C. Chivens	The Pump-Testing Laboratory of the Metropolitan Water District of Southern California	California Inst. of Tech.

nomic conditions which made it impossible for them to obtain engineering employment or perhaps any employment.

Another important development during the past year was the extension of Student Meetings from five in number to ten, made necessary by the addition of Groups VI and VII. The geographical area covered by these Groups is so enormous that it is impractical to schedule a single meeting for each Group with the expectation of any reasonable attendance from all of the colleges within the Group area. Therefore, the Committee deemed it wise to arrange two meetings for Group VI and three meetings for Group VII. The other Groups comprise practically all colleges east of the Mississippi and have but one meeting for all colleges in each Group.

Only twice in the history of the Student Branches has any Branch been discontinued. Last year the University of South Dakota discontinued its course in mechanical engineering, and this year upon request of the Student Branch at Harvard University it was discontinued. One new Student Branch was authorized at the Northwestern University, Evanston, Illinois.

The Committee is pleased to report that it was able to authorize five loans to Student Members from the Max Toltz Fund amounting to $850, thus enabling these students to continue their engineering studies.

Eugene W. O'Brien resigned from the Committee but was persuaded to serve as advisory member. Edward W. Burbank was appointed to fill his unexpired term.

Respectfully submitted,

WILLIAM L. ABBOTT, *Chairman* WILLIAM A. HANLEY
EDWARD W. BURBANK F. V. LARKIN
ROY V. WRIGHT EUGENE W. O'BRIEN, *Advisory Member*

AWARDS

The Committee on Awards made the following recommendations to the Council for awards which were to be presented during the fiscal year 1934–1935:

A.S.M.E. Medal to Willis H. Carrier, for his pioneer work in air conditioning.

Holley Medal to Irving Langmuir, for his contributions to science and engineering, including the development of gas-filled incandescent lamps, thoriated filament for thermionic emission, atomic hydrogen welding, phase-control operation of the thyratron tube, and fundamental research in oil films.

Worcester Reed Warner Medal to Ralph E. Flanders, for his contributions to a better understanding of the relationship of the engineer to

economic problems and social trends as exemplified by the many papers which he has presented.

Junior Award to John I. Yellott, Jr., for his paper, "Supersaturated Steam."

Charles T. Main Award to Philip P. Self, for his paper on "Air Conditioning—Its Practicability and Relation to Public Welfare."

Student Award, Undergraduate, to H. Reynolds Hudson, for his paper on "Dynamic Balance and Functional Utility Applied to Automatic Design."

No recommendations were made for the Melville Medal and Postgraduate Student Award.

The topic for the 1936 Charles T. Main Award is "Development in the Generation and Distribution of Power and Their Effect Upon the Consumer."

Upon recommendation of the Committee on Policies and Budget, the Council approved the extension of the work as heretofore carried on whereby a Board of Honors would be established. Council named the same personnel on the Board of Honors as comprises the Committee on Awards. It was understood that the Board of Honors would operate in an advisory or trial capacity for a period of two years. Acting in this capacity they proceeded to study and make recommendations regarding changes in the By-Laws and Rules of the Society and methods of procedure.

The first recommendations made to Council were as follows:

Resolved that the By-Laws be duly amended to change Par. 23 of Article B-8 of the By-Laws which now reads: "The Standing Committee on Awards shall, under the direction of the Council, have supervision of the awards of the Society as detailed in the Rules or prescribed by Council. The Committee shall consist of five (5) members and the term of one member shall expire at the close of each Annual Meeting," to the following:

"The Board of Honors and Awards shall, under the direction of the Council, have supervision of the awards of the Society as detailed in the Rules or prescribed by Council. Recommendations for representatives on joint bodies of award shall be made to Council by this Board. The Board shall consist of five (5) members, and the term of one member shall expire at the close of each Annual Meeting". . . .

Further resolved that the Board of Honors and Awards shall be authorized to constitute a Medal Committee to be comprised of twenty (20) persons, five of whom shall be the members of the Board of Honors and Awards, and in addition fifteen persons, three appointed each year for a period of five years.

It is anticipated that this Medal Committee will suitably organize itself into a functioning body which shall be charged with the duty of recommending to the Council nominations for the A.S.M.E. Medal, the Holley Medal, the Warner Medal, and in addition thereto nominations for representatives of the Society on joint Boards of Award.

The Board desires to provide better methods for the review of papers submitted for awards and intends to experiment with various means to this end. For this year the Publications Committee has been asked to submit its recommendations regarding papers that should be considered for the Melville Medal and the Junior Award. These papers will be reviewed by qualified persons or agencies and through them a recommendation made to the Board. It is expected that student papers may be reviewed by the faculties of the various universities under a plan to be definitely formulated and the assistance of the Committee on Relations With Colleges will be invited to this end.

The objective behind these recommendations is, first, that there should be a single responsibility for all awards in which the Society is interested; second, that there should be a body of highly representative members of the Society who may give to the consideration of awards, the attention which the subject deserves; and third, that the creation of the Medal Committee would afford a body which should be particularly charged with forward-looking plans and policies, not alone for those honors which are now available but for others which may later be available for various types of recognition.

It is the belief of the present Standing Committee on Awards that these suggested steps will contribute to the elevation of the whole awards situation and will enable them to be used in a larger manner to the good of the Society and the profession.

The nominations which the Awards Committee offered to the Council for the Medal Committee cover the fields of education, technical journalism, consultation, and industry, and represent a geographical cross section of the membership as well. The names are: E. O. Eastwood, A. M. Greene, Jr., D. C. Jackson, R. H. Fernald, J. H. Herron, F. M. Gunby, J. L. Harrington, H. C. Meyer, Jr., K. H. Condit, R. V. Wright, Robert Sibley, J. W. Parker, C. L. Bausch, E. R. Fish, and L. W. Wallace.

Respectfully submitted, W. L. Batt, *Chairman*

R. C. H. Heck — Herman Diederichs
Harte Cooke — L. P. Alford

EDUCATION AND TRAINING FOR THE INDUSTRIES

Due to several changes in the personnel the Committee on Education and Training for the Industries was reorganized during the year.

One of its important activities was the evolving of a statement of its objectives as it is felt that the opportunities for this Committee have broadened and become considerably more important because of the changed economic conditions during the past five years.

The Committee sponsored a session at the Annual Meeting of the Society and at its Semi-Annual Meeting. The session was well attended and caused much favorable comment.

Respectfully submitted,

George A. Seyler, *Chairman*
Clement J. Freund — John A. Randall
John Younger — Warner Seely

LIBRARY

The work of the Engineering Societies Library has been carried on steadily during the year with marked appreciation by its users. These numbered over forty thousand, of whom over ten thousand were members living at a distance who were assisted by correspondence.

Sixty-five hundred books were added in 1934 to the collection, which now contains about 147,000 volumes and maps.

The conditions portrayed so graphically in our report of last year still continue to hamper the growth of this useful activity.

The Library is called upon for a constantly increasing variety of services. More and more it is becoming a general information bureau for the profession, as well as its outstanding depot for the literature. An increasing demand for assistance constantly calls for more books, increased staff, and larger quarters. With a budget much lower than it was five years ago, it is impossible to provide these facilities. We trust that the time is near when more generous provision may be made for this important activity, which at some time or another is used by almost every member of the Society.

Respectfully submitted,

E. P. Worden, *Chairman*
G. F. Felker — J. S. Kerins
L. K. Sillcox — C. E. Davies, *Ex-Officio*

RESEARCH

A review of the annual reports of the Society's special research committees reveals an unexpected amount of activity and strength in organization. Only five of the twenty-four committees reported no activity during the year and a considerable number of them have functioned in a normal way.

As in previous years, a number of these committees have sponsored sessions at the general meetings of the Society or have provided the papers for the programs of other meetings set by the A.S.M.E. and similar organizations. For example, during the 1934 Annual Meeting the following five special research committees sponsored and conducted regular technical sessions; Fluid Meters, Thermal Properties of Steam, Cutting of Metals, Mechanical Springs, and Boiler-Feedwater Studies. In addition, three committees, Fluid Meters, Wire Rope, and Cottonseed Processing, cooperated with certain A.S.M.E. professional divisions in the preparation of the programs for three other sessions.

At the Society's Semi-Annual Meeting in Cincinnati in June and the Machine-Tool Congress in Cleveland in September the committees on the Cutting of Metals and Mechanical Springs supplied papers for certain of the technical sessions sponsored by the professional divisions.

The financial condition of the committees has remained much the same this year as it was last. Approximately $3000 was secured from industry. The Engineering Foundation has been both considerate and generous in its responses to the requests for assistance addressed to it by several of the committees. In all $7500 was given as grants and an added $1500 was pledged as a loan to the Subcommittee on Metal-Cutting Data. This latter sum is intended to assure prompt publication of the first of the series of handbooks to be issued by this committee.

Sometimes the members of administrative committees such as the Research Committee are tempted to be skeptical as to the value of the results accomplished by an activity for which they are responsible. At such times it is reassuring to find, in the reports of a special committee, statements such as the following which was taken from the report of the Committee on Lubrication:

"An interesting letter was received a few days ago from Mr. F. P. D. of the M. C. Company. After describing the work of his company in installing oil-film roll-neck bearings to withstand shock loads exceeding 1,500,000 pounds, he says: 'The operating ZN/P for these bearings is low. But, according to experiments made by the members of the lubrication committee, with this factor as a criterion, these bearings should and do perform satisfactorily. I know of no better way to pay tribute to the efforts of the committee than to outline this example of a very practical use of the reports of the Special Research Committee on Lubrication.' "

Brief reports of the special and joint research committees which were organized and are sponsored by the Society will be found in the following sections of this report.

Special and Joint Committee Reports

Lubrication, A. E. Flowers, Chairman. A successful meeting of the A.S.M.E. Special Research Committee on Lubrication was held in New York on December 5, 1934. Reports were received on the Committee's activities from the members present. The chairman made a statement concerning the committee's funds which covered an expenditure of approximately $500 and a balance on hand of $524. Mr. Hersey reported on the progress he had made in the preparation of abstracts of the 249 papers listed in the committee's selected bibliography. Approximately 100 have been completed. He presented specimens of these abstracts and after discussion it was decided to reduce further the number of titles in the selected bibliography to those papers of prime scientific importance and to include in each of the abstracts the usable data and the summary or conclusions given in the paper. A general discussion of the work of the committee followed during which the members reported a total of 12 papers prepared during the year or in course of preparation by members of the committee or their immediate associates.

A reorganization of this committee is under way in order that a broad program of work may be undertaken that will cover both the physics and chemistry of lubrication and practical service problems. To this end the Society's Research Committee at its meeting in December, 1934, appointed a special Survey Committee on Lubrication to investigate the possibilities and to formulate a program.

This committee under the chairmanship of N. E. Funk held two meetings in March and May, 1935, and subsequently presented its report to the Research Committee. It was unanimous in its recommendation that the A.S.M.E. should continue to sponsor a special Research Committee on Lubrication. A consideration of the scope of the project in the light of a review of the 19 years of activity of this special research committee led to the recommendation that the scope of the reorganized committee should be broad enough to give it freedom in the selection of problems but narrow enough to insure the interest of industry. The proposed scope is to include the following: (1) Investigations of the fundamental physical and mechanical problems of lubrication, (2) interpretation of the results of research in this field for practical application, and (3) coordination of data from contemporary research in lubrication.

Fluid Meters, R. J. S. Pigott, Chairman. The Special Research Committee on Fluid Meters has had as its principal work for the year the completion of the revision of Part 1, "Fluid Meters—Their Theory and Application." This revision is divided into three sections: Section *A* on the classification and nomenclature of fluid meters, Section *B* on the theory of fluid measurement, and Section *C* which is to contain figures and tables for use in solving practical fluid-measurement problems and illustrative examples. The Committee expects that the completed revision will be ready for publication early in 1936.

The joint research on orifice coefficients for the measurement of air and water was completed by the A.G.A.-A.S.M.E. Joint Committee on Orifice Coefficients in the fall of 1934 and the final report on these studies is now practically completed.

At present the special committee is perfecting its plans for research at the National Bureau of Standards on flow nozzles. This program is being developed in cooperation with the A.S.M.E. Power Test Codes Committee and a campaign to raise the necessary funds is under way. H. S. Bean will be in direct charge.

Though no reports have been received this year from Prof. W. H. Carson the committee understands that he is continuing his experimental work on meter coefficients for use in measuring viscous fluids at the University of Oklahoma.

Thermal Properties of Steam, W. L. Abbott, Vice-Chairman. Following the Third International Steam Tables Conference held in the United States in September, 1934, there has been a natural pause in the work assigned to the special research committee. Prof. J. H. Keenan undertook for the committee the preparation of the summary of the results of the conference. A revised skeleton table is its principal part. This report will be published in the November, 1935, issue of *Mechanical Engineering*. With the completion of the committee's present program Alex Dow asked to be relieved of his duties as chairman. His resignation was accepted with much regret but he was urged to continue to serve as a member of the committee.

Strength of Gear Teeth, R. E. Flanders, Chairman. The financial assistance given by the Engineering Foundation has made it possible for the Special Research Committee on the Strength of Gear Teeth to keep a research assistant engaged since the beginning of 1935 on tests of the surface fatigue of materials in rolling contact under the direction of Prof. Earle Buckingham. Tests have been made on rolls one inch wide with diameters up to four inches. In all of these tests, one roll was of hardened and ground steel. The mating rolls were of several varieties of cast iron, leaded brass, chilled phosphor bronze, and phenolic laminated material. A progress report on these tests is now in preparation.

With these materials, the tests indicate a tendency of an outer lamina of the material to travel by plastic flow in the direction of rolling, and also for this lamina to start to shear under the surface. On some of the cast-iron alloys, it is not yet certain whether the initial failure starts below the surface, or starts at the surface. It is hoped that investigations may be continued with other combinations of materials, and that it will be possible also to make still further tests with the same combinations of materials under combined rolling and sliding contact. Thus far, the tests have shown a very consistent relationship between load and number of repetitions of stress to cause surface failure, giving hopes that some definite relationships may eventually be established between surface fatigue and flexural or bending fatigue. Such tests take much time, but the information to be obtained from them will be invaluable to the designer in the selection of combinations of materials to avoid or minimize wear.

Cutting of Metals, Coleman Sellers, 3rd, Chairman. The work of this Committee during the past year consisted mainly of coordinating and encouraging the work of its four subcommittees. The personnel of the special committee has been enlarged and changed to include only those taking an active part in the work.

Metal Cutting Data. The Subcommittee on Metal Cutting Data formed to carry on the work so ably started by Frederick W. Taylor has been engaged for the past three years in examining all available experimental data on the cutting of metals, supplementing this with research of its own, and preparing the data thus obtained for publication in the form of handbooks for the use of industry. This should be a very valuable contribution to metal manufacturers as there is nothing of its kind in existence although the need for it has long been felt. The subcommittee has been generously supported by the Engineering Foundation. In June, 1935, the Foundation agreed in addition to underwrite the preparation of the first publication to the extent of $1500. During the coming year, the subcommittee expects to bring this first handbook on the Cutting of Metals with Single-Pointed Paring Tools to publication. It is also continuing to encourage experimental work already under way in various parts of the country in an effort to bring them to successful conclusions. L. P. Alford is chairman of this special research committee and R. C. Deale is its secretary.

Cutting Fluids. During the past year the Subcommittee on Cutting Fluids has been reorganized and enlarged under the chairmanship of Prof. O. W. Boston, of the University of Michigan. The sixth progress report of the committee was presented at the semi-annual meeting of the Society in Cincinnati in June in the form of a paper entitled "The Influence of Cutting Fluids on Tool Life in Turning Steel," by Messrs. Boston, Gilbert, and Kraus. The committee has prepared a research program of a comprehensive nature and is now attempting to raise funds from industry which, with the $1000 grant from the Engineering Foundation already appropriated, will be used in a research on cutting fluids with particular reference to the influence of cutting fluids on the tool life of single-point tools. Various physical and thermal properties of the oils also will be determined, and it is hoped that a correlation between all known properties may be obtained by which specifications may be set forth for use in selecting the proper cutting fluid to give tool life, low power, or good finish as desired on any particular material.

Bibliography. The Subcommittee on Bibliography on the Cutting of Metals issued its second report during the past year. This new portion of the bibliography is a continuation of Part I, published in 1930, and consists of 1257 new references with abstracts.

Metal Cutting Materials. The accomplishment of the Subcommittee on Metal Cutting Materials during the year will be its report on the "Questionnaire on the use of New Cutting Materials." This questionnaire was sent out to approximately 750 concerns in April, 1935. A detailed report on the data and information received was made at the Machine-Tool Congress held in Cleveland, Ohio, in September, 1935, during one of the sessions sponsored by the A.S.M.E. Machine Shop Practice Division. In addition this subcommittee has

discussed the important development of the diamond-impregnated wheels for the shaping of the cemented carbides, and expects to sponsor a paper regarding the same in the near future.

The special Research Committee on the Cutting of Metals has felt severely the lack of funds for publication by the Society. This has made it increasingly difficult to obtain research papers. Some means should be found to preserve for reference, papers of this type which, although not of wide and popular interest, are nevertheless valuable as contributions to the extremely large subject of the cutting of metals.

Mechanical Springs, J. R. Townsend, Chairman. The Special Research Committee on Mechanical Springs held one meeting during the past year in December, 1934. Two research programs have been practically completed during this period. The research at Wright Field directed by J. B. Johnson, chief of the Materials Branch of the Air Corps, has progressed to the point where the report is in preparation. This work covers fatigue tests on large-size helical springs. The second study by E. E. Weibel on the correlation of spring-wire torsion and fatigue data for small wire springs under the sponsorship of Prof. F. P. Zimmerli and his subcommittee at the University of Michigan has been completed and the report presented. This work was supported by funds subscribed by industry. Dr. D. J. McAdam's work on a monograph entitled "A Résumé of the Physical Properties of Spring Materials" has been carried forward and a portion of this report was presented at the Semi-Annual Meeting of the Society in June, 1935. At the present time the committee is reviewing several papers for presentation at the Annual Meeting of the Society in December, 1935. These papers are on the correlation of spring-wire bending, torsion-fatigue tests, and maximum shearing stress in an eccentrically loaded helical spring of circular wire. In February, 1935, Dr. W. G. Brombacher at the National Bureau of Standards completed and distributed the tenth supplement to the Committee's Bibliography on Mechanical Springs.

Effect of Temperature on Properties of Metals, H. J. French, Chairman (Joint Committee with the American Society for Testing Materials). Two meetings of the joint committee were held during the year in December and June and meetings of the subcommittees as required.

During the calendar year 1934, an additional contribution of $3000 to the Joint Committee's funds was received from Engineering Foundation, which made possible continuation of the sponsorship of researches at the Battelle Memorial Institute during the year 1935. Procurement of additiona' funds for the sponsored researches of the Joint Committee is in the hands of a newly organized Committee II on Finances, the chairmanship of which has been accepted by R. A. Bull.

Work has been continued on the study of embrittlement of austenitic nickel-chromium steels as a result of prolonged exposure to high temperatures and a summary has been prepared. The work in question relates to the progressive changes in toughness of an austenitic steel when exposed for a long period to high temperatures, both with and without stress. Work was initiated on a second project, relating to the interpretation of creep tests, the results of which are now broadly utilized by engineers in determining allowable stresses for high-temperature service.

So many logical questions are still unanswered respecting the behavior of steels under creep, especially in very long periods of time, that the Joint Committee decided to sponsor a program of research at Battelle Institute, in which steels of known creep characteristics (as determined by the customary test of 1000 hr or more) would be used and these steels further tested to durations of two or more years. For one of the materials, K-19 was selected to represent the austenitic type because creep values by the usual orthodox test have already been reported on this identical steel. A pure ferritic steel (K-20) was also selected. The latter is a 0.40 per cent carbon commercial steel of exceptional physical uniformity, furnished gratis by the Bethlehem Steel Company through the good offices of P. E. McKinney. The first progress report on this steel, dated June 2, 1935, was presented to the Joint Committee at the Detroit meeting by Messrs. A. C. Cross and F. B. Dahle. At that time it was voted to continue the 8000 lb per sq in. load at 850 F and also to maintain a sample at 7500 lb per sq in. also at 850 F. The K-19 steel is under test at the load and temperature decided upon as the creep limit under the former tests, i.e., 8345 lb per sq in. and 1200 F.

During the year a number of subcommittees have been at work on other parts of the program and in some cases they have enlisted the cooperation of company and university laboratories. Space available will permit only a list of the committees and the names of their chairmen. "High-Temperature Test Methods," N. L. Mochel, chairman; Subcommittee D, H. J. Kerr, chairman, checking Method E21–34; Subcommittee E, M. S. Northrup, chairman, checking Method E22–34T; Subcommittee F, H. W. Gillett, chairman, work on fatigue suspended for the present; Subcommittee N, J. W. Bolton, chairman, has prepared a report summarizing published data on methods for the determination of wear and seizure at high temperatures; Subcommittee O, Jerome Strauss, chairman, on corrosion of austenitic nickel-chromium steels at elevated temperatures, has prepared a report during the year; and Subcommittee P, H. W. Russell, chairman, organized in March, 1935, to consider the effects of low temperatures on metals.

Committee III on Projects, C. E. MacQuigg, chairman, made a comprehensive report at the June, 1935, meeting of the Joint Committee and pointed out the importance of raising $10,000 from industry in the next two years.

It has been impracticable during the past year to formulate a program acceptable to all interests represented on Committee V on Oil Refinery Problems, but such a program is considered to be necessary before funds can be secured for support of research in this field.

The Joint Committee has been in close touch with the interested committees of the A.S.T.M. and the A.S.M.E. on questions relating to the effect of temperature on the properties of metals and a considerable amount of time has been devoted to these semi-official cooperative projects during the past year.

Boiler-Feedwater Studies, C. H. Fellows, Chairman (Joint Committee with the American Boiler Manufacturers Association, American Railway Engineering Association, American Society for Testing Materials, American Water Works Association, and Edison Electric Institute). During the period covered by this 1934–1935 annual report the activities of the Joint Research Committee on Boiler Feedwater Studies have been limited to a continuation of the work in which its subcommittees were engaged during the preceding fiscal year.

An important change in the organization of the committee has occurred as the result of the resignation of S. T. Powell as chairman. Early in the past decade Mr. Powell perceived the importance of extending the knowledge of the industry in the reactions between water and steel under the conditions obtaining as the temperature and pressure of boiler operation increased and organized the joint research committee. With the aid of leaders in the industries vitally interested in these studies, with whom he associated himself, a comprehensive program of research was outlined. Not all phases of the general problem were studied at once; but emphasis was laid first on methods of water analysis and on a study to determine the cause of foaming and priming. The interest stimulated by Mr. Powell's leadership, however, has in the past ten years, advanced in a remarkable manner our knowledge of the reactions occurring within industrial water itself and between it and boiler metal under the conditions of association in modern steam power plants. It was, accordingly, with considerable regret that the members of the Executive Committee acceded to Mr. Powell's wishes and allowed him to relinquish the chairmanship.

The following officers were elected by the executive committee at its meeting in Cincinnati in May of this year to carry on the work of the joint research committee: C. H. Fellows of The Detroit Edison Company, chairman; R. C. Bardwell of The Chesapeake & Ohio Railway Company, vice-chairman; and J. B. Romer of The Babcock & Wilcox Company, secretary. These officers are planning a reorganization of the joint research committee in an effort to stimulate increased financial interest in its work and, at the same time, to further the objectives originally drawn up.

During the past year the work of the Subcommittee on Methods of Boiler Water Analysis was continued at the University of Michigan. A progress report on the incompleted research program concerning methods for determining dissolved oxygen was presented before a session on Boiler Water at the Annual Meeting of the American Water Works Association at Cincinnati in June, 1935, by C. H. Fellows, then chairman of the subcommittee. The research work on the determination of dissolved oxygen undertaken by this technical committee has served to stimulate a number of other investigators in this field. As a result M. C. Schwartz and W. B. Gurney, J. D. Yoder and his associates, D. O. Lima, and others have published results of investigations in this field. The future work of this committee will be under the direction of Prof. A. H. White of the University of Michigan. Professor White has accepted the invitation of the Executive Committee to undertake the chairmanship of this group, which was made vacant when its former chairman was elected to the chairmanship of the joint committee.

The work of the Subcommittee on Zeolite Softeners, Internal Treatment, Priming and Foaming, Electrolytic Scale Prevention under Prof. C. W. Foulk dealing primarily with the causes and prevention of foaming and priming, has been temporarily discontinued. It is planned, however, that this work will be resumed during the coming year.

The work of the Subcommittee on Alkalinity and Sulphate Relations in Boiler-Water Salines, under the direction of J. H. Walker as chairman, has progressed to an important extent during the past

year. W. C. Schroeder has been actively engaged on this project since its inception under the direction of E. P. Partridge at the New Brunswick Station of the U. S. Bureau of Mines. The original objectives have been reached and a report covering this research will be presented at the coming Annual Meeting of the A.S.M.E.

In addition to this completed study, Mr. Walker's committee has initiated a more basic research on the phenomenon of caustic embrittlement. Through the continued prosecution of these studies it is anticipated that many new and important data will be disclosed regarding this subject, permitting a clearer understanding of its development and prevention.

Condenser Tubes, A. E. White, Chairman. The results of the work of the Special Research Committee during the year 1934 were coordinated and presented at a meeting of the Committee held during the Annual Meeting of the Society in December, 1934. This report included the progress of short-time methods of corrosion testing of condenser-tube alloys, particularly, by methods of impingement attack and by the use of experimental condensers operating under controlled conditions. This latter work included a comparison of the effect of circulating-water velocity on the corrosion rate of the tubes. Research work on a modified form of apparatus for impingement testing was presented for further investigation and calibration with comparative tube life in service.

Some rather well-defined cases of corrosion in condenser tubes caused by the presence of foreign matter within the tube were shown. Conjecture regarding the effect of foreign matter on tube life is a matter of long standing, however, very few concrete cases taken from service have been available.

A rather comprehensive survey of the experience in service of a number of the newer tube alloys were made. The use of the newer alloys has been increasing steadily. They apparently have a very definite field, at least in certain places, where the tube life of the older alloys has been short.

During 1935 the committee has continued its development of standard methods for corrosion testing and will include in its December, 1935, report a discussion of causes of end corrosion and improved methods for prolonging tube life in condensers where end corrosion is a serious problem.

Boiler-Furnace Refractories, W. A. Carter, Chairman. During the past year there has been little progress because of lack of funds. However, some laboratory work on the equilibrium diagram for the alumina-lime-silica-iron oxide system has been continued at the National Bureau of Standards. In addition, the chairman has endeavored to get some help from co-members of the A.S.T.M. Committee C-8 on Refractories to carry on the laboratory slag-test program that the committee was forced to discontinue at the University of Illinois because of lack of funds. The prospects of getting this project under way in the near future are, however, encouraging.

Absorption of Radiant Heat in Boiler Furnaces, W. J. Wohlenberg, Chairman. The Society authorized the appointment of a special research committee on absorption of radiant heat in boiler furnaces early in 1928. In 1930 a fellowship was established under the direction of Professor Wohlenberg and financed by The Superheater Company in order to study the problem from both the experimental and theoretical points of view. The experimental work was to consist of radiation and temperature measurements in boiler furnaces together with other data necessary for establishing the energy distribution, the particular furnaces in which the measurements were to be taken to be selected after a study as to type and convenience of arrangements for obtaining the information desired. These tests were carried out on ten boilers in different power plants in the United States and involve stokers, pulverized-fuel, oil, and gas firing with various combinations of refractory protected and water-cooled furnaces.

When the results of the investigations were presented to the Committee at its December 5, 1934, meeting, it was decided to present this information to the Society in the form of one or more papers and to further recommend that one session of the 1935 Annual Meeting be devoted exclusively to this subject. Such a session is now being sponsored by the Fuels Division and the Subcommittee on Heat Transfer of the Process Division. The papers to be read at this session have been written by W. J. Wohlenberg, W. H. Armacost, C. W. Gordon, and H. F. Mullikin.

Velocity Measurement of Fluid Flow, W. F. Durand, Chairman. A variant method for determining air velocity in a pipe using sound impulses rather than wave trains of definite frequency was investigated. The method consists in starting a sound pulse at a point in the pipe carrying the air and adjusting a length measured upstream against a fixed length measured downstream so that the pulse arrives at the two terminations simultaneously. The method employed for determining simultaneity consisted in converting the arrived sound pulses to electrical pulses by means of telephone receivers and applying the electrical pulses to the grids of two gas-type electronic tubes so coupled that the tube receiving the impulse registers and thereby prevents the other tube from registering. By manipulating the length of one of the sound paths, either one or the other electronic tubes can be made to register for a steady state of fluid flow. This enables the path length of simultaneous sound-pulse arrival to be determined. The difference in path length of the adjustable arm over that determined when the fluid is at rest, is a measure of the fluid velocity.

The method was devised to avoid the effect of sound reflections in the pipe which hitherto have been found extremely troublesome. This scheme depends for its operation only on the first pulse arriving, the apparatus thereafter being rendered automatically inoperative for a time sufficient to allow sound disturbances to subside.

The scheme was found to work successfully over the fluid-velocity range possible with the apparatus at hand, namely velocities from 1 to 22 ft per sec. The fluid velocities were checked by means of a gasometer and stopwatch. The reproducibility of velocity readings obtained with the acoustic method was superior to that obtained with the gasometer and the average velocities determined by the two methods agreed to within one per cent.

Measurements were made of air velocity in two different pipes, the first an iron conduit of 1.37 in. internal diameter, the second a brass tube with an internal diameter of 0.293 in. Fluid velocities from 1 to 7 ft per sec could be produced in the large pipe, and velocities up to 22 ft per sec in the small tube.

Fluid turbulence apparently does not affect the operation of the device in a significant way, at least for the velocities and pipe diameters investigated. Also it was found that it was not necessary to use an arbitrary correction factor to reconcile the velocity values obtained by the acoustic method with those obtained with the gasometer standard. Accordingly it appears that the acoustic method may be regarded as an absolute method yielding correct velocity values from simple length measurements and the velocity of acoustic propagation in the fluid medium.

Strength of Vessels Under External Pressure, W. D. Halsey, Chairman. The special research committee is at present investigating the possibilities of furnishing simple means for computing the dimensions and stresses of vessels under external pressure constructed of materials other than steel and also of steel vessels but at elevated temperatures. Whereas it would be possible to provide charts for the calculation of such vessels, the preparation of such charts would entail an enormous amount of work and it is hoped that a more simple means may be developed.

The committee expects to furnish also within the near future a discussion of the underlying principles of the report it has already published and which has been incorporated as a section of the A.S.M.E. Code for Unfired Pressure Vessels. In the meantime, it is undertaking to answer questions raised by the membership regarding the application of the rules given in its first report.

Wire Rope, W. H. Fulweiler, Chairman. The National Bureau of Standards has completed the report of the tests on some 200 samples of discarded wire rope. This report shows the close relationship between wear and broken wires in a rope and its remaining strength. Publication of the report is being delayed until after its findings have been checked by wire-rope inspectors in the field.

Heavy-Duty Anti-Friction Bearings, W. Trinks, Chairman. During the year the committee has continued its search through published and privately obtained data for additional findings relating to the various phases of its research program. While some additional information has been obtained, no developments have been brought to light which require revision or immediate amplification of the committee's previous reports. The report summarizing the results of the committee's experimental investigation has just been published as a separate pamphlet under the title "Roll-Neck Bearings."

In so far as the committee's plans are concerned, the immediate future may be characterized as a period of watchful waiting, to be continued until foreign or private investigators unearth new data, or until demand arises for resumption of an active program by the committee.

Rotary Drilling of Oil Wells, D. D. Trax, Chairman. The activity of the Special Research Committee on Rotary Drilling of Oil Wells has been limited this year to a recasting of the report on performance and efficiency of gas-electric prime movers for rotary drilling which was presented at the Petroleum Division meeting held in Tulsa in May, 1934. When the report is completed the committee proposes to recommend its publication as a separate pamphlet.

Critical-Pressure Steam Boilers, A. A. Potter, Chairman. The major portion of the year was devoted to a study of the viscosity of water and of steam. There are no data available for the viscosity of water at temperatures above 320 F and in the case of steam the values for viscosity above atmospheric pressure are not known with sufficient accuracy. Up-to-date data are available on the viscosity of water from 212 F up to and including the critical temperature.

Interesting results have also been secured on the effect of pressure on the viscosity of subcooled water.

The viscosity of steam has been investigated since June, 1935, at pressures up to 3500 lb per sq in. and at temperatures up to 1000 F. The results of the investigations of the viscosity of water and of steam under the previously mentioned conditions will be presented in a paper at the coming Annual Meeting. The plans for the next year include a study of dissociation at high pressures and temperatures.

Sampling of Pulverized Fuel in Moving Gas Streams, K. M. Irwin, Chairman. At its meeting in New York in December, 1934, the committee decided not to solicit funds to cover further laboratory tests but to limit the committee's activities to an inquiry from the present users of pulverized-fuel equipment relative to the methods they are now using to obtain pulverized-fuel samples and also to attempt to secure an expression of opinion from them as to the relative accuracy of the methods which are being employed.

A questionnaire is in preparation for this purpose which has been reviewed by a few members of the special research committee. It is hoped that before the end of 1935, final approval on the form of the questionnaire will be reached and that during the next year the committee will be successful in collecting a considerable amount of information.

Cottonseed Processing, W. R. Woolrich, Chairman. The University of Tennessee, the Tri-State Cotton Oil Mill Superintendents Association, the Tennessee Valley Authority, the Engineering Foundation and the A.S.M.E. Special Research Committee are cooperating in this research program. Through laboratory investigation at the University, fundamental and basic facts relative to the processing of cottonseed are uncovered and proved. When necessary, experimental equipment is built and trial runs made to determine the value of new processes or products. A progress report was presented to the Society during the year at the 1934 Annual Meeting, by Chairman Woolrich.

Future plans involve the finding of more new uses for the cottonseed bi-products and the extension of the research program into the demonstration stage, especially that of a continuous cooker of the type which has been developed within the laboratory.

Inactive Committees. Five of the twenty-four special research committees on Elevator Safeties, Worm Gears, Measures of Management, Removal of Ash as Molten Slag from Powdered-Coal Furnaces, and Automatic Oil Pipe Line Pumping Stations have been inactive during the past year for financial and other reasons.

Respectfully submitted,

G. M. Eaton, *Chairman*
D. B. Bullard — H. A. Johnson
N. E. Funk — C. R. Richards

STANDARDIZATION

A review of the year's activity among the standardization committees sponsored by the Society reveals a commendable amount of progress and the Standardization Committee takes considerable pleasure and pride in reporting the results accomplished. Within the fiscal year just closed (October 1, 1934, to October 1, 1935) eight standards were completed and presented to the American Standards Association for approval. These standards are as follows:

Shafting and Stock Keys
Screw Threads
Adjusted Pressure Ratings for Steel Flanges and Flanged Fittings
Jig Bushings
Drawings and Drafting-Room Practice
Graphical Symbols
Code for Pressure Piping
Hose Coupling Screw Threads
Wrought-Iron and Wrought-Steel Pipe
Cast-Iron Soil Pipe and Fittings

In the paragraphs which follow will be found brief statements covering the year's progress of every committee that has been active during that period. For the convenience of reference the present status of the several projects for which the Society holds sponsorship or joint sponsorship under the A.S.A. procedure is indicated also by classifying them under the following six heads that represent definite steps in that procedure but in reverse order according to time: (1) Before the A.S.A. for final approval and released for publication; (2) proposed standard before sponsor bodies; (3) revised proposal before sectional committee; (4) completion of report by subcommittee; (5) review of comments by subcommittee; and (6) development of proposal by subcommittee.

(1) Before the A.S.A. for Final Approval and Released for Publication

Shafting and Stock Keys, C. M. Chapman, Chairman. Four standards formerly approved by the A.S.A., B17a—1924, B17b—1925, B17d—1927, and B17e—1927 were revised with additions and republished in one pamphlet after approval in December, 1934.

Screw Threads, R. E. Flanders, Chairman. The two sponsor bodies, the Society of Automotive Engineers and The American Society of Mechanical Engineers approved the first revision of the American Standard for Screw Threads, originally published in 1924, in February, 1935, and November, 1934, respectively. Accordingly, in March, the proposal was transmitted to the American Standards Association for final approval and designation as an American Standard. This designation was given in April, 1935, and the standard known as B1.1—1935 is now available in pamphlet form.

Adjusted Pressure Ratings for Steel Flanges and Flanged Fittings, A. M. Houser, Chairman. The letter-ballot vote of the members of the Sectional Committee on the Standardization of Pipe Flanges and Fittings was completed in March, 1935, and resulted in a favorable recommendation in regard to the revised tables for pressure-temperature ratings that were prepared by Subcommittee No. 4 on Materials and Stresses to replace Table 1 in the American Standard for Steel-Flanged Fittings and Companion Flanges (B16e—1932). The Heating, Piping, and Air Conditioning Contractors National Association, one of the sponsors, approved this proposal in April, 1935, while the other two sponsors, the Manufacturers Standardization Society of the Valve and Fittings Industry and The American Society of Mechanical Engineers gave their approval in May, 1935. The proposal was placed before the A.S.A. for approval in May, 1935. This was granted in September.

Jig Bushings, F. S. Walters, Chairman. The National Machine-Tool Builders Association, the Society of Automotive Engineers, and The American Society of Mechanical Engineers, as sponsors, approved the proposed American Standard for Jig Bushings during the past year, and it was presented to the American Standards Association for final approval in March, 1935. This approval was given in April and this new American Standard (B5.6—1935) is now available.

Drawings and Drafting-Room Practice, F. DeR. Furman, Chairman. The American Society of Mechanical Engineers as one of the sponsors for the proposed American Standard for Drawings and Drafting-Room Practice signified its approval of this proposal in February, 1935. Approval of the other sponsor, the Society for the Promotion of Engineering Education, was given the previous June. It was transmitted to the American Standards Association in March and its approval and designation as an American Standard was given in May. This standard therefore, is available now in pamphlet form with the serial designation 214.1—1935.

Graphical Symbols, T. E. French, Chairman. The proposed American Standard for Graphical Symbols was approved by The American Society of Mechanical Engineers as sponsor in May, 1935. The other joint sponsor, the Society for the Promotion of Engineering Education gave its approval in June, 1934, contingent on approval by the sectional committee and the A.S.M.E. However, several suggestions made by certain members of the Sectional Committee on the Standardization of Drawings and Drafting-Room Practice at the time of the letter-ballot vote made necessary a further review of a number of the proposed standard symbols. Accordingly, in June, 1935, a summary of these suggestions was sent to the entire membership of the sectional committee for vote by letter ballot. The changes which were approved by this ballot were included in the proposed standard submitted to the A.S.A. in September, 1935.

Code for Pressure Piping, E. B. Ricketts, Chairman. The letter-ballot vote of the members of the Sectional Committee on Code for Pressure Piping was completed in December, 1934. The Code was then submitted to The American Society of Mechanical Engineers for approval in its capacity as sole sponsor. This approval was given in February, 1935, and in March the proposed American Tentative Standard Code for Pressure Piping was presented to the American Standards Association for final approval. Favorable action was announced in June, and the code was made available immediately in pamphlet form with the number B31—1935.

Wrought-Iron and Wrought-Steel Pipe, H. H. Morgan, Chairman. In November, 1934, the American Society of Mechanical Engineers, as one of the two joint sponsors, gave its approval to the proposed American Tentative Standard for Wrought-Iron and Wrought-Steel Pipe, and The American Society for Testing Materials, the other sponsor for this project, gave its approval in February, 1935. While the proposal was presented to the A.S.A. in March, 1935, some delay in securing its approval has resulted from a disagreement concerning slight changes which had been made by the editing committee in the wording of Paragraph 3 of the introductory notes.

Hose Coupling Screw Threads, H. W. Bearce, Chairman. Objec-

tions raised during A.S.A. vote necessitated another meeting of Sectional committee. Standard finally approved and published in July, 1935.

Cast-Iron Soil Pipe and Fittings, J. J. Crotty, Chairman. The proposed American Standard for Cast-Iron Soil Pipe was completed in April, 1935; it was submitted to the members of the Sectional Committee on Plumbing Equipment for approval by letter ballot in May and was presented to the two sponsor societies in July, 1935. The American Society of Sanitary Engineering and The American Society of Mechanical Engineers, gave their approval to the proposed standard in August, and in the same month it was transmitted to the A.S.A. for final approval and designation as an American Standard. W. C. Groeniger is chairman of the Sectional Committee.

(2) Proposed Standard Before Sponsor Bodies

Brass Fittings for Flared Copper Tubes, F. L. Riggin, Chairman. The development of a standard for brass fittings for flared copper water tubes was initiated by a subgroup composed principally of manufacturers and in 1930 a tentative draft was submitted for review to the members of Subcommittee No. 7 of the Sectional Committee on Plumbing Equipment. After some revision, the proposed standard was distributed broadly to industry for criticism in February, 1931. Then followed considerable correspondence between the members of the subcommittee and groups in the industry. Finally in March, 1934, it was approved in revised form by Subcommittee No. 7 and submitted to the sectional committee for vote on approval by letter ballot. This vote was favorable and in September, 1935, the proposed standard was submitted to the sponsor bodies, the American Society of Sanitary Engineering and The American Society of Mechanical Engineers for approval and transmission to the A.S.A.

Socket Set Screws and Socket-Head Cap Screws, H. Koester, Chairman. In April, 1935, the final draft of the proposed American Standard for Socket Set Screws and Socket-Head Cap Screws was released by Subcommittee No. 9 to the Sectional Committee on the Standardization of Bolt, Nut, and Rivet Proportions for vote on approval by letter ballot. This vote was favorable and the proposed standard was submitted to the two sponsors, the Society of Automotive Engineers and The American Society of Mechanical Engineers in August, 1935.

(3) Revised Proposal Before Sectional Committee

Ammonia Flanged Fittings and Companion Flanges, W. R. Kremer, Chairman. The letter-ballot vote of the members of the Sectional Committee on the Standardization of Pipe Flanges and Fittings on the proposed American Tentative Standard for Ammonia Flanged Fittings and Companion Flanges was completed in October, 1934. The results of this ballot indicated, however, that certain extensive changes and additions were desired by the members of the sectional committee. The officers of the committee, after considerable correspondence prepared a revised draft of the proposal and resubmitted it to the members of the sectional committee in September, 1935, for vote on approval by letter ballot.

(4) Completion of Report by Subcommittee

Taper Pipe Threads, S. B. Terry, Chairman. Subcommittee No. 2 completed its revision of the American Standard for Pipe Threads (B2—1919) in September, 1935. As the next step in the development of the proposed revision, it will be submitted to the members of the Sectional Committee on Pipe Threads for approval by letter-ballot vote.

Machine Tapers, F. S. Blackall, Jr., Chairman. The final draft of the proposed American Standard for Machine Tapers with certain minor corrections and changes was approved by Technical Committee No. 3 of the Sectional Committee on Small Tools and Machine Tool Elements at its meeting in December, 1934. After final checking of all details, the proposed standard will be mailed to the members of the sectional committee for vote by letter ballot.

Spindle Noses and Collets, J. E. Lovely, Chairman. Technical Committee No. 4 on Spindle Noses and Collets of the Sectional Committee on Small Tools and Machine-Tool Elements was organized in December, 1928. It cooperated with Technical Committee No. 11 in the preparation of a draft standard on Spindle Noses and Chucks distributed to industry for comment in May, 1930.

However, as a result of suggestions made at numerous conferences with members of the industry, Technical Committee No. 4 in March, 1931, drew up a revised draft of this proposal dealing only with lathe-spindle noses. In October, 1932, this draft was approved by the lathe groups of the National Machine Tool Builders Association.

During 1933, the committee carried on tests on new forms of spindle noses. Subsequently sufficient experience with the proposed standard type of spindle nose has been had and recorded, and the new designs have met with such universal approval by industry that in October, 1934, copies of the proposal in its final form covering spindle noses for turret lathes and automatic lathes were sent to the members of the Technical Committee. In March, 1935, the Technical Committee released this proposed standard to the Nomenclature Committee for review. Following this review it will be submitted to the members of the Sectional Committee for vote by letter ballot.

Chucks and Chuck Jaws, J. E. Lovely, Chairman. Work on the preparation of a proposed standard for Chucks and Chuck Jaws was begun in December, 1928, with the organization of Technical Committee No. 11. Subsequently, Technical Committee No. 11 collaborated with Technical Committee No. 4 on Spindle Noses and Collets in preparing a draft standard on Spindle Noses and Chucks. In May, 1930, these committees distributed to industry for comment a joint proposal entitled proposed American Standard for Spindle Noses and Chucks. The next year a revised draft of this proposal dealing only with chucks and chuck jaws and based on the comments received as a result of the previous canvass of industry was circulated to industry for further comment.

After extensive correspondence relating to the adjustment of various changes and corrections suggested by the manufacturers of chucks, Technical Committee No. 11 completed the final draft of the proposed standard and released it to the Sectional Committee in March, 1935. Following review by Technical Committee No. 17 on Nomenclature, it will be submitted to the members of the Sectional Committee for vote by letter ballot.

Circular Forming Tools and Holders, W. C. Mueller, Chairman. Work on a proposed standard for circular forming tools and holders for automatic screw machines was begun in 1931 by Technical Committee No. 10. During the course of the next three years, four questionnaires were distributed to industry for criticism and comment and the suggestions received were, incorporated as far as possible, in successive revisions of the proposed standard. In August, 1934, a final draft of the proposal was sent to the members of the Technical Committee, and in November, 1934, it was released to the Sectional Committee.

Technical Committee No. 17 was asked to develop the nomenclature for this standard and when this is completed the proposed standard will be sent to the members of the Sectional Committee for vote on approval by letter ballot.

(5) Review of Comments by Subcommittee

Inspection of Gears, F. W. England, Chairman. In May, 1935, the Recommended Practice of the American Gear Manufacturers' Association for Inspection of Gears was mailed to a selected list of users of gears with a request for their criticism and comment. Subcommittee No. 9 of the Sectional Committee on the Standardization of Gears proposes that these rules form the basis of the American Standard for the Inspection of Gears. The replies which were received are now in the hands of the subcommittee for study.

Large Rivets, R. N. S. Baker, Chairman. As a result of the meeting of Subcommittee No. 1 on Large and Small Rivets held in New York in December, 1934, the proposed American Standard for Large Rivets was broadly distributed in June, 1935, for criticism and constructive suggestions. The replies received are now in the hands of the subcommittee.

Plain Washers, C. W. Squier, Chairman. During the past year a tentative draft of the proposed American Standard for Plain Washers for use with American Standard Bolt Heads and Nuts was completed by Subcommittee No. 1 and distributed broadly for the general criticism and comment of industry. Consideration is now being given to the replies received.

Speeds of Machinery, A. E. Hall, Chairman. The special subgroup appointed to study the comments received from industry following the distribution of copies of a tentative draft of the proposed American Standard for Machine Speeds held a meeting in New York, in April, 1935. A revised draft of the proposal based on the subgroup's recommendations is now being prepared.

Traps, A. R. McGonegal, Chairman. In February, 1935, a draft of the proposed American Standard for Traps for use with plumbing fixtures was distributed to industry for review and comment. Subcommittee No. 5 of the Sectional Committee on Plumbing Equipment is now reviewing the replies which were transmitted to the chairman late in April. These suggestions will form the basis of a further revision of this proposal.

Pressure and Vacuum Gages, M. D. Engle, Chairman. Subcommittee No. 3 on Gage Sizes and Mounting Dimensions, H. B. Reynolds, chairman, and Subcommittee No. 4 on Accuracy and Test Methods, O. J. Hodge, chairman, are reviewing letters received as a result of the general distribution of their parts of the proposed standard to industry for criticism and comment. Section 3 was mailed in November, 1934, and Section 4 was distributed in April, 1935. There is a possibility that all of the three sections of this proposed

standard will be ready early this fall for the editing committee, which is to mold them into a unified whole.

(6) DEVELOPMENT OF PROPOSAL BY SUBCOMMITTEE

Round Unslotted Head Bolts. At the December, 1934, Meeting of Subcommittee No. 5, a proposed revision of the American Tentative Standard for Round Unslotted Head Bolts published in 1928 (B18e—1928) was approved. Draft copies of this proposed revision had been distributed previously to the committee members and others interested for their consideration. It was found necessary to prepare a new table for thread lengths, copies of which were distributed to the members of the committee in July, 1935. If satisfactory, this table will be incorporated in the proposed revision which then will be circulated to industry at large for criticism and comment.

T-Slots, Erik Oberg, Chairman. Technical Committee No. 1 of the Sectional Committee on Small Tools and Machine-Tool Elements completed its report on the "Nomenclature and Glossary of Terms for T-Slots," in May, 1935. This report is now in the hands of Technical Committee No. 17 on Nomenclature after which this supplement to B5a—1927 will be submitted to the members of the sectional committee for approval.

Punch-Press Tools, D. M. Palmer, Chairman. The reorganized Technical Committee No. 9 on Punch-Press Tools held a meeting in Detroit in February, 1935, at which substantial progress was made toward the completion of a tentative draft of the committee's proposal intended to cover certain parts of all classes of die sets considered suitable subjects for standardization.

Single-Point Cutting Tools, F. H. Colvin, Chairman. Technical Committee No. 19 which was organized in December, 1933, completed its report on the nomenclature for single-point tools in May, 1935. This report will be submitted shortly to the members of the sectional committee for approval.

Preferred Practice in Graphic Presentation, A. H. Richardson, Chairman. Subcommittee No. 3 of the Sectional Committee on Standards for Graphic Presentation at its meeting held in New York in June, 1935, adopted, with a few minor changes, a tentative draft of a code for preferred practice in graphic presentation which had been in course of preparation for a number of years. The subcommittee plans to have about five hundred copies of this proposed code printed for preliminary review, the expense to be covered by sales to the public. This would be in the nature of a trial edition which thus could be tested in practice and, if found to be satisfactory, presented to The American Society of Mechanical Engineers as sponsor society for approval and transmission to the American Standards Association.

Engineering and Scientific Graphs, W. A. Shewhart, Chairman. The special subgroup of Subcommittee No. 4 appointed in April, 1934, to prepare a standard nomenclature for the shapes of curves and plots, under the chairmanship of E. T. Cope, completed its report in May, 1935, and distributed copies of it to the members of the subcommittee in June of this year for examination and comment.

The special subgroup under the chairmanship of H. F. Dodge appointed also in April, 1934, held a meeting in December of that year to consider a preliminary draft of a brochure on "Engineering and Scientific Graphs for Publications." Consideration was given also at this meeting to an outline of the subgroup's report submitted by Messrs. Stone and Hanscom. Three subsequent meetings were held in January, February, and April and the suggestions developed at these meetings have been incorporated in a redraft of the proposal.

Tolerance Systems, R. E. W. Harrison, Chairman. Subcommittee No. 1 of the Sectional Committee on Allowances and Tolerances for Cylindrical Parts and Limit Gages held a meeting in New York in December, 1934. At this meeting a full discussion of the differences between the present standard (B4.1—1925) and the I.S.A. Standard with special reference to ranges and classes of fit took place. D. R. Miller, a member of the committee, then was requested to prepare a set of ranges and tolerances following the general trend of B4.1—1925 and the I.S.A. standard but with the fewest possible and widest practical ranges. This task was completed and copies of the report were distributed to the members of the subcommittee in June, 1935.

Cut and Ground Thread Taps, C. M. Pond, Chairman. At its meeting in December, 1934, Technical Committee No. 12 discussed and approved revisions of the American Standard for Cut and Ground Thread Taps (B5e—1930). This revision is based on comments and suggestions received as a result of the distribution of a tentatively revised draft to industry at large in May, 1934. After approval by the members of the Sectional Committee on Small Tools and Machine-Tool Elements this revision will be submitted to the sponsor societies and the American Standards Association.

Gasoline, Oil, and Grease Separators, J. J. Crotty, Chairman. Meetings of Subcommittee No. 9 were held in November, 1934, and March, 1935, and good progress was made toward the completion of the first draft of a proposed American Standard for Gasoline, Oil, and Grease Separators. At the November, 1934, meeting, a report on the "Recommended Use for Oil Separators and Their Construction" was presented and discussed. There is now before the subcommittee for its consideration a draft of a proposed standard ordinance to regulate the handling, storage, transportation, and disposition of waste oils and grease resulting from the use and operation, cleaning, repairing, or servicing of vehicles, machinery, or appliances of any kind. This project is part of the program of the Sectional Committee on Plumbing Equipment.

Iron and Steel Bars, F. H. Frankland, Chairman. The Sectional Committee, on the Standardization of Stock Sizes, Shapes, and Lengths for Hot-Rolled and Cold-Finished Iron and Steel Bars held a meeting in New York on April 23, 1935. The committee discussed seriously the need for this standard and the form which it should take. It was finally decided that the gathering together of the several present trade practices within the scope of the committee's work and the placing them in form for review and approval by the American Standards Association would render a useful service.

Accordingly, certain members of the committee agreed to supply a list of shapes, sizes, lengths, and tolerances of hot-rolled bars together with similar data for hot-rolled reinforcing bars. Another group offered to supply the same data for cold-finished steel bars. It was then decided that, when this material had been assembled and worked up into the form of a standard, it should be distributed to the members of the Sectional Committee as a tentative proposal.

Classification and Designation of Surface Qualities, C. G. Mettler, Chairman. Subcommittee No. 1 on Standardization of Surfaces Produced by Tools and Abrasives, J. Cetrule, chairman, held a meeting in December, 1934, at which a comprehensive report of Subgroup No. 2 on Machine Surfaces Produced by Tools, of which J. S. Chafee is chairman, was read and discussed. As a result of this discussion the subgroup was assigned further duties and from subsequent correspondence with Mr. Chafee it is expected that a report will be forthcoming shortly.

In December, 1934, a meeting was held also by Subcommittee No. 5 on Ways, Means, and Apparatus for Measuring Quality of Surface, J. R. Weaver, Chairman, at which Prof. F. A. Firestone's report on definitions and notation for measurement of surface quality was read and discussed. At this meeting consideration was given also to a program of experimental work which had been outlined in a letter sent out by the secretary of the subcommittee the previous spring and, as a result of the discussion, a subgroup headed by G. A. Bouvier, was appointed to carry out that part of the program relating to the measurement, by various methods, of samples of representative surfaces.

Furnaces, C. E. Bronson, Temporary Chairman. Upon the recommendation of the A.S.M.E. Pure Air Committee together with a large number of representative and interested organizations, a Sectional Committee on the Unification of Rules for Dimensioning of Furnaces for Burning Solid Fuel was organized in June, 1933, in Chicago under the procedure of the American Standards Association. The present economic conditions have operated to delay the completion of the personnel of this sectional committee and the five subcommittees which were authorized by the sectional committee at its first meeting. Mr. Bronson gives assurance, however, that this task is now nearly completed.

As a matter of record, the following statistics are given for the purpose of indicating the extent of this activity and the number of persons having a part in it. Number of Sectional Committees 31; number of subcommittees and subgroups 273; number of committee members, members of A.S.M.E. 371, non-members 812; number of committee meetings held in year, 24; number of cooperating organizations, 206.

Respectfully submitted,

C. W. SPICER, *Chairman*
ALFRED IDDLES — WALTER SAMANS
L. A. CORNELIUS — O. A. LEUTWILER

POWER TEST CODES

The Committee on Power Test Codes takes pleasure in reporting that during the fiscal year 1934–1935 one new test code and one revised code were completed, approved, and published while two new sections of Instruments and Apparatus and one revised section were completed and approved by the Council. A more detailed statement covering this activity is given in the following paragraphs.

ITEMS OF GENERAL INTEREST

Election of Acting Chairman of Power Test Codes Committee. In recognition of the service which Dr. Robert H. Fernald had so willingly rendered the main Committee during the period of Dr. Low's illness, the committee requested him at its December, 1934,

meeting to serve as its acting chairman until such a time as Chairman Low will be able again to take his place.

Btu per Hour Equivalents of Horsepower and Kilowatt. In a comment on the November, 1934, draft of the proposed revision of the Test Code for Steam-Condensing Apparatus attention was called to the disagreement between the values there given for the Btu per hour equivalents for "horsepower" and the "kilowatt," and the similar values given in the Keenan Steam Tables. The constants 2543 and 3413 Btu per hr respectively in the code were taken from the Code on Definitions and Values and those in the Keenan Steam Tables, 2543.1 and 3411.5, are based on the International calorie which was defined at the 1929 International Steam Tables Conference (London) as 1/860 of the International watt-hour.

Since the publication of the Keenan Steam Tables, the National Bureau of Standards has adjusted the basic values of its electrical standards to agree with the International values and the American Standards Association has accepted similar modifications.

In view of these developments which have taken place since the Code on Definitions and Values was issued in June, 1931, Committee No. 2 on Definitions and Values has been requested to revise its Btu-per-hour equivalents for horsepower and the kilowatt for use in new or revised power-test codes.

A.S.T.M. Committee on Gaseous Fuels. Because of the direct interest in this subject of the Power Test Codes Committee No. 3 on Fuels, E. X. Schmidt, a member of that committee was named as its representative on the A.S.T.M. committee, which now has been organized to standardize the nomenclature and the methods of sampling and testing gaseous fuels in so far as they apply to purchases and sales and the requirements of regulatory bodies. Mr. Schmidt has been active in the development of the A.S.M.E. Power Test Code for Gaseous Fuels.

Committee Meetings. As a matter of record it should be stated that the following committees held regularly called meetings during the past twelve months: Power Test Codes Committee, three meetings, October, December, and April; Committee No. 6 on Steam Turbines; Committee No. 10 Subcommittee on Fans; Committee No. 11 on Complete Steam Power Plants; Committee No. 18 on Hydraulic Prime Movers; special Subcommittee on Measurement of Fluid Flow of Committee No. 19 on Instruments and Apparatus; and Committee No. 21 on Dust-Separating Apparatus.

Committee Progress

Fuels. Committee No. 3 on Fuels, W. J. Wohlenberg, Chairman, completed its review of the preliminary draft of the Test Code for Gaseous Fuels in November, 1934. The code is now in shape for distribution to a selected list of individuals and firms for criticism and comment.

Reciprocating Steam Engines. Committee No. 5 on Reciprocating Steam Engines, A. G. Christie, Chairman, completed an extensive revision of the Test Code for Reciprocating Engines and on February 6, 1935, it was approved by the Council and subsequently published in pamphlet form.

Steam Turbines. Committee No. 6 on Steam Turbines, C. H. Berry, Chairman, met during the 1934 Annual Meeting of the Society to discuss the voluminous material that had been distributed to the members dealing with the proposed revision of the Test Code for Steam Turbines. A subcommittee of three was appointed at that time to develop the revision of the code. This subcommittee is working effectively and definite progress is being made toward the completion of the revised draft of this test code.

Centrifugal and Rotary Pumps. Committee No. 8 on Centrifugal and Rotary Pumps, W. B. Gregory, Chairman, is now considering the advisability of an immediate revision of this code which was approved and published in February, 1928. This step was urged in a communication received from the Hydraulic Institute. In the use of this code as its standard of testing practice, the Institute has realized more and more that it is not altogether adequate and, through the efforts of one of its committees, it has been endeavoring to agree upon certain desirable revisions, and additions, and the standardization of certain of the testing methods and equipment. As the principal purpose of these codes is to serve the practical needs of industry, the Committee, when it has acquainted itself with the exact nature and extent of the changes desired, will begin work on a revised draft.

Displacement Compressors and Blowers. Committee No. 9 on Displacement Compressors and Blowers, Paul Diserens, Chairman, is now laying plans for a complete revision of the Test Code for Displacement Compressors and Blowers. Before undertaking this work the committee is awaiting the report of the Instruments and Apparatus Special Subcommittee on the Measurement of Fluid Flow covering rules for the measurement of air flow from a gaging tank into the atmosphere and from the atmosphere into a gaging tank.

Centrifugal and Turbo-Compressors and Blowers. Chairman, A. T. Brown, Committee No. 10, reports the publication in pamphlet form in March, 1935, of Part 1 on Compressors and Blowers of the Test Code for Centrifugal Compressors, Exhausters, and Fans.

The Subcommittee on Fans, M. C. Stuart, Chairman, held two meetings within the year, during which the first tentative draft of the Test Code for Fans was outlined. The development of the code has been delayed due to the lack of adequate information and agreement on the standard methods of measuring air. Accordingly, several subgroups have been organized to formulate standard methods for the measurement of air under the conditions to be found in the testing of fans. To provide the necessary data and information investigations are under way at Lehigh University under the direction of Professor Stuart; at Harvard University, under the direction of Professor Marks; and in the laboratories of several of the fan manufacturers. They cover (1) measurement of flow by pitot tube in inlet or discharge ducts; (2) measurement of flow by nozzle in inlet or discharge ducts; and (3) measurement of flow with large chamber by nozzle or orifice. The subcommittee hopes that before the end of another year it will have completed the first tentative draft of the Test Code for Fans.

In order to bring about closer cooperation between the A.S.M.E. committee and the committees of the American Society of Heating and Ventilating Engineers interested in fan testing, Thomas Chester, consulting engineer of Detroit, has been appointed to membership on the committee. Mr. Chester is chairman of the Special Council Committee of the American Society of Heating and Ventilating Engineers, organized to review that Society's Standard Code for Disk and Propeller Fans, Centrifugal Fans and Blowers.

During the two years since the organization of the Subcommittee on Fans it has been consolidating data and information bearing on its work. To develop further some of the ideas which have been advanced it applied for permission to hold a technical session during the 1934 Annual Meeting. This was granted and on Tuesday, December 4, a session was presided over by Willis H. Carrier and papers were presented by L. S. Marks, N. P. Bailey, W. E. Somers, N. C. Ebaugh and R. Whitfield, and M. C. Stuart. So great was the interest in this session that another is being planned for the 1935 Annual Meeting.

Steam-Condensing Apparatus. Geo. A. Orrok, Chairman, of Committee No. 12 on Condensers, Water-Heating and Cooling Equipment, reported in December, 1934, the completion of the proposed revision of the Test Code for Steam-Condensing Apparatus. The present revision of the code includes a tentative method for determining the cleanliness factor of condenser tubes. Copies of a tentative draft have been distributed to an extensive selected list of firms and individuals for criticism and comment. As a result of this mailing a number of constructive criticisms of this proposed revision of the code have been received. The duplication of this material was generously arranged for by the Brooklyn Edison Company through P. H. Hardie, secretary and member of Committee No. 12.

Hydraulic Prime Movers. E. C. Hutchinson, Chairman of Committee No. 18 on Hydraulic Prime Movers, reports that the committee has completed the drafting of the proposed revision of the Test Code for Hydraulic Prime Movers. The committee held meetings during the annual meetings of the A.S.M.E. and A.S.C.E. which made it possible to reach agreement on all of the controversial points which had been raised in the development of the earlier drafts. Its plans call for the distribution of copies of the code to a selected list of firms and individuals for criticism and comment before it is presented for final approval.

Instruments and Apparatus. C. F. Hirshfeld, Chairman, Committee No. 19 on Instruments and Apparatus, reports that the work completed by the committee during the year just closed includes the following sections which were approved for publication, namely: Part 1 on General Considerations (second edition); chapter 2 on Radiation Pyrometers of Part 3 on Temperature Measurement, and Part 15 on Measurement of Surface Areas.

In addition to the above, Committee No. 19 has made good progress toward the completion of Part 2, Pressure Measurement, chapter 4 on Bourdon, Bellows, Diaphragm and Deadweight Gages and chapter 5 on Manometer or Liquid Column Gages; Part 3, Temperature Measurement, chapter 3 on Thermocouple Thermometers; and chapter 4 on Resistance Thermometers.

Special Subcommittee on Measurement of Fluid Flow. Inasmuch as there had been some misunderstanding concerning the scope of the work of this special Instruments and Apparatus subcommittee, it was deemed advisable to change its name from Instruments and Apparatus Subcommittee on Flow Nozzles to Instruments and Apparatus Special Subcommittee on Measurement of Fluid Flow.

Due to the urgent need for its reports, the subcommittee is preparing as quickly as possible recommended rules for the measurement of fluid flow which can be made mandatory in the codes prepared by the several individual committees. Preliminary drafts of sections

covering nozzles, orifices, and venturi tubes are being written by the members of the subcommittee. The preliminary draft of the orifice section has been completed and it is expected that similar drafts of the sections on flow nozzles and venturi tubes will be completed within the next few months.

Industry is now being canvassed for funds for the research on flow nozzles which is to be made at the National Bureau of Standards under the auspices of the A.S.M.E. Special Research Committee on Fluid Meters.

As a representative of the American Standards Association, W. A. Carter, Chairman of this special subcommittee, attended the meeting of the International Standards Association Committee No. 30 on the Measurement of Fluid Flow held in Stockholm, Sweden, in September, 1934. He presented the American comments on the I.S.A. Proposal for Measurement of Fluid Flow and urged the inclusion of certain other rules covering the use of nozzles.

A meeting of this special subcommittee was held in New York during the A.S.M.E. Annual Meeting in December, 1934.

Dust-Separating Apparatus. The organization meeting of Committee No. 21 on Dust-Separating Apparatus was held on Wednesday, December 5, 1934. At this meeting the members of Committee No. 21 expressed an appreciation of the magnitude of the project and a feeling that several years would elapse before a final report would be forthcoming. M. D. Engle was elected chairman of the committee. The following subcommittees have been appointed to carry forward the program in the development of the Test Code for Dust-Separating Apparatus: (1) on plan and scope; (2) on definitions and terms, bibliography; (3) on collection of data on test methods employed in past and results obtained, equipment available; (4) on the obtaining of representative samples from gas streams carrying dust in suspension; and (5) on separation of the solid matter from the gas of the sample obtained.

International Cooperation

Through membership on the U. S. National Committee of the International Electrotechnical Commission,[1] the Society, and for it the main Committee on Power Test Codes has been actively engaged in assisting to bring about international agreements on acceptance tests for steam turbines and internal-combustion engines. The Secretariat for the Advisory Committees on Steam Turbines, Internal-Combustion Engines and Hydraulic Turbines is held by the U. S. National Committee of the I.E.C. The Society was represented on this committee this year by Harvey N. Davis, Francis Hodgkinson, and Ely C. Hutchinson, with C. Harold Berry and Paul Diserens serving as alternates.

PROFESSIONAL CONDUCT

During this past year this Committee has had but one case referred to it. Investigation developed that no charge of unprofessional conduct on the part of a member of the Society was made. Accordingly no action could be taken by this Committee. This case was referred to the Secretary of the Society.

Respectfully submitted,

SAFETY

The Standing Committee on Safety has continued during the past year to promote industrial safety through the activities of the Society and, in reporting the progress made during that period, desires to record first the technical session in the form of a symposium on the engineering aspects of occupational-disease disability, which it sponsored during the 1934 Annual Meeting of the Society. Five papers dealing with different phases of the subject of industrial-disease hazards were read by authorities in each field and were freely discussed. This session drew such a large and interested audience that the committee was encouraged to plan for a similar session at the 1935 Annual Meeting. Good progress has already been made toward the selection of speakers and the subjects of the papers which are to be presented. At the Committee meeting on June 14 it tentatively agreed to the following three divisions of the subject as an outline for the meeting: (*a*) occupational-disease legislation, (*b*) engineering control of occupational-disease hazards, and (*c*) limitations of protective devices and equipment available.

The committee has agreed to act as co-sponsor with the Management Division of the Society for a session on compensation laws which is also to be held during the 1935 Annual Meeting. There are many aspects of this subject in which the committee is directly interested since it holds that there is a close relation between the compensation laws of a state and its laws bearing on disease disability.

Safety Code for Machinery for Compressing Air, D. L. Royer, Chairman. During the past year the Sectional Committee on a Safety Code for Machinery for Compressing Air released for criticism and comment two successive drafts of its proposed code which indicates that good progress is being made in its work.

Safety Code for Cranes, Derricks, and Hoists, J. C. Wheat, Chairman. No meetings of the Sectional Committee or any of its subcommittees have been held during the past year but from correspondence which this committee has had with Mr. Wheat it has assurances that by the first of the next fiscal year more active work will be resumed toward the completion of this important code which is now in the hands of the editing subcommittee.

Safety Code for Elevators, Sullivan W. Jones, Chairman. The Sectional Committee on a Safety Code for Elevators held a meeting on April 26, 1935. This meeting was called to consider certain changes in the American Standard "Safety Code for Elevators" published in 1931 which had been proposed by the Subcommittee on Elevator Research, Interpretations and Recommendations. The subcommittee had held meetings on October 30, 1934, and April 24, 1935.

The proposed American Recommended Practice in the form of an Inspector's Handbook was approved by letter-ballot vote of the Sectional Committee. The committee plans to delay its submittal to the sponsor societies, however, until the new references to the revised Safety Code for Elevators are known.

Junior Advisory Member. Upon the recommendation of the Committee Carl Endlein, mechanical engineer connected with the C. J. Tagliabue Manufacturing Company, Brooklyn, N. Y., was appointed by President Flanders as the Junior Adviser to the Safety Committee.

It is with deep regret that the committee reports the death of one of its members, M. H. Christopherson, on September 9, 1935.

Respectfully submitted,

W. M. Graff, *Chairman*
H. H. Judson
H. L. Miner
J. B. Chalmers

Special Committees

ADVISORY BOARD ON TECHNOLOGY

On December 7, 1934, the Council of The American Society of Mechanical Engineers took the following action:

Voted: That the Advisory Board on Technology be established for two years, under the direction of the Council, with functions as stated below:

(1) Assume the responsibility of coordinating the activities of the general meetings and congresses, divisions, research, and publications of the Society.

(2) Assume the responsibility of leadership and initiative with respect to coordination.

(3) Interpret the provisions of the Society's By-Laws concerning the jurisdictions and policies of the several committees represented on the Board.

(4) Review and recommend policies proposed by the several committees for the control of their activities.

(5) Hold at least two meetings each year.

(Note: This Board is to consist of five, a Chairman from the Council, named by the President, and one member of each of the following Standing Committees: Meetings and Program, Professional Divisions, Research, and Publications.)

[1] For Report of A.S.M.E. representatives see page 26.

In the discussion, it was emphasized that the responsibilities of coordination, leadership, and initiative gave the Board a tremendous opportunity to advance the Society's purposes which are embodied in the new By-Laws adopted by Council on December 3, 1934, as follows:

(*a*) Encouraging engineering research, tests and other original work.

(*b*) Encouraging the preparation of original papers on engineering topics.

(*c*) Holding meetings for the presentation and discussion of original papers and participating in international engineering congresses.

(*d*) Publishing papers and reports and disseminating knowledge and experience of value to engineers.

Personnel

The members of the Board appointed by President Flanders (for a term of two years) and the committees they represent are: Robert I. Rees, Meetings and Program; K. H. Condit, Professional Divisions; S. W. Dudley, Publications; D. B. Bullard, Research; and A. A. Potter, Council, chairman.

Meetings and Actions

Two meetings of the Board have been held, January 25 and April 18, 1935. Discussions at both meetings centered around problems relating to the coordination of the activities of the committees represented on the Board and to publications. At the second meeting the principle of planning the work of the Society in the technical and educational development of the profession and of members was also discussed.

The view was expressed that every encouragement be given to local sections to send in for consideration by the Committee on Publications the manuscripts of papers presented at their meetings. The committee and the editor were represented as being willing to consider, as in the past, original papers of permanent value for publication in the Transactions, and papers of current interest for publication in *Mechanical Engineering*, which is a record of advancement.

The problems of the Committee on Publications in adequately serving the committees and agencies that provide papers and reports were discussed. Every effort is to be expended in raising the quality of papers and assuring that the papers of permanent value are received sufficiently in advance of meetings to insure adequate review and preprinting so that full discussion will result when the papers are discussed. The principle of budgeting space in the publications to these committees and agencies, as a first step in coordination and planning, was approved.

Relations with the technical press were clarified.

The relation of the professional divisions to the programs of local sections was discussed.

The importance of research as related to other activities of the Society was emphasized, including the opportunity for the research committees and professional divisions to cooperate in preparing bibliographies.

Emphasis upon educational quality should be the major guide and it was considered important to keep the individual member engineering-minded.

A coordinated budget for the committees represented on the Board of Technology was approved.

Respectfully submitted,

A. A. Potter, *Chairman*
D. B. Bullard — S. W. Dudley
K. H. Condit — R. I. Rees

ADVISORY BOARD ON STANDARDS AND CODES

One of the recommendations of the Special Committee on Policies and Budget of which Harry R. Westcott is chairman, was the establishment of an Advisory Board on Standards and Codes. It is expected that this Board will further coordinate the activities of the four committees in charge of the standardization and code-making activities of the Society. Several conferences of representatives of these activities with members of the Committee on Policies and Budget were held last fall and the statement of purpose of this board was finally developed at a meeting of these representatives on December 6, 1934. It was approved by the Council on December 7.

The Advisory Board on Standards and Codes is established for two years, under the direction of the Council, with the following organization and functions. This Board is to consist of five members, a chairman appointed by the President from the membership of the Council and one member named by each of the following four committees, Boiler Code, Standardization, Power Test Codes, and Safety. This Board shall be advisory to the Council and shall assist in (1) establishing general policies pertaining to standards and codes, (2) initiating and developing standards and codes, and (3) coordinating the activities of the several committees which are represented in its membership. It plans also to cooperate with the Board of Technology.

The first meeting of the Board was held on May 9, 1935, at which the time was spent principally in discussing general policies and the methods of work of the constituent groups. It considered also the request of the Committee on Policies and Budget to the effect that the Advisory Board on Standards and Codes cooperate with it in determining the broad purposes and long-range policies which should control the Society's standards and codes activities.

Respectfully submitted,

A. D. Bailey, *Chairman*
L. A. Cornelius (Standardization) — W. M. Graff (Safety)
V. M. Frost (Boiler Code) — Francis Hodgkinson (Power Test Codes)

BOARD OF REVIEW

The Board of Review held nine meetings during 1935 to consider the requests of members for dues cancelation and inactive status, provided in the policy which was adopted by the Council on December 2, 1934.

The number of requests received for consideration total 378, and in response, recommendations were made to the Executive Committee of Council, as follows:

Approved (in part or in full)	345
Denied	30
Tabled	3
	378

Dues canceled in connection with the 345 requests approved and the fiscal years to which such dues applied are given below. The cancelation of this amount in reality does not represent a real financial loss in Society revenues since the Board in each instance received satisfactory evidence of the impossibility of collecting such arrears. Furthermore, in some cases, the cancelation of part-dues arrears was made contingent on and resulted in the immediate payment of the dues-arrears balance or dues for the current year.

Fiscal year dues ending	Amount canceled
1930	$5.00
1931	60.00
1932	350.00
1933	1,597.07
1934	4,782.58
1935	4,418.33
	$11,212.98

In considering each request to cancel dues, the Board carefully weighed the all-important matter of loss of income to the Society. In several instances the unsolicited pledge of the member was voluntarily given that, if temporarily relieved of previous dues incurred and for which no publications or other services were rendered by the Society, he would immediately assume current dues obligations or those payable after October 1, 1935. In recommending favorable action in such cases, the continued interest of the member in the Society's welfare was retained with a reasonable certainty that active status with regular dues payments would follow in the near future. Further, the grateful acknowledgments received after notification was sent of favorable action leads the Board to believe that the Society will continue to hold indefinitely the good will of those members who have suffered serious misfortunes during the past few years. Where circumstances deemed it advisable, the Board canceled only that part of the dues arrears that would permit retaining the delinquent member on the Society roster. In such cases the member was asked to endeavor to pay the balance of arrears and current dues.

With each request for dues cancelation a detailed confidential statement was submitted by the member and individual attention given by the Board to the facts presented in such application. Where complete information was omitted, a communication was dispatched to the member and a further opportunity given to submit additional details. The recommendations of Local Sections received in certain instances were most helpful in assisting the Board.

In acting for the Council, the Board was most sympathetic in its treatment of cases where there had been a long period of faithful membership. On the other hand, the employment difficulties of the

recently graduated Junior members received equally sympathetic consideration.

In the majority of cases where dues cancelation were recommended to Council, two or more of the following conditions existed:

(*a*) Continued period of unemployment
(*b*) At present temporarily employed in relief projects
(*c*) At present unemployed
(*d*) Drastic salary readjustment
(*e*) Loss of income, due to bank failures, bankruptcies, etc.
(*f*) Loss in income due to ill health or old age.

The Board is firmly convinced of the necessity of handling promptly the membership status of dues-delinquent members and of the return to the enforcement of the Society's By-Laws canceling membership after a lapse of 15 months in membership dues. Continuation of such a policy in the future insures elimination of the suspension and dropping of several thousand delinquent members at one time as resulted in September, 1934, following a most liberal dues policy.

In conclusion, the Board offers the following recommendations for further consideration by Council:

1 That the Council continue to enforce the provisions of Par. 4, Article B5, Fees and Dues, with a liberal policy toward those members anxious to retain their membership but unable to pay annual dues for the reasons enumerated above.

2 That the provision for inactive status without membership privileges be extended one year from October 1, 1935.

3 That no member of the Board of Review serve longer than a three-year term.

Respectfully submitted,

HENRY B. OATLEY, *Chairman*
A. D. BLAKE
JOHN P. NEFF

BOILER CODE

The Boiler Code Committee submits the following report for the fiscal year ending September 30, 1935, covering activities other than its regular routine work.

During this period the Committee held nine regular meetings and several executive committee meetings which were devoted to interpretations of the various sections of the Code and to the formulation of revisions and addenda thereto.

To keep abreast of the progress being made in the development of pressure vessels and of the materials of which they are constructed, the Committee has made necessary revisions and additions to the various sections of its Code. These changes are to a great extent the result of suggestions from manufacturers, inspectors, users, and others. These revisions were formally adopted by the Council on July 23, 1935, and distributed in pink-colored addenda sheets.

The Committee has under consideration the adoption of more comprehensive rules for the use of cast iron in the construction of cast-iron unfired pressure vessels under limited conditions. It has been brought out that there appears to be a continued demand for permission to use cast iron in Code vessels. It also appears that there are a great many unfired pressure vessels in use with some portion made of iron castings and, therefore, it appears desirable that some recognition be given in the Code to the use of cast iron which will enable manufacturers to take advantage of the extensive use of this material.

Various non-ferrous alloys as well as ferrous alloys are being developed which appear to have considerable merit for use in the construction of special pressure vessels for varying types of service. As a result, a special committee is investigating these materials with the expectation of introducing suitable provisions for Code specifications and working stresses for such materials.

Consideration was given to a request for provisions in the Code for acceptance of malleable iron for pressure parts of pipes, fittings, valves, and their bonnets. A similar provision has appeared in the Code for some time for the use of cast iron and the feeling was expressed that malleable iron should also be provided for. As a result a rule has been incorporated in the Code to allow for the use of high-grade malleable iron, which complies with the material specifications in the Code for malleable iron, for boiler and superheater connections under pressure.

Three A.S.T.M. specifications for condenser tubes and ferrule stock for unfired pressure vessels have been added by the Committee for incorporation in the Material Specifications Section of the Code. These specifications are as follows: Specifications S-29 for Seamless 70-30 Brass Condenser Tubes and Ferrule Stock (A.S.T.M. Designation B55-33); Specifications S-30 for Seamless Muntz Metal Condenser Tubes and Ferrule Stock (A.S.T.M. Designation B56-33); Specifications S-31 for Seamless Admiralty Condenser Tubes and Ferrule Stock (A.S.T.M. Designation B44-33).

Since the adoption in 1934 of a new set of rules for flat heads, the desirability of providing for additional types of flat heads was reported on by the Subcommittee on Special Design. As a result, additional rules have been added to cover the designs of crimped flat heads, of screwed-in flat heads, and of flat heads with mechanical locks.

Further study has been given to the Rules for Bolted Flanged Connections which required qualification of some of its requirements. As a result, revisions have been made of some of its requirements to eliminate the inconsistencies.

Consideration has been given to a proposal for coordination of the A.S.M.E. and the A.P.I.-A.S.M.E. Codes for Unfired Pressure Vessels. As a result, a special committee has been appointed to revise Section VIII of the A.S.M.E. Boiler Code which will embody the best features of the A.S.M.E. and the A.P.I.-A.S.M.E. Codes for Unfired Pressure Vessels.

As a result of data submitted to substantiate the reliability and safety of the flame-cutting method of preparing the edges of plate for pressure vessels to be welded under the requirements of the Code, the Code has been revised to permit the use of this method.

New rules have been adopted and incorporated in the Unfired Pressure Vessel Code to cover the use of electric-resistance butt welding for unfired pressure vessels. The requirements are similar to those in the Power Boiler Code.

After considerable experimentation and work, the Special Committee on X-Ray Requirements has selected a master set of radiographs, reproductions of which are now available.

The Committee has cooperated with the U. S. Naval Experiment Station in submitting comments on its specifications for boiler-water gages, including glasses, frames, fittings, illuminators, etc.

New rules for the construction of marine boilers and pressure vessels adopted by the U. S. Bureau of Navigation and Steamboat Inspection and based upon a report of the Special Committee to Coordinate the Marine Boiler Rules were finally adopted and issued. The part taken by the A.S.M.E. in preparing these rules was outlined in a statement published in the September, 1935, issue of *Mechanical Engineering*.

The Committee appointed V. M. Frost as its representative on the Advisory Board on Standards and Codes which was formed by the Council to establish general policies pertaining to standards and codes.

C. A. Adams, A. J. Ely, and Walter Samans were appointed members of the Main Committee of the Boiler Code Committee. John A. Darts was appointed a member of the Subcommittee on Heating Boilers. C. E. Bronson was appointed to replace M. F. Moore as a member of the Subcommittee on Heating Boilers. E. O. Waters was appointed a member of the Subcommittee on Special Design. Commander W. P. Portz replaced Commander R. F. Frellsen as the representative of the Bureau of Engineering of the U. S. Navy Department.

The Committee reports with regret the death of C. D. Thomas, chief boiler inspector of the State of Oregon and a member of the Conference Committee to the Boiler Code Committee.

The States of Maine and North Carolina have adopted the A.S.M.E. Boiler Code as their standard for the construction of power boilers, which makes a total of 21 states in which the Code is operative.

Respectfully submitted,

The Boiler Code Committee

BOND ISSUE

During the current fiscal year, the Bond Issue Committee has received subscriptions for $8200 for the purchase of Certificates of

Indebtedness, bringing the total up to $44,650, of which $600 in certificates are held in the treasury of the Society, being gifts of the purchasers.

Collateral of the face value of $68,750 is being held by the Trustees of the Certificates of Indebtedness. The interest due on the outstanding certificates of indebtedness was paid in full on January 1 and July 1, 1935, and for the coming fiscal year there is provision in the budget for the payment of interest when due and for the retirement of 10 per cent of the face value of the certificates outstanding.

It is expected that further activity of this Committee will not be required and it therefore requests its discharge.

Respectfully submitted,

DEXTER S. KIMBALL, *Chairman*
PAUL DOTY
W. A. HANLEY
C. F. HIRSHFELD
JOHN H. LAWRENCE
W. R. WEBSTER
W. H. WINTERROWD
ERIK OBERG, *Ex-Officio*

CAPITAL-GOODS INDUSTRIES

The situation in the captial-goods industries in the United States has been so confused and uncertain during the current year, largely because of the impact of economic forces without the industries, that the committee has found little that it could do effectively.

One research project was carried to completion, however. The January, 1935, issue of *Mechanical Engineering* published a paper on "Code Restrictions on Machinery and Production," by W. E. Hopkins and J. F. Nelson. It is a privilege to express appreciation of the diligent work of these two Junior Members of The American Society of Mechanical Engineers, and through them to acknowledge the cooperation of the Junior group in Society affairs.

Respectfully submitted,

L. P. ALFORD, *Chairman*
R. E. FLANDERS
L. W. W. MORROW
ERIK OBERG

CITIZENSHIP MANUAL

The committee during the course of the year has printed and distributed approximately sixty-five hundred copies of a pamphlet entitled "The Engineer's Duty as a Citizen," by Roy V. Wright. This pamphlet was the revision of one used in a discussion course given by Dr. Wright at the Newark College of Engineering. A copy of the pamphlet was mailed to every Student and Junior Member of the Society, and in the letter of transmittal the committee directed attention to the fact that:

"It is the object of this pamphlet to stimulate, help, and direct young men toward a larger participation in community activities, both political and otherwise; and if there is any matter which you think should be added or modified or deleted, the committee would value your suggestions very highly. Particularly in the matter of suggested questions, we are anxious to secure the reaction of the younger members of the Society.

"We are asking for this contribution on your part because we know that the success of this movement depends upon the younger men, and it is absolutely necessary that we have your suggestions and criticisms if this material is to be really helpful."

The committee received a very considerable number of criticisms and suggestions widely scattered over the United States. Most of the criticisms were from student members and came from suggestions arising from discussion in the student branches of the Society. The criticisms in the main were constructive and pointed out the need of some group discussion in connection with the distribution of the pamphlet.

The great need for something of this kind and the particular necessity for focusing the attention of the younger man on this phase of the fuller life of an engineer was generally accepted, and it was felt that the pamphlet, supplemented by some discussion conducted by a local engineer of prominence, would be particularly fruitful.

Dr. Wright has during the past few months made a further revision, and this is now ready for mailing. The committee contemplates the distribution of this pamphlet to the student branch advisers in the various colleges in the United States with the particular hope that it will furnish the basis for discussion on the part of the student members of the Society.

Respectfully submitted,

ALLAN R. CULLIMORE, *Chairman*
ROY V. WRIGHT
W. H. WINTERROWD
LILLIAN M. GILBRETH
JOS. W. ROE

COOPERATIVE RELATIONS

This Committee was asked to study the problem of the relations of the Society to the various bodies in engineering and the relations between the functions of the joint bodies. Its report was presented to the Council in June, 1935, and the recommendations are under consideration by the Council.

Respectfully submitted,

HAROLD V. COES, *Chairman*
ROBERT I. REES
D. ROBERT YARNALL

THE ECONOMIC STATUS OF THE ENGINEER

The general economic status of the engineering profession has improved somewhat during the past year. The improvement in the manufacturing industries has been reflected in the slight improvement in engineering employment. Durable-goods industries are still operating at only partial capacity, and although statistics available show that losses were incurred in these industries during the past year the earnings of the group as a whole have increased.

In cooperation with the American Engineering Council the United States Department of Labor conducted a questionnaire study of the earnings of engineers. About seventy thousand responses were received by the Department. These are being tabulated and it is expected that a report will be available shortly after the first of October. This Committee is holding itself in readiness to interpret the findings of the study in so far as they affect mechanical engineers and present them for publication and discussion if such discussion will prove helpful.

Respectfully submitted,

C. F. HIRSHFELD, *Chairman*
D. S. KIMBALL
N. B. OATLEY
H. L. WHITTEMORE
W. E. WICKENDEN
C. N. LAUER
W. L. DUDLEY, *Ex-Officio*
W. L. ABBOTT, *Ex-Officio*

ENGINEERING HISTORY

At the 1934 Annual Meeting of The American Society of Mechanical Engineers a session on Engineering History was held, at which a resolution was adopted asking the A.S.M.E. to take the lead in organizing a joint movement for the study of Engineering History.

A committee has been organized with representatives on it from the A.S.C.E., A.I.M.E., and the A.I.Ch.E.

Progress is being made.

Respectfully submitted,

GEO. A. ORROK
JOS. W. ROE

JUNIOR PARTICIPATION

The Committee on Junior Participation approved the following methods for stimulating interest among the 3500 junior members of the Society in mechanical engineering as a profession and in the work of the Society:

1 All Local Sections should arrange dinner meetings at which at least two members should be assigned to each Junior Member with the idea of bringing the Juniors in contact with the older members of the profession in their own localities, and with the hope that personal friendships would thereby be stimulated.

2 Meetings should be arranged at which the program would be entirely in the hands of the Juniors, or, if this is not possible, that Juniors should be urged to present papers at Section Meetings.

3 Juniors should be encouraged to take part in the discussion of papers at Section Meetings, by appointment, and by sending them advance copies of the papers if possible.

4 Juniors should be urged to prepare articles for publication in *Mechanical Engineering*, and the Publications Committee should be asked to give special consideration to these papers.

5 Members of the Society should be designated as special advisers to Junior Members in their Sections.

6 The Committee should offer its assistance to General Rees of the E.C.P.D. in carrying out his program for recent graduate engineers with reference particularly to developing the characteristics which the proposed examination for certification demand.

7 In every Local Section one or more of the older and more promi-

nent members should be requested to bring about the proper mental attitude of the members in their locality with reference to the younger entrants to our profession. Invitations to Juniors to the homes of the older members should be the more general custom.

8 The Secretary of the A.S.M.E. should send every year a list of Junior Members in each Local Section to the chairman or secretary of that Section. Upon the receipt of this list the chairman should send a communication to each Junior Member inviting him to visit him personally and to attend the meetings of the Section. In the case of large Sections the chairman may wish to divide the Junior list among a number of prominent members who will be willing to correspond and to show special courtesies to a small group of Juniors.

This program is being carried out in cooperation with the Committee on Local Sections.

Respectfully submitted,

D. B. Prentice, *Chairman*
W. A. Hanley
A. A. Potter
W. H. Winterrowd

MANUAL OF PRACTICE

The procedure adopted by the Committee looking to the ultimate preparation of a manual for the Society has been that of citing specific instances or classes of problems with which the manual should be concerned. At the Council Meeting of December, 1934, there was presented a statement concerning the engineering duties and practices to be expected of the engineer and the manufacturer, respectively. This statement was approved by Council and published in *Mechanical Engineering* for February, 1935. Subsequent to the appearance of this statement the Committee has had numerous interviews with consulting engineers and manufacturers in various commercial fields. There has been a unanimity of approval in all cases for the principles contained in the statement.

Since the promulgation of the Committee's first statement several other specific matters have been brought to our attention but it is unfortunate that because of their limited scope no action is considered advisable at this time.

On the other hand the Committee feels that the general membership of the Society should be kept constantly aware of our problems, particularly through the issues of *Mechanical Engineering*, and the Committee again urges that a definite program be initiated to ask the Society membership for cases, items, and matters which might be the subject of Committee discussion and action.

The Committee regrets the retirement of W. A. Shoudy as his leadership was of inestimable worth.

Respectfully submitted,

B. F. Wood, *Chairman*
Alfred Iddles
Wynn Meredith
J. M. Todd
C. G. Spencer, *Ex-Officio*
Theodore Baumeister, Jr., *Acting Secretary*
Philip Werner, *Junior Adviser*

POLICIES AND BUDGET

The first phase of this Committee's work, completed in 1933, was a study of Society operation and finances used as a basis for a reduced budget for 1933–1934. The second phase of its work, which is still under way, was initiated with a new statement of Society purposes, approved for inclusion in the By-Laws by Council in December, 1934, the suggestion of changes in membership grades which are to be voted by the membership at the end of the fiscal year, and certain modifications in Society organization to simplify it and make it more responsive to the needs of the membership.

PUBLIC AFFAIRS

The Committee on Public Affairs was authorized by Council in July, 1934, to recommend to the Society policies in regard to participation in national, state, and local affairs in accord with a modification of the By-Laws made in December, 1934, which included the following statement:

"Increasing the usefulness of the organized engineering profession by ..... (*C*) encouraging engineers to participate in public affairs."

To insure complete cooperation with American Engineering Council, this Committee was constituted of present and past representatives of this Society on the Council.

This Committee has held one meeting at which a number of procedures for carrying out the purposes of the Committee were canvassed. Further activity depends in some measure on the program of American Engineering Council.

Respectfully submitted,

D. Robert Yarnall

CALVIN W. RICE MEMORIAL

The Committee on Calvin W. Rice Memorial was appointed in October, 1934, to consider suggestions for a suitable memorial to Dr. Calvin W. Rice.

As guides for the purposes of suitable memorials, the Committee has selected Dr. Rice's keen interests in international friendliness, in young men, and in the portion of the membership not able to attend the great annual gatherings of the Society in New York.

The Calvin W. Rice Memorial Lecture has been established. This lecture is to be given at the Semi-Annual Meeting of the Society by a distinguished foreign engineer or other person with international interest. In the record book of the lectureship are the names of Dr. John H. Finley of New York, who delivered the tribute to Doctor Rice at the 1934 Annual Meeting, and of Dr. Adolph Meyer of Switzerland, lecturer at Cincinnati in June, 1935.

Further plans are under consideration.

GEORGE WESTINGHOUSE BUST

This committee is charged with the responsibility of advising the Council as to the custody of a Bust of George Westinghouse, Honorary Member and Past-President of the A.S.M.E.

At a meeting of the Committee, December 5, 1934, Ambrose Swasey was elected honorary chairman of the committee, Dean Dexter S. Kimball chairman, L. B. Stillwell, vice-chairman, and C. E. Davies, secretary. On nomination of the Committee Messrs. L. A. Osborne and Karl T. Compton were added to its personnel.

Respectfully submitted,

Joint Activities

Reports for the year 1933–1934 were also presented to the Council by representatives of the Society on a number of joint activities. Reference to some of these will be found in the Report of the Council and others are presented or summarized in the following pages.

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE

Section M

During the period between October 1, 1934, and September 30, 1935, one meeting of Section M, Engineering, of the American Association for the Advancement of Science was held in connection with the winter meeting of the Association, in Pittsburgh, December 27,

1934, to January 2, 1935. The principal feature of the meeting was the address of the retiring vice-president, Dr. C. F. Kettering on "Some Future Problems of Science and Engineering." The program included also problems of stress distribution and plastic deformation in metals and joint sessions on Cost and Cost Theory and History of Interesting Technological Developments, with the Section on Social and Economic Sciences and the Section on Historical and Philological Sciences, respectively.

No session of Section M was held during the summer meeting of the A.A.A.S. in Minneapolis in June, 1935.

The coming winter meeting of Section M will be held at St. Louis and active steps are under way to develop a strong engineering program.

Respectfully submitted,

SUMNER B. ELY, JOHN R. DUPRIEST } *A.S.M.E. Representatives*

AMERICAN BUREAU OF WELDING

The relations between the A.S.M.E. Boiler Code Committee and the American Bureau of Welding continue to be on the most cordial basis and all items of welding which are referred jointly to the American Welding Society Committee and our Subcommittee on Welding are given most careful attention.

Cooperation of the American Welding Society is perfect, and our relations most satisfactory.

Respectfully submitted,

JAMES PARTINGTON, *A.S.M.E. Representative*

AMERICAN ENGINEERING COUNCIL

The membership of The American Society of Mechanical Engineers participates in national public affairs of engineering significance through the American Engineering Council, with offices in Washington, D. C. In keeping with its long-established policy of seeking to serve the common interests of all engineers as well as those of its own members, the A.S.M.E. has actively supported the work of the A.E.C. from the beginning.

The membership of American Society of Mechanical Engineers is officially represented in these common activities of the American Engineering Council through five delegates. Both nationally and locally, many other members participate in the work. Their delegates, on the occasion of the annual meeting of the Council, held in January, in Washington, and through the year, through their service on committees of the Council and through coordination between the staff of the A.S.M.E. and the staff of the Council forward many matters of common interest to all engineers and especially to the members of our society.

With the great increase in the legislative and administrative activities of the Federal Government as they have affected industry and engineering during the past three years, there has been ample opportunity for mechanical engineers to relate themselves to this work. Contacts in Washington, long established, understanding of the procedures of the Federal Government, and the development of staff and committees to relate the American Engineering Council to these rapidly growing government activities have enabled the profession to participate intimately through what has come to be called the Washington Embassy of American engineers and engineering.

This rapid development of Government agencies relating in one way or another to the development of our natural resources, our public utilities, our capital goods, including machinery and construction, and our transportation and communication industries, has made the task of the American Engineering Council very much greater than ever before.

The following of legislation, the interpretation of Executive Orders, and the aiding in the staffing of government bureaus and consultations on policies and methods of fulfilling much of the new legislation has related American Engineering Council in new ways to our national program. It is literally true that more legislation has been passed directly affecting the welfare of engineers during the last two years than through the ten years preceding. To the original purpose of the founders of the American Engineering Council to provide an organization to aid in molding legislation on engineering matters of public interest has been added the past year or two the practical task of molding methods in the application of legislation.

The first organized approach to the study of the present widely expanded government program with regard to furnishing a means of interpreting to the profession as a whole the details of the many legislative programs took place at the annual meeting of the Council in January, 1935. In line with the need, instead of devoting the entire time to business sessions, a symposium of Federal activities was held and a first hand account was given by members of the Federal Government announcing their plans and deeper purposes as related to:

(1) Planning and the development of natural resources
(2) Construction
(3) Durable-goods industries.

Among the prominent Federal officials who addressed the several sessions were: Hon. Marriner S. Eccles, Governor, Federal Reserve Board; Hon. M. L. Wilson, Assistant Secretary of Agriculture; Dr. Harlow S. Person, of the National Resources Board; Capt. R. S. Patton, director, U. S. Coast and Geodetic Survey; Dr. Isador Lubin, commissioner of labor statistics; Col. D. H. Sawyer, director, Federal employment stabilization office; Clarence McDonough, chief of the engineering division, Public Works Administration; Charles C. Anthony, industrial adviser, and Thomas Hibben, chief engineer, Federal Housing Administration; Wm. P. Witherow, vice-chairman, industrial advisory board, National Recovery Administration; and R. E. W. Harrison, chief, machinery division, U. S. Bureau of Foreign and Domestic Commerce.

Dr. Harold G. Moulton, president, The Brookings Institution, addressed the largest group ever assembled to attend the Annual Dinner. He discussed the economic trends leading to the depression.

The opportunity to hear these Government officials was afforded not only to members of the assembly and to engineers resident in Washington and environs, but also to secretaries of engineering societies who had assembled from all parts of the United States to discuss their own problems at a conference held under the auspices of American Engineering Council and in conjunction with its annual meeting.

In line with this aggressive policy of coordination, the annual assembly voted to provide a method for further correlation of activities of engineers in public affairs through a plan for local membership whereby local organizations as well as national organizations could participate in the work of Council without duplicating financial structures. To this end a committee, consisting of Messrs. Bickelhaupt, Alford, Trullinger, and Wendt, with Dr. McClellan as adviser, proposed a plan of membership to open the way to affiliation with the Council to a large number of state and local engineering organizations. This new plan permitted such an organization to become a member for the nominal fee of $25 per thousand members per year, the expenses of the delegate at the annual meeting to be paid by the member-organization.

Under this plan the following engineering organizations have joined Council since the first of the year:

Arkansas Engineers Club
Cleveland Engineering Society
Engineers Club of Baltimore
Engineers Club of Columbus
Engineers Club of Philadelphia
Engineers Club of St. Louis
Engineering Societies of New England
Engineering Society of Western Pennsylvania
Florida Engineering Society
Louisiana Engineering Society
Michigan Engineering Society
Providence Engineering Society
South Carolina Society of Engineers

A third policy established during the year was to strengthen and further cooperation between member-organizations and the Council through the dissemination of information as widely as possible. With the cooperation of the editors of the journals of the Founder Societies and of the editors of the other technical journals, regular monthly reports of Council's activities are published for the information of the members.

Beginning July 1, 1935, the information service has been further strengthened by the establishment of a plan of placing on file in the offices of member-organizations the basic laws of the administrative and executive orders dealing with engineering matters. This additional "Washington Embassy Service" has been developed from the viewpoint of increasing not only the general knowledge of members of the societies but of making available locally information concerning government expenditures which would constitute the basis for employment of many individuals.

A mimeographed monthly news letter is mailed to delegates, committee members, and officers of local sections, for their personal information.

The fourth policy in course of development is the establishment in each state of public-affairs committees. In accordance with a plan approved at the annual meeting in January, these committees are

to be coordinated with the national Committee on Public Affairs. This plan of coordination of state committees on public affairs rests for its success upon the cooperation of local sections and of local engineering societies and can only come about gradually through the active participation of local organizations in districts not now represented in national affairs. The general purpose of this program is to take advantage of present organizations to provide the machinery for securing the organized discussion of public problems by engineers instead of setting up any new organization or duplicating the activities of others.

In the fifth place, to provide coordination within the committee activities of American Engineering Council itself. The Executive Committee of Council approved the development of three broad classes of committees:

(1) Public-affairs committees
(2) Engineering and economic research and inquiry committees
(3) American Engineering Council operating committees.

In order to simplify procedure, in so far as possible, special committees have been made subcommittees of standing committees.

In the first group is included the Committee on Public affairs and related to it as subcommittees are the committees on administration of public works, aeronautics, competition of Government with engineers in private practice, engineers water power policy, flood control, patents, rural electrification, and water resources, also representation on the Advisory Council of the Federal Board of Surveys and Maps.

In the second group are included the committee on engineering and allied technical professions, the relation of consumption, production and distribution, and the naval towing tank; also representation on the board of directors of the National Bureau of Economic Research and the Board of National Councilors of Purdue Research Foundation.

In the third group, are included the committee on constitution and by-laws, to which the committee of tellers serves as a subcommittee, the finance committee, committee on membership and representation, publicity and publications, and regional activities.

The activities of four committees of the Council will have special interest for members of The American Society of Mechanical Engineers.

(1) The Committee on Aeronautics, under the chairmanship of Grover C. Loening, is proceeding actively in carrying out the program by Council. The major features of the program are:

(*a*) That a sum of $50,000 be appropriated each year as an addition to the budget of the National Advisory Committee for Aeronautics and subsequently earmarked for research work to be done by universities and other institutions of public learning.
(*b*) That none of such appropriation should be employed for educational purposes, construction of buildings or basic equipment.
(*c*) That a committee be appointed entitled "Committee on Cooperation between the N.A.C.A. and Universities Interested in Aeronautical Engineering;" further that this committee should contain representatives of the National Advisory Committee for Aeronautics, of the Army, of the Navy, of the Department of Commerce, of the industry selected by the Aeronautical Chamber of Commerce, and of the universities engaged in aeronautical work.
(*d*) That scientific workers at the universities or technical institutes desiring to conduct research would submit to the N.A.C.A. a formal plan for such research, stating the object of the investigation, and the personnel available for execution for a given piece of research. The allotment of funds would be entirely within the discretion of these committees.
(*e*) Publications of worth-while research would be in the form of N.A.C.A. technical reports or technical notes.

Dr. Alexander Klemin, secretary of the committee, has made several contacts in Washington in the interest of forwarding the program.

(2) Committee on Engineering and Allied Technical Professions.

The work of this committee is described in a later part of this statement.

(3) The Committee on Patents, under the chairmanship of Dean A. A. Potter, is studying ten bills relating to patents and to copyright laws which are pending before the Patents Committee of the House of Representatives. The legislation deals with such subjects as provision of counsel for the defense and prosecution of rights of indigent patentees, recording of patent-pooling agreements and contracts with the Commissioner of Patents, permitting single signature in patent applications and validating joint patent for sole invention; limiting the life of a patent to a term commencing with the date of application, compensation of owner for infringement of patents by U. S. Government, prevention of fraud, deception, and other improper practice in connection with business before the U. S. Patent Office, providing protection for registration of designs for textiles and other materials, making effective in the United States provisions of the International Convention for the Protection of Industrial Property relating to time limitations in which a foreigner may make application for a design patent, or a trade-mark application.

A.S.M.E. members of the committee are Dean A. A. Potter, chairman, W. C. Lindemann, Edwin J. Prindle, and E. N. Trump.

(4) The Committee on Water Resources, under the chairmanship of Wm. S. Conant, a former representative of the A.S.M.E. on the assembly of the Council, has submitted a report which the Council approved. The report points out that two fundamental needs for a National Water Resources Policy are: (1) complete and correlated data; (2) comprehensive study of water-control legislation. A federal Bureau of Water Resources is endorsed in principle and an interdepartmental Board of Water Resources Investigations is recommended to correlate investigational functions of federal units. Extension of the work of the Water Planning Committee is recommended through a National Advisory Water Planning Agency for comprehensive, integrated drainage-basin planning.

The annual report of the Council will include an analysis of the work of all the committees.

Procedure as to Legislation

With so much of engineering interest at stake in the session of Congress just passed, it seems timely to summarize the policies and methods followed by the Council in legislative matters. The staff has had for its guidance:

(1) Policies adopted by the Assembly and Administrative Board at Annual Meetings.
(2) Advice on new matters from special and standing committees.
(3) Precedent of several years on matters which do not require new rulings.
(4) The viewpoint of public interest as a fundamental reason for participating in legislative activities.
(5) The corollary viewpoint of advancing the economic status of the profession.

The factors of public interest and the status of the profession are closely related in problems constantly arising in connection with the Federal program, due to the extraordinary relation of government to business at present. *Competent engineers must be employed where engineers belong if the public interest is to be protected* against faulty planning and wasteful execution.

Although the "Washington Embassy" of engineers may not jump into drastically new lines of action in the name of the profession without due consultation and approval, it is not hemmed in by ponderous procedure. The precedent set on past work, recognized as in the interest of the profession, gives sufficient latitude for quick action on immediate, practical steps and leaves only the long-range phases for more deliberate action.

Legislation which Council follows for engineers includes the following general categories:

(1) *Construction:* Federal appropriations and administrative machinery for construction. (The work-relief bill.)
(2) *Development of Industries:* Amendments to the National Industrial Recovery Act, new patent legislation, etc.
(3) *Development of Natural Resources:* Bills relating to water power, navigation, reclamation, soil-erosion control, surveys and maps, and similar public activities wherein the engineer serves in the development of "our national plant."
(4) *Engineers' Welfare:* General legislation in the field of unemployment insurance, old-age pensions, etc; bills such as civil-service measures, engineers' compensation on federal and relief work, etc., more directly affecting the engineer.

Scores of bills under each of the above headings have been under consideration. With its limited staff the Council has found itself obliged to concentrate on those of the greatest importance to the profession. Where needed, information and arguments have been presented to Congressional Committees in open hearings or otherwise. The Public Affairs Committee and its subcommittees are sent copies of important bills and documents and kept generally informed.

Cooperation With Government and Placement of Engineers

As indicated above, so active have been the developments of Government agencies that what might be called a by-product in normal Council activities has become very important.

From time to time the Council has been called upon to recommend engineers for positions and works in cooperation with the Engineering Societies Employment Service in which the A.S.M.E. participates. At the request of the Government, names of engineers technically qualified for positions, have been submitted to various agencies. Some 74 Government divisions now employ engineers.

In addition to working from day to day on placement problems, the Council has made a number of analyses of the number and distribution of engineers. These analyses led to a further activity, namely, the census of engineers which is being made with the cooperation of the national, state, and local societies. Under the direction of a standing committee of Council on engineering and allied technical professions the Bureau of Labor Statistics of the U. S. Department of Labor

conducted a special census of engineers with particular reference to educational background, occupation, income, and present status of employment. The results of the questionnaire will be presented in a report by the Bureau of Labor Statistics and it is expected to have a far-reaching influence on policies concerning engineering education and percentage distribution of engineers both by profession and by industry, the basis for professional consideration or compensation, and other policies of direct interest to the individual engineeer.

Officers and Delegates

President J. F. Coleman, past-president of the American Society of Civil Engineers, and consulting engineer of New Orleans, La., is serving the second of his two-year term as president. C. O. Bickelhaupt, of New York, Alonzo J. Hammond of Chicago, Paul Doty of St. Paul, and W. H. Woodbury of Duluth are vice-presidents. C. E. Stephens of New York is treasurer.

Work of the Council in Washington is essentially a staff activity. The personnel of the organization is headed by Frederick M. Feiker, as executive secretary, serving his second year. During the year, with the approval of the executive committee, Lemuel V. Reese joined the organization as assistant secretary. Mr. Reese, joining the staff from the F.E.R.A. organization, brought a first-hand knowledge of the present government personnel, as well as a background of experience in engineering and industry. The secretaries of Council and of the national member organizations meet each month to assure coordination of effort.

The last three years have seen a constantly increasing opportunity for the engineering profession to contribute its viewpoint and constructive suggestion in public affairs. The delegates of The American Society of Mechanical Engineers believe it fortunate that there has been available in Washington an organization and headquarters for service, the American Engineering Council. The organization has been pointed to by societies of the other professions as an example to be followed.

The American Society of Mechanical Engineers, from the beginning has supported this coordinated center for common action and its representatives believe it has possibilities of even wider and greater usefulness to the public and indirectly to the profession.

Respectfully submitted,

R. E. Flanders, *Chairman*
L. P. Alford
Paul Doty
A. A. Potter
D. Robert Yarnall

AMERICAN STANDARDS ASSOCIATION

On April 25, 1935, the Standards Council of the American Standards Association voted to reorganize parts of the Association's structure to cope with the widening range of standards work. The chairman of the Standards Council, J. C. Irwin, was authorized to organize a mechanical committee, a textile committee, and a building-code correlating committee. Other intra-industry committees will be formed from time to time as the need develops. Because of the increased interest in standards for consumer goods, an advisory committee on ultimate consumer goods was authorized. This body will advise the Standards Council on the problems in this field.

During the year the Federal Housing Administration became a member body of the American Standards Association, and the American Automobile Association, Manufacturing Chemists Association, and the Motor Truck Association of America have become associate members. A total of 36 member bodies represents 40 national organizations. Of these nine are governmental bodies, eight are technical societies, and 19 are trade associations. The 13 associate members consist of six technical societies and seven trade associations. More than 600 national groups are now cooperating in developing and revising standards and safety codes under the procedure of the American Standards Association.

Officers of the Association are: Howard Coonley, representing the A.S.M.E., president; F. E. Moskovics, representing the Society of Automotive Engineers, vice-president; P. G. Agnew, secretary, and Cyril Ainsworth, assistant secretary. J. C. Irwin is chairman of the Standards Council and F. M. Farmer is vice-chairman.

As of September 10, 1935, the Association has approved 301 standards, 65 of which are in the mechanical field. Since October 1, 1934, 36 standards have been approved, six important projects being in the mechanical field. During the past 12 months nine requests for the initiation and approval of existing standards were received.

Respectfully submitted,

C. W. Spicer, *A.S.M.E. Representative*

THE ENGINEERING FOUNDATION

The most important feature of The Engineering Foundation's year of activity was the celebration of the twentieth anniversary of its founding. For the celebration the regular meeting, October 18, 1934, was selected. Dr. Swasey accepted the Foundation's invitation to be the guest of honor. Invitations to a subscription dinner drew acceptance from 78 persons: past and present members of the Foundation and United Engineering Trustees, Inc., officers of the Founder Societies and cooperating organizations of engineers and scientists, and a few personal friends of the Founder. Chairman Charlesworth presided and at the close of the program presented Dr. Swasey an engrossed testimonial signed by all the persons present. Addresses were made by Harry P. Charlesworth, Frank B. Jewett, a former vice-chairman of the Foundation, Karl T. Compton, president of Massachusetts Institute of Technology, and representing Harold V. Coes, president, United Engineering Trustees, Inc., vice-president George L. Knight.

Total book value of endowments, December 31, 1934, was $882,000; and the E. H. McHenry bequest in the hands of executors until decease of two life beneficiaries, appraisal at probate of will in 1931, was approximately $400,000. These capital funds are held and administered by United Engineering Trustees, Inc. The net income from endowment was $5000 in 1915 and $40,000 in 1934. The Foundation Board has discretionary power in the use of income. For enterprises which the Foundation has aided, large contributions of money, services, and materials have often been obtained from organizations and firms in industry.

The activities in 1934 included investigations of concrete and reinforced-concrete arches, earths and foundations, and plastic properties of concrete in the civil-engineering field; critical review of the world's literature on alloy irons and alloy steels since 1890, and barodynamic research, both sponsored by the American Institute of Mining and Metallurgical Engineers; in cooperation with committees of The American Society of Mechanical Engineers, studies of effect of temperature on properties of metals, cutting of metals, thermal properties of steam, mechanical springs, riveted joints, wire rope, boiler-feedwater studies, fluid meters, and strength of gear teeth; under sponsorship of the American Institute of Electrical Engineers and electric-welding research on pure-iron electrodes.

Assistance was given also to the Engineers' Council for Professional Development, Personnel Research Federation, and for a survey by The Engineering Index.

The present officers of the Engineering Foundation are: Chairman, Harry P. Charlesworth; first vice-chairman, D. Robert Yarnall; second vice-chairman, Edwards R. Fish; members of executive committee, Otis, E. Hovey, John V. N. Dorr, and Edwards R. Fish; representative on executive board of National Research Council, Harry P. Charlesworth; director and secretary, Alfred D. Flinn.

Revised Rules of Administration have been drafted in accordance with the revised by-laws of the United Engineering Trustees, Inc. Copies of these rules are now available in pamphlet form. They govern applications for grants and the other procedures of the Foundation.

Welding Research. On the invitation of A.I.E.E. a conference was held on April 22 of 18 representatives of technical organizations and the industry. This conference discussed plans and possibilities for a comprehensive welding research project, and nominated eight members of a Committee to be appointed by the Foundation. This Committee was appointed on April 25 and held a meeting on May 6 attended by all members, the chairman of the conference and the director of the Foundation. This meeting stated the principal elements of a program, appointed a Subcommittee on Literature and a Subcommittee on Research Projects, and directed that a canvass be made of contributions to be expected from industrial concerns, especially of services and materials for the research.

The members of the Welding Research Committee are: Comfort A. Adams, chairman, professor of electrical engineering, Harvard Engineering School; David S. Jacobus, advisory engineer, Babcock and Wilcox Company; Henry M. Hobart, consulting engineer, General Electric Company; James H. Critchett, vice-president, Union Carbide and Carbon Research Laboratories; Glen F. Jenks, commanding officer, Watertown Arsenal; Frederick T. Llewellyn, research engineer, U. S. Steel Corporation; John J. Crowe, engineer in charge of apparatus research and development for the Air Reduction Company; and William Spraragen, secretary, consulting engineer.

Respectfully submitted,

W. H. Fulweiler (1936)
D. Robert Yarnall (1936)
A. E. White (1939)

ENGINEERING SOCIETIES EMPLOYMENT SERVICE

The Engineering Societies Employment Service, a joint activity conducted by the four National Societies, maintains offices in the Engineering Societies Building in New York, at Chicago, and San Francisco. Each of these offices is in charge of a manager who is supervised by a local Advisory Board. Each Advisory Board is made up of a member of each of the Four National Societies.

In New York, the Society of Naval Architects and Marine Engineers participates; in Chicago, the Western Society of Engineers; and in San Francisco, the Engineers' Club and the California Section of The American Chemical Society.

It has been found necessary during the last few years to restrict the service to members of the participating organizations, unless no member can be found who has the necessary qualifications. In New Yorl , non-members of the Societies have been aided through a special activity, known as the Professional Engineers' Committee on Unemployment, which was organized and conducted by the New York Local Sections of the four National Societies. In Chicago and San Francisco, where there was no activity comparable to that carried on by the P.E.C.U., the Employment Service served a reasonably large number of non-members. This was in cases of openings for stationary engineers, chemical engineers and special classifications generally found within the membership of the participating societies. The fees collected through these placements reduce the expense of operation on the part of the societies to underwrite any deficit that occurs from year to year.

Tables showing the registrations and placements for each of the offices follow directly.

REGISTRATIONS, BY SOCIETIES

For New York, Chicago, and San Francisco offices from August 1, 1934, to July 31, 1935, inclusive

Respectfully submitted,

C. E. DAVIES, *A.S.M.E. Representative*

ENGINEERS' NATIONAL RELIEF FUND

From August 15, 1934, to September 4, 1935, the Board of Direction of the Engineers' National Relief Fund considered and acted upon seven applications for loans. Of these cases two were those of the A.S.C.E., one, A.S.M.E., and four were of non-members. A total of $570 was paid out of which $345 was returned during this time.

Except in extreme and exceptionally worthy cases, the Loan Fund was available only to members of the four National Societies or to members of local societies with which the Local Sections of the four National Societies are affiliated. It was understood that the loan was to be on the basis of a revolving fund, made for the briefest possible period consistent with providing an emergency service. The basis for this policy was to have the fund circulating to the greatest extent. Assistance to engineers in dire distress was generally determined by a study of answers to a group of questions, which answers wherever possible were furnished as a result of investigation by local organizations.

Respectfully submitted,

WILLIAM G. ATWOOD (Am.Soc.ofC.E.), *Chairman*
LANDON F. STROBEL (A.I.M.E.)
E. B. MEYER (A.I.E.E.)
WILLIAM A. SHOUDY (A.S.M.E.)[1]

[1] W. W. Macon, A.S.M.E. representative, died January 1, 1935. Mr. Shoudy was appointed to succeed him on the Board of Direction.

INTERNATIONAL ELECTROTECHNICAL COMMISSION

The eighth Plenary Meeting of the International Electrotechnical Commission convened on June 18, 1935, at Scheveningen, Holland, for the first week of meetings and continued during the following week in Brussels, Belgium.

There were over four hundred and fifty delegates present, of whom 14 represented the United States National Committee of the I.E.C. The American delegation was led by Dr. C. H. Sharp, President of the U.S.N.C., and the delegates were selected in the greater part from the sectional committees of the A.S.A. and the A.S.M.E. Committees on Power Test Codes. American industry, therefore, participated directly in the deliberations of the I.E.C.

Twenty advisory-committee meetings were held during the two weeks, including those on steam turbines and internal-combustion engines. The committees which held sessions at Scheveningen dealt with nomenclature, aluminum, insulating oils, rules and regulations for overhead lines, radio communication, electrical installations on ships, electric cables, electronic devices and steam turbines, while at Brussels meetings were held on symbols, lamp caps and holders, standard voltages and currents and high-voltage insulators, electric-traction equipment, measuring instruments, terminal markings, switchgear, accumulator batteries, and internal-combustion engines.

The International Electrotechnical Commission embraces practically every branch of the electrical industry and from the point of view of standardization in its broadest sense is dealing with matters of the highest commercial importance. The I.E.C. is engaged in preparing standard specifications which can serve as models for the use of the several member nations in international trade. In its 30 years of existence it has accomplished more than is generally recognized. And, although the I.E.C. recommendations are not so much in the public eye as they might be, they are constantly permeating the national standards as well as industry as a whole, where their identity or origin is often lost.

The U. S. National Committee of the I.E.C. functions as Secretariat for Advisory Committees No. 1 on Nomenclature; No. 4 on Hydraulic Turbines; No. 5 on Steam Turbines; No. 14 on Rating of Rivers; and No. 19 on Internal-Combustion Engines. During the year preparations had been made for the meetings of Advisory Committees No. 1, No. 5, and No. 19.

Advisory Committee No. 5 on Steam Turbines held a week of meetings at Scheveningen while No. 19 on Internal-Combustion Engines met for a week in Brussels. At both meetings a considerable degree of international agreement was attained, which was due, in part, to the fact that all business coming before the committees had been the subject of extended correspondence between the various national committees and the Secretariat over a period of four years. The written opinions of the various national committees were condensed into a number of printed Secretariat reports which were submitted at the meetings.

At the meetings of Advisory Committees No. 5 and No. 19, the U. S. National Committee was represented by Francis Hodgkinson, Acting Director of the Secretariat on Steam Turbines and Director of that on Internal-Combustion Engines, by K. McH. Irwin, delegate and by C. B. LePage, Assistant Director of both of the Secretariats.

Respectfully submitted,

H. N. DAVIS
E. C. HUTCHINSON
FRANCIS HODGKINSON } *A.S.M.E. Representatives*

ENGINEERS' COUNCIL FOR PROFESSIONAL DEVELOPMENT

The program of Engineers Council for Professional Development looking toward the enhancement of the status of the engineer is divided into four parts:

(1) Educational and vocational orientation of young men
(2) Cooperation between the engineering profession and engineering schools
(3) Further personal and professional development of young engineering graduates
(4) Establishment of suitable standards for professional recognition.

During the year substantial progress has been made in all elements of this program.

The most tangible progress has been made in the matter of co-operation between the profession and education. In this field the preliminary work on the program for accrediting curricula in engineering schools has been completed and as the year drew to a close steps were being taken to accredit some twenty institutions in the New England and Middle Atlantic areas.

In the establishment of suitable standards for professional recognition, two Societies, the American Society of Civil Engineers and our own, have initiated changes in their Constitutions to provide for modification of the requirements for the grade of Member and the addition of a grade of Fellow.

In the vocational orientation of young men, groups have been organized in over a score of centers throughout the United States to provide this guidance for prospective candidates for engineering schools.

In the post-college development work a leading list and a personal self-analysis blank have been perfected and distributed.

The complete report of the work of this important body may be secured for the sum of ten cents by writing to the Secretary at 29 West 39th Street, New York City.

Respectfully,

C. F. HIRSHFELD
W. E. WICKENDEN
WILLIAM L. BATT

JOINT AWARDS

The A.S.M.E. participates in a number of joint awards. These follow together with brief statements giving the purpose of the awards, the participating bodies, the names of the A.S.M.E. representatives for 1934–1935, and the awards made between October 1, 1934, and September 30, 1935.

John Fritz Medal, for notable scientific or industrial achievement; Am.Soc.C.E., A.I.M.E., A.S.M.E., A.I.E.E.; R. V. Wright, C. N. Lauer, A. A. Potter, Paul Doty. Award for 1935 to Frank Julian Sprague.

Gantt Gold Medal, for distinguished achievement in industrial management as a service to the community; Institute of Management Division of A.S.M.E.; Jos. W. Roe, David B. Porter, F. E. Raymond. Award for 1935 to Arthur Young.

Daniel Guggenheim Medal, for notable achievement in advancement of aeronautics; A.S.M.E., S.A.E., Canada, England, France, Germany, Holland, Italy, Japan; H. I. Cone, Porter H. Adams, E. E. Aldrin, B. M. Woods. Award for 1935 to William F. Durand.

Herbert Hoover Medal, for distinguished public service; Am.Soc. C.E., A.I.M.E., A.S.M.E., A.I.E.E.; Ambrose Swasey, C. N. Lauer. No award.

Alfred Nobel Prize, for most meritorious technical paper published by participating societies; Am.Soc.C.E., A.I.M.E., A.S.M.E., A.I.E.E., Western Society of Engineers; Arthur M. Greene, Jr. Award for 1935 pending.

Washington Award, for advancing human progress through engineering; Am.Soc.C.E., A.I.M.E., A.S.M.E., A.I.E.E., Western Society of Engineers; Geo. F. Gebhardt, C. B. Nolte. Award for 1935 to Ambrose Swasey.

NATIONAL MANAGEMENT COUNCIL

During the past year the National Management Council has been engaged primarily in plans for American participation in the Sixth International Congress for Scientific Management, held in London, England, July, 1935. The A.S.M.E. Management Division cooperated in this effort. The Congress was reported as being highly successful with an attendance of over 2000. The American management bodies were represented by five, all members of the A.S.M.E. The next International Management Congress will be held in the United States in 1938.

The informal suggestion from the National Management Council resulted in the planning and organizing of a series of nine meetings in the Metropolitan area under the joint auspices of the Sections of societies and associations concerned with management problems.

Respectfully submitted,

J. A. PIACITELLI,
C. W. LYTLE
H. V. COES
A.S.M.E. Representatives

NATIONAL RESEARCH COUNCIL

DIVISION OF ENGINEERING AND INDUSTRIAL RESEARCH

In the Division of Engineering and Industrial Research there are four main research projects in which steady progress is being made: highway research; electrical insulation; heat transmission; and welding research.

Highway Research. The Highway Research Board held the largest meeting of a series of 14 annual meetings on December 6 and 7, 1934. The registered attendance was 383 against 314 for last year and 282 for 1932. From the program of this meeting 20 papers have been selected for publication in the Proceedings of the Board which will be issued later (in an edition of 2000 copies). In addition the Board issues Highway Research Abstracts (mimeographed) ten times during the year for the presentation of information concerning important unpublished research work.

Among its active projects are:

(*a*) Investigations on the use of high-elastic-limit steel for concrete reinforcement
(*b*) The warping of concrete pavement slabs
(*c*) The stabilization of the surface of low-cost-type roads
(*d*) Studies on highway costs in relation to economic planning.

Electrical Insulation. The Committee on Electrical Insulation held its seventh annual meeting on October 25 and 26, 1934, at the University of Illinois with an attendance of about 90. Nineteen technical papers were presented dealing with current investigations on the theory and practice of electrical insulation. These papers have been published (in planographed form) for the committee with the assistance of the Brooklyn Edison Company.

Annual meetings of this Committee are now recognized as very useful occasions for the exchange of information in regard to current research in this country on dielectrics. In addition to publishing the papers at these meetings, the Committee has sponsored the preparation of a series of four monographs (published commercially) the last of which will be issued next spring. These monographs deal with "The Nature of a Gas," "Liquid Properties of Glass," "Liquid Dielectrics," and "Impregnated Paper Insulation."

Heat Transmission. The Committee on Heat Transmission has sponsored the preparation of a second treatise on heat insulation which will be prepared by E. C. Rack, of the Johns Manville Corporation, and is expected to be issued early in 1936. This new volume, together with the book on "Heat Transmission" of Prof. W. H. McAdams, of the Massachusetts Institute of Technology, issued in 1933, will provide a complete review of present knowledge of the transmission and conservation of heat.

Welding Research. The Committee on Fundamental Research in Welding held its fourth annual conference in New York on October 2, 1934, with an attendance of 42. The object of this Committee is to place welding engineers in touch with university physicists and metallurgists who can undertake research on fundamental problems encountered in the fusion of metals in welding, particularly iron and steel. Ten special reports were completed during the year, by collaborators with this committee and the committee is in touch altogether with some 66 research projects now in progress in university, governmental, and industrial laboratories.

Cooperation With the Science Advisory Board. The Division of Engineering and Industrial Research has also materially assisted the Science Advisory Board of the National Research Council throughout the year by maintaining contacts with government officials in the Department of Commerce. The Director of the Division has made frequent trips to Washington and has been closely in touch with a number of governmental agencies which are concerned with progress of industrial research.

Respectfully submitted,

DAVID S. JACOBUS

UNITED ENGINEERING TRUSTEES, INC.

The United Engineering Trustees, Inc., has three departments, The Engineering Foundation, the Engineering Societies Library, and the Administrative.

Under By-Laws revised in 1934, operations have been greatly simplified and clarified. The newly created Real Estate Committee has functioned efficiently in matters outside the technical operation of the Engineering Societies Building. It has cooperated in many ways with the Finance Committee, thereby distributing the heavy responsibilities placed upon a few men already overloaded by their

professional interests. Distinct progress has been made toward the initiation of another permanent committee for the purpose of raising funds by gift, deed, bequest, or other method, "for the furtherance of research in science and engineering or for the advancement in any other manner of the profession of engineering and the good of mankind."

The corporation continues as treasurer for the Professional Engineers' Committee on Unemployment and has recently accepted appointment as treasurer for Engineers' Council for Professional Development, thus further serving the profession and its interrelated organizations, and fulfilling the purpose of its creation by the Founder Societies.

Members of the governing bodies of the Founder Societies and officers of their joint functional organizations met on the evening of May 20 and heard progress reports of the many projects which are operated jointly by the Founder Societies. The benefit of social contact by members of these groups was felt to be an important factor in tending to knit together more firmly the entire profession, through better understanding of the work and objectives of the different groups of joint activities of the Founder Societies.

Important improvements are being made in the public-address system in the Engineering Auditorium in order that it shall represent the ultimate in service to its users. This new system, coupled with our motion-picture projectors will make possible sound and color pictures in the auditorium, and should prove attractive to Society users and patrons and bring additional engagements. Seats have been added on the main floor of the auditorium thus increasing comfort by the more judicious use of space. Windows throughout the Engineering Societies Building have been repaired to prevent drafts and discomfort to the occupants of the offices, at the same time conserving steam, and the physical property.

The several departments of United Engineering Trustees, Inc., have remained within their budgets which were made on a most conservative basis. The income from the Engineering Societies Building activities was at a minimum owing to the continued reduction on a most conservative basis.

Full statistical and detailed reports on the activities of the United Engineering Trustees, Inc., is presented to the Societies in the Annual Reports of the President and the General Manager in October of this year.

Respectfully submitted,

D. Robert Yarnall
Walter Rautenstrauch
Harold V. Coes
A.S.M.E. Representatives

Service Rendered by the Office of the Society

The function of the office of the Society is to perform the regular duties connected with the many committee activities of the Society, to serve as a service bureau to the members and on behalf of the members as a service bureau to the public, in so far as facilities and resources permit. In general, the office staff keeps the books, maintains an accurate address record, edits the publications, secures the advertising, and maintains contacts with the Local Sections, Professional Divisions, Student Branches, and Technical Committees, all under the policy direction of the Council. In detail, however, the activities of the office are complicated. To aid in understanding them the following brief statement is given as an indication of the volume of work being performed in each group.

Secretary's Department (*3*): Secretary and two assistants.

Supervision. Coordination. Contacts with joint bodies. Direct service to the Council, Executive Committee, and Special Committees.

Field Department (*12*): Assistant Secretary and eleven assistants nine in New York, one in Chicago, one in Tulsa.

Seventy-one Local Sections (visited 38 in 1935), correspondence, speakers lists, appropriations.

Seventeen Professional Divisions (with about 60 subcommittees), six National Meetings.

Annual Meeting, 50 sessions, 105 authors, 60 committee meetings.

Semi-Annual Meeting, 20 sessions, 42 authors.

One hundred and thirteen Student Branches (visited 48 in 1935), 3300 applications for student membership; 10 district conferences.

Admissions, 2000 applications requiring 6000 communications, 340 resignations.

Employment, Engineer's National Relief Fund, Professional Engineers' Committee on Unemployment, Engineering Societies Employment Service.

Special Duties, technical inquiries, foreign visitors, awards, Max Toltz Fund, Freeman Fund, handling cases of 6240 dropped or suspended members.

Editorial Department (*6*): Editor, five full-time assistants, two part-time. Twenty-one hundred pages in *Mechanical Engineering* text and Transactions (including *Journal of Applied Mechanics* and Student Branch Bulletin), edited, styled, proofread, and published. Reports of Committees, Codes, etc., and special-meeting printing.

Advertising and Sales Department (*15*): Advertising manager, three sales representatives, seven on production of *Mechanical Engineering* advertising and Catalog including promotion, special service, layout, proof checking, publishing, and billing. Separate distribution list of 14,000 for catalog.

Publications Sales (**4**): Sales of codes, reports, reprints, etc.

Technical Committee Department (*6*): Assistant Secretary and five assistants.

Four hundred and thirty-nine Committees and subcommittees of Boiler Code, Power Test Codes, Standardization, Safety, and Research. Follow-up and publication of reports. Committee meetings, etc.

Relations with American Standards Associations, International Electrotechnical Commission, etc.

General Office (*22*): Office manager in charge.

Accounting (3): 15,000 individual accounts, 200 commercial accounts, 30,000 individual cash receipts annually, 5000 checks written annually.

Shipping, stores, and mail (4): 250,000 pieces of mail received, 8400 orders for publications, badges, etc. handled.

Addressograph and mimeograph (4): 16,000 address plates, 8000 changed each year; 30,000–40,000 address imprints per month; 50,000 copies from 250 stencils each month.

Filing (2).

General clerical and stenographic (8): master address record, 14,000 names, reception (800 visitors per month), stencil cutting, mail opening, etc.

C. E. Davies, *Secretary*
